Au premier abord une objection s'élève contre cette manière d'envisager le phénomène, car il est évident que si la réaction électro-dynamique du courant est égale et contraire à la force motrice, il doit en résulter non le mouvement mais le repos, l'état statique dans la conséquence du principe qui dit que deux forces égales et de sens contraires se détruisent. Or, si la réaction d'un ressort est égale à 10 kilogr., je suppose, alors que la force qui tend à le faire fléchir est aussi égale à 10 kilogr., il ne peut y avoir déplacement.

Pour tourner la difficulté, nous admettrons qu'un certain temps s'écoule entre le moment où la puissance en application et celui où la résistance se manifeste. Cela n'a rien de contraire aux expériences faites jusqu'à présent. D'ailleurs une force dynamique quelconque, même celle due aux explosions, ne se produit pas instantanément ; il est logique de penser que la force croît depuis le moment où elle prend naissance jusqu'à celui où elle atteint son maximum, et que ces deux instants ne auraient coïncider un même moment horaire.

Décomposons la force en nous arrêtant aux moments où elle passe de 0 aux valeurs + 1, + 2, + 3,... — 9, + 10 kilogr. ; il nous suffira d'admettre que les valeurs des résistances partielles — 1, — 2, — 3,... — 9, — 10 kilogr. s'opposent aux valeurs des actions partielles + 1, + 2, + 3, + 4,... + 9, + 10, ainsi que le montrent les deux progressions suivantes, c'est-à-dire que la résistance — 1, fait obstacle à

l'induit marche dans le sens des flèches. La partie *b*, *c*, de l'inducteur tend à repousser la partie *n*, *m*, de l'induit et à attirer *n*, *o* ; *o*, *l* ; et *l*, *m* ; mais comme la force répulsive décroît avec la distance et avec la grandeur de l'arc que font les courants entre eux, il en résulte que l'action exercée par *b*, *c* sur *n*, *o*, *o*, *b* et *l*, *m*. D'ailleurs, le sens général du courant développé dans le noyau E F un pôle austral N, de même nom que N ; or comme les pôles de même nom se repoussent, leur action s'ajoute à la précédente.

La répulsion va en augmentant jusqu'à ce que *n*, *m* et *b*, *c* se trouvent l'un au-dessous de l'autre ; cette position correspond à un maximum (1re position de la figure 1, page 323 du 15 août).

Arrêtons-nous un instant sur cette position.

Les ondes électriques développées dans l'induit tendent à le repousser de A B. Cette action extérieure E F n'en pas la seule qu'il produise : il agit aussi sur lui-même de la manière suivante.

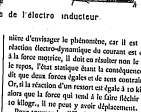

Fig 1.

de l'électro inducteur

Ms. Jones Trowbridge, of Harvard University, Cambridge, Mass., has published some very interesting results respecting the behaviour of the earth's surface as a conductor of electricity, and its capacity for transmitting electric signals without the aid of a conducting wire. The experiments were made between Boston and Cambridge, a distance of 3 miles. The method of observation was by telegraphing, the existence of an electric current was plainly registered upon the tick. ing which the making and breaking of the circuit produced in the [illegible] Signal. The conclusions [illegible] are somewhat startling, and, if correct, are to [illegible] to telegraph across the Atlantic Ocean. Some of these experiments [illegible] were made in 1901 (Nos. 1299) was taken out [illegible] by C. E. Mining, for a method of telegraphing [illegible] water without wires, and a mode of using [illegible] Siemens and Amelon by means of wires from [illegible] Edison (No. 1241) for effecting a similar object was taken out in 1854 by Mr. J. B. Lindsay.

In a note to the Vienna Academy (Mon. December 16) [illegible] Stefan describes experiments on the influence of terrestrial induction in the development of an electric current, and of excitement of the telephone by currents from a rotating coil. The coil used was [illegible] 56 mm. in external diameter, and 11 mm. in width. The earth's influence is best shown by so connecting the apparatus with a galvanometer that the circuit is closed during one half of the coil's rotation, and broken during the other half ; if the completion of the circuit correspond to the positive maximum of electromotive force of the earth's magnetism, and the interruption to the negative, the galvanometer is positively deflected. The deflection may be increased to zero by displacing the contact, and from the displacement and the number of rotations the potential may be inferred in absolute measure. Next the telephone was so connected with the coil that the fall alternately opposite currents went successively through the circuit. This gave a simple tone. With 100 rotations per second the horizontal component of the earth's magnetism did not suffice to excite an ordinary telephone, but it excited one having a horse-shoe magnet. (When the intensity of the field was doubled the ordinary telephone was also excited.) The tone corresponded to the number of rotations. When the coil was rotated 220 times in a second the ordinary telephone sounded. The telephone was shown to be less sensitive to currents whose intensity periodically changes than to interrupted currents (an ordinary telephone sounded with 100 rotations or fewer, when the circuit was closed only during a short time of each rotation).

THE INDUCTION BALANCE.

Upon the Electrical Experiments to determine the Location of the Bullet in the Body of Mr. Ida Presidents Garfield; and upon a new Instrument, the Balance of Induction Balance for the prolonged Detection of Metallic Masses in the Human Body.

By ALEXANDER GRAHAM BELL.

The subject of my paper is simply a line of intense excitement and long suspense. The long weary struggle with the ultimately fatal result, the increasing anxiety, the feeling known or keenly and well by the whole people, that Garfield—must still be fresh in every recollection. The whole world watched by his bed-side, and hopeful days of hours filled every passing hour. No one could venture to hope that he could so long as the position of the bullet remained unknown. The bullet might become safely encysted, but, on the other hand, the wound might directly cause his extinction. The search, cautious and gentle among vital and sensitive tissues could not be made with too patient and diligence and the thought constantly arises that science should be able to discover some instrument of exploration.

Among those most the thought occurred that the bullet might be located by some effect resulting in modifying the induction of a coil brought near to the body of the President, and that the locality of the bullet might be thus determined without danger to the patient and without pain; for it is well known that induction can be powerfully exerted through the human body without producing any sensation whatever.

Upon the Laws of Electric Induction.—The influence that I expected upon induction by metallic masses has formed the subject of numerous experiments in my laboratory for years; and the principle of balancing the effects of induction on one portion of a circuit by equal and opposite effects on another portion has been applied with success in nearly all such investigations.

The Induction Balance.—The instrument for this purpose appears to have been devised independently by Prof. Hughes about the year 1881, and a description of it in the London English language may be found in his letter of June 22nd, 1881, to the Electrician (1881 edition, vol. i., pp. 166—168). The earlier and superior arrangement for the same end is the well-known induction balance of Prof. D. E. Hughes.

The static induction balance of J. E. H. Gordon,* through primarily intended for experiments upon specific inductive capacity, might also, perhaps, be employed in the same class of investigations.

My attention was directed to the balancing of induction a number of years ago by the disturbing noises in telegraphic instruments by the operation of telegraphic instruments upon lines running near the telephone conductor.

The difficulty was remedied by using two conductors instead of one, and by so arranging the instruments that the induction effect upon the one should exactly balance that of the telephone conductors were exactly equal and opposite in direction to each other. In this way the disturbing noises were produced and a quiet circuit secured for telephonic purposes. This method was first patented in England in November, 1877, and during the whole winter of 1877-8 I was engaged in London upon experiments to perfect the system.

Another source of these researches I made frequent use of the induction balance, which I described in the paper by the Prof. Hughes† in his experiments upon induction.

My method was to use a carefully interrupted voltaic current through one half of a primary coil, and to balance it by the induction of another half opposed and connected with a telephone. The currents induced in the latter coil produced a musical note from the telephone.

At every point in the field of induction it was found that by turning the plane of the exploring coil a position of perfect silence was obtained, and another of maximum sound, the two positions making a right angle with each other.

It was also noticed that when a position of silence was obtained, any metal mass brought within the field of induction would cause a disturbance to sound. The effect was most marked when the two coils were close to each other proximity, and were arranged with their planes parallel, as shown in Fig. 1.

Fig. 1.

If a silver coin, such as a half-crown or florin, was placed across the face of the two coils, the silence of the telephone was broken three times. The instrument could be used as a musical tone when the micrometer screw passed the points marked 1, 2, and 3 in the illustration, but the

* A paper read before the American Association for the Advancement of Science, at the Montreal meeting, in which position many notes relating to the matter was published in the *Comptes Rendus* of the French Academy of Sciences, October 29, 1881.

†† Gordon's Patent, 1879, 3,529 ; 1880-81, 209, xii. 117.

loudest effect was produced when the coils crossed the position 2, where the two coils intersected.

I may return to America I embodied these and other results in a paper "On Methods of Exploring the Field of Induction of Flat Spirals," which was read before the association at the Montreal meeting, August, 1882.

Practical Application.—While brooding over the problem of the detection of the bullet in the body of President Garfield, these experiments made in England returned vividly to my mind. It seemed as even if the cooperation of the two coils shown in Fig. 1 could be brought over the body of the bullet without disturbing the relative position of the coils, the telephone would probably announce the presence of the bullet by an audible sound.

A crude experiment was at once made to test the idea. The primary induction-magnet (the core of which was formed of a bundle of fine iron wires) was used in place of one of the coils, and it was found that the induction upon the other coil could be balanced by the induction of a single coil of fine insulated wire wound upon a bundle of soft iron wires. The small coil passed through the coil of the electromagnet, and the whole system was tended and looked by an assistant.

Under these circumstances a much better balance was obtained than could possibly have been anticipated. There was nothing a trifle bulky near the instrument. The slightest motion of the coils, the telephone would instantly announce the presence of the bullet by an audible sound.

Being absent from my laboratory, and not possessing facilities for experiment, I commissioned my assistant, Mr. Sumner Williams, Jun., of Boston, manufacturer of electrical apparatus, to construct the instrument, who kindly placed the resources of his large establishment at my service; and, at great expense, and with much labour, completed his best instrument for my experiments.

Upon attempting to produce a comparable form of instrument for the special purpose in view, I found that there was great practical difficulty in the way of obtaining the two coils shown in Fig. 1, and to overcome this difficulty the apparatus of Professor Hughes might perhaps be employed with great advantage as the basis of my experiments. In the ordinary form of Hughes' induction balance four coils are used, as shown in Fig. 2.

The object of this arrangement is to enable the balancing of a clock circuit containing the two primary coils, A B, without disturbing the two secondary coils, C D, which are connected with the telephone circuit. The primaries are so arranged that the currents induced in the telephone circuit through the coils C D by the coils A B are directly opposite, the thickness of the clock is heard very faintly, but if they are in the same direction no sound is heard.

In the latter case the action of one primary coil A on the secondary C of the other, C, and a electrical balance was obtained. If now a piece of metal is brought near one of the clock's audible at the telephone. The arrangements of the coils A, B, C, D, was the point to be studied,

Fig. 2.

the microphone attachment seems of no importance in the combination; for it is well known that a resistance in circuit with the primary circuit consequently at intervals can be secured to use that two of the coils, A B in the Hughes induction balance might be advantageously used in parallel circuits, so as to be moved over the body of the all the while maintaining the balance in the position of the coils, the necessary might be made on the other pair of coils, which would be fixed in position. Two coils would not therefore be liable to disarrangement. If the coils were to be moved over the body of the patient, a single pair of coils were to be used, and the balance secured by the movement of the coil B, Fig. 1, that if during the process of exploration the coil B, Fig. 1, was moved from the position parallel even in the extend only of a few degrees from a millimetre, the balance would be destroyed and the telephone would cease to be silent. This might have a fatal termination. These considerations Hughes induction balance was accordingly abandoned for the purpose, and I immediately commenced the construction of the instrument.

Experimental Trials.—Just at this time I learned from the newspapers that Sir Charles Bright, Messrs. Sheldon, and Professor Jenkin were making a magnetic needle to facilitate the detection of the bullet in the body of President Garfield, these experiments made in England returned vividly to my mind. It seemed as even if the cooperation of the two coils shown in Fig. 1 could be brought over the body of the bullet without disturbing the relative position of the coils, the telephone would probably announce the presence of the bullet by an audible sound.

A crude experiment was at once made to test the idea. The primary induction-magnet (the core of which was formed of a bundle of fine iron wires) was used in place of one of the coils, and it was found that the induction upon the other coil could be balanced by the induction of a single coil of fine insulated wire wound upon a bundle of soft iron wires. The small coil passed through the coil of the electromagnet, and the whole system was tended and looked by an assistant.

Under these circumstances a much better balance was obtained than could possibly have been anticipated. There was nothing a trifle bulky near the instrument. The slightest motion of the coils, the telephone would instantly announce the presence of the bullet by an audible sound.

Being absent from my laboratory, and not possessing facilities for experiment, I commissioned my assistant, Mr. Sumner Williams, Jun., of Boston, manufacturer of electrical apparatus, to construct the instrument, who kindly placed the resources of his large establishment at my service; and, at great expense, and with much labour, completed his best instrument for my experiments.

Upon attempting to produce a comparable form of instrument for the special purpose in view, I found that there was great practical difficulty in the way of obtaining the two coils shown in Fig. 1, and to overcome this difficulty the apparatus of Professor Hughes might perhaps be employed with great advantage as the basis of my experiments. In the ordinary form of Hughes' induction balance four coils are used, as shown in Fig. 2.

The object of this arrangement is to enable the balancing of a clock circuit containing the two primary coils, A B, without disturbing the two secondary coils, C D, which are connected with the telephone circuit. The primaries are so arranged that the currents induced in the telephone circuit through the coils C D by the coils A B are directly opposite, the thickness of the clock is heard very faintly, but if they are in the same direction no sound is heard.

In the latter case the action of one primary coil A on the secondary C of the other, C, and a electrical balance was obtained. If now a piece of metal is brought near one of the clock's audible at the telephone. The arrangements of the coils A, B, C, D, was the point to be studied,

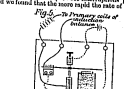
Fig. 3.

ENGINEERING.

[JAN. 5, 1883.]

To test the influence of speed of interruption, Mr. Marconi, superintendent of the Western Union Telegraph Company in Washington, arranged a rotating disc by means of which we were able, with the aid of a metallic contact-spring, to vary the interruptions of the primary circuit from about 100 to 600 interruptions per second,* and we found that the greater the rate of interruption

Fig. 5. *Primary coils of Induction Balance.*



the more distinct was the sound in the telephone. The hearing distance, however, was not appreciably affected by speed. The microscopic interrupter shown in Fig. 5), working about 100 interruptions per second, was found to be very satisfactory. The microscopic interrupter and the microphone interrupter were therefore afterwards used exclusively in our experiments.

The two principal forms of coil suggested by Professor John Trowbridge were carefully tested, and the one proposed by Professor Hughes was finally adopted.

The arrangement was quite simple. The bullet was placed in the centre of the primary coil, and the secondary coil or bullet external to the coils was no greater than before.

Fig. 6.

Professor Hughes proposed to have two flat superposed coils wound on a single reel, so that the two coils should be, as it were, at opposite their relative distances; and Mr. F. W. Stubbs, of Messrs. Siemens' establishment, offered to wind the coils for us. After a single coil, as shown in Fig. 7, had been wound, the balance could be readily obtained by Mr. Chas. R. Bailey and Dr. Chichester A. Bemis, who proceeded to determine the depth of the bullet the balancing coil by causing a similar bullet to approach secondary bullet. When the balance was restored the same distance from the balancing coils as the embedded bullet was from the exploring coils.

The results of all the experiments so far made were satisfactory, and I at once tried everything that had been suggested, and I also measured the extreme limit of audibility of the induction balance. The results are given in the following table, in which a bullet was flattened by being fired against a board, and was presented with its flat side parallel to the coils of the explorer—the most favourable mode of presentation—no better result was obtained.

Fig. 7.

	34	36	2		34	36	2
	36	37	1		36	37	1

These figures show that the distance from the primary coil A (Fig. 6) at which the influence of the bullet B becomes perceptible, increased with the diameter of the primary coil A, and that the secondary coil D was affected comparatively considerably beyond the plane of the primary coil, as shown in the diagram, Fig. 6.

The second column represents a constant ratio between the diameter of the secondary coil and the distance of projection A B of the secondary coil should proportionally increase with the diameter of the primary coil but the last tabulated figures did not fully confirm the inference.

The experiments were therefore repeated on a smaller scale then, and I thought the difference between the results that should have been observed according to the above hypothesis, and those that were actually observed might have been due to the gradual extension of the iron in the battery employed and to the polarization, although every care had been taken to preserve its power unchanged by frequent renewal of the solution, and by allowing when no observation was made. To test whether the battery exerted any material influence upon hearing distance, a further series of experiments was made with the same battery.

The following table contains the tabulated statement which shows that the maximum hearing distance (6 feet) was obtained with a primary ring 17.5 cm. in diameter and a secondary A A 3 cm. from the primary coil, when only coils was one centimetre. This arrangement of the instrument was therefore adopted throughout the following experiments:—

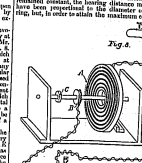
	Hearing Distance.
1. Apparatus tried with 1 cell Daniell battery	(10 C. Plg. 8 cm.
2. Coil in series	(10 C. Plg. 8 cm.
3. Six cells in multiple arc	(10 C. Plg. 8 cm.
4. Same experiment repeated	(10 C. Plg. 8 cm.
5. Same experiment repeated	(10 C. Plg. 8 cm.
6. Same experiment repeated by Mr. Hanscom	(10 C. Plg. 8 cm.

* I desire specially to express my gratitude to Dr. Frank Hamilton for very much assistance rendered me at a later date when sympathy and encouragement were greatly needed.

These experiments proved that battery power did exert an influence upon the hearing distance, and also that the battery in use was not powerful enough.

A considered, therefore, that if the battery power had been increased in the same proportion as the primary ring, but, in order to attain the maximum effect, the primary

Fig. 8.



position of the secondary coil beyond the plane of the primary coil might also have been found to increase its fine proportion.

This led me to try the effect of a second primary coil A with the secondary B at the apex, as shown in Fig. 9, but this arrangement proved unsatisfactory.

Subsequently enough Mr. J. H. C. Wattz, to Baltimore, and Dolbear suggested a method of using a single primary coil and with the instrument shown in Fig. 10 he had obtained

Fig. 9.

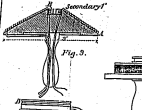


Fig. 10.

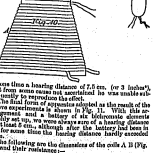

Fig. 11.

At one time a hearing distance of 7.5 cm. (or 3 inches), with the secondary coil reversed, he was unable to obtain a sound, and consequently reduce the effect.

The final form of instrument adopted as the result of the above experiments is shown in Fig. 11. It consists of a suspension and a battery of six Leclanché elements (Fig. 12), and a telephone (Fig. 13). The primary coil consists of an insulated wire, although after the battery had been in use for some time the hearing distance hardly exceeded 3 cm.

The following are the dimensions of the coils A B (Fig. 11) and their resistance:—

Coil A	External diameter	9 cm.
	Internal diameter	4 cm.
	Depth	4.5 cm.
Wire used, No. 36 Brown covered	Resistance, 2 ohms.	
Coil B	External diameter	3.2 cm.
	Internal diameter	1 cm.
	Depth	2 cm.
Wire used, No. 36 silk covered	Resistance, 2 ohms.

THE INDUCTION BALANCE.

Upon The Electrical Experiments to determine the Location of the Bullet in the Body of the late President Garfield; and upon a successful Form of Induction Balance for the positive Detection of Metallic Masses in the Human Body.

By Alexander Graham Bell.

(Continued from page 72).

The Late President Garfield.—During the forger experiment (*July 20*) a sudden increase in the sound was observed upon passing a point near the spot where the surgeon supposed the ball to be lodged, but I had been unable to verify this by a second observation, although the exploring instrument (A B, Fig. 12) was repeatedly passed over the same spot. The sound had been so loud that I had supposed that the position of the ball must have been found by a sudden intensity in the vibration of this end of the rheotome used to interrupt the primary circuit, for the arrangement (as explained above, p. 28) was not perfectly balanced, and any irregularity of the steel would, under these circumstances, have affected the telephone. At the same time the coincidence was remarkable, and I had hoped that the experiment might at that time be one in our favour; but the sound was faint, and the key to the thought that perhaps after all the bullet had been the cause of the sound. I felt confident that the new instrument (Fig. 12) would at once decide the question, for the extreme hearing distance of the former apparatus (Fig. 12) was only 9 ins., and the sound heard at the spot in question was superior to the point that if the sound had not been due to the bullet it would also exhibit with the new instrument distinct and well marked effects. When the new engineer (Fig. 19) was passed over the suspected spot nothing was heard excepting a slight pulsating sound as the instrument was moved to and fro. This was evidence to me that the former sound was due to the bullet, and, again, that the bullet was there now. I think that the most astonishing new error of observation caused by the pulsation of the artery was the movement of the instrument, I lifted the latter (without changing the inclination of the coils) to a height of about 50 centimetres above the body of the President, and moved it to and fro in as nearly as possible the same way as I had done at the former attempts.

I perceived that if the pulsation heard were due simply to the movement of the instrument, that the sound with great strength at the two elevations when the position of the successive effect was due to the influence of the bullet, the pulsations at the two elevations would be different in intensity. I was struck by the fact that, although the sources pulsation was very feeble, they were exactly louder when the instrument was close to the body than when it was held at a height of 50 cm. Confirming the explanation, I found that a sudden noise over which similar effects were noticed, but upon moving the instrument towards the back of the President, the difference between the pulsations produced at the two elevations grew less and less, and finally could not be distinguished.

The difference in the loudness of the sound at the two elevations was so slight that it probably would not have been noticed by me unacquainted with the nature of these effects, and I found that the general conviction that the bullet would be found in that part of the body might have led me to imagine a difference that did not exist. For the purpose of eliminating as far as possible any personal error, I requested Mr. Sumner Tainter (who was the only other experimenter whose ear had been sufficiently trained to be reliable) to make observations for me, as he was experienced and it was know his search. Upon his return to my laboratory we compared notes, and I found that our observations tallied with mine. He declared he could not obtain a distinctly localised effect, but stated that he had heard the movement of the pulsation over an area of at least two centimetres in the neighbourhood of the spot to which his attention had been directed, and that he was of the opinion that the bullet was there that area.

It appeared reasonably certain that the sound of the bullet would was due to some external cause, and was not simply an effect of experiency. In the absence of any other explanation for the phenomenon I was forced to agree with Mr. Tainter that it was due to the presence of the bullet, and I proceeded to act upon this supposes. * I was by no means satisfied, however, with the results obtained, for no such effects had been observed in any of our experiments with bullets. I tried to reproduce the effects by moving the instrument (Fig. 19) at different distances from a bullet, but in every case where an effect was observed the sound was quite sharply localised. I thought that perhaps the vibrations of the patient might have affected the result, and so experimented upon a bullet buried in a piece of meat, but the effects were the same as before. This led me to fear that the extended area of audible sound might have been due to some extraneous cause in the room. The experiments were repeated at the time, and I personally and Mr. Sumner Tainter went through (August 2) to ascertain if there was any way whether they were perfectly insulated of the bed. Iron removed from the neighbourhood of the bed. Every precaution was taken to understand the insulate matters so as to ascertained that by was another mattress composed of steel wires.

After obtaining a duplicate, the mattress was found to consist of a net of net of woven steel wires, with large meshes. The wires, which were somewhat springy, were small, so compared with the area of the bed, it seemed reasonable to conclude that the effect matters had produced no detrimental effect. I was unable to continue experiments with the steel mattress, as at this time I

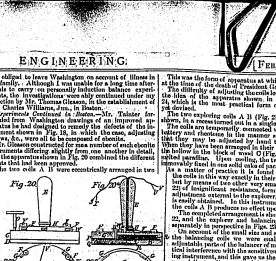
* See Appendix, note H.

was obliged to leave Washington on account of illness in my family. Although I was unable for a long time afterwards to carry on personally induction balance experiments, the investigations were ably continued under my direction by Mr. Thomas Cleaver, in the establishment of Mr. Chester Williams, Jun., in Boston.

Upon my return to Washington Mr. Tainter forwarded from Washington drawings of an improved instruments he had designed to remedy the defects of the instrument shown in Fig. 12, in which the case, adjusting screws, &c., were all to be composed of ebonite.

Mr. Cleaver constructed for me a number of such electric instruments differing slightly from one another in detail, and the two principal ones shown in Fig. 20 combined the different points that had been approved.

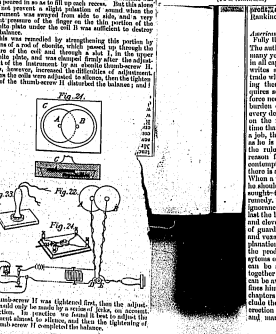
The two coils A B were eccentrically arranged in two



circular discs of ebonite, C D, and the adjustment was obtained by means of an elastic key (), like the key used in Gutta-percha, which turned a cam M provided on the spindle and working in a slot X in the lower disc.

In order to prevent any movement of the coils, except that produced by the adjusting key (), each coil was firmly secured to its disc by means of a screw S, the ends of which were bevelled so as to fit. Paraffine was then poured in so as to fill up each slot. This, while it did not prevent a slight rotation of sound when the instrument was swayed from side to side, and a very slight pressure of the finger on the portion of the ebonite plate under the coil B was sufficient to destroy the sound.

This was remedied by strengthening this portion by means of a screw of ebonite, which passed through the centre of the coil and through the disc, in the upper ebonite plate, and was clamped by a milled nut on the top of the screw, by an ebonite thumb-screw H. This, however, increased the difficulties of adjustment. When the coils were adjusted to silence, then the tightening of the thumb-screw H disturbed the balance; and I



the thumb-screw H was tightened first, then the adjustment would only be made by a series of jerks, on account of friction to resolve we found it best to adjust the instrument almost to silence, and then the tightening of the thumb screw H completed the balance.

This was the form of apparatus at which we had arrived at the time of the death of President Garfield.

The difficulty of adjusting the instrument to ultimately to the idea of the apparatus shown in Fig. 21, in which the two principal faces of the instrument were horizontal.

The two exploring coils A B (Fig. 21) are arranged as shown, and are connected one in a single block of wood C.

The coils are temporarily fastened within the block by rubber and elastomer in a manner shown in Fig. 1, so that they may be adjusted to the same plane of action. When they have been arranged in this way they are fixed in the hollow in the block of wood C (Fig. 21) is filled with paraffine wax. Upon melting, the two coils are found immovably fixed in one solid cake of paraffine.

It is then found impossible to fix the coils in this manner with any exactly in their position of silence by means of the adjusting screws, but by means of a coil of insignificant resistance, forming a part of the adjustment external to the engineer, a perfect balance is easily obtained. In this instrument the engineer E and the coils A B produces no effect upon the balance.

The completed arrangement is shown in plan in Fig. 21, and the engineer and balancing coils are shown separately in connection in Fig. 21a.

The amount of balancing coil of slight resistance in the balancing coils we were enabled to obtain the adjustable point of the balance of maximum silence, and elicited interference with the sensitiveness of the exploring instruments, and this gave us the power of making very delicate adjustments of the balancing coils.

The most delicate instrument, so would plastic of the two sensitive ears of the coils, as had been done in the instrument shown in Fig. 20.

In the balancing apparatus shown in Fig. 23 (which is the most perfect one yet constructed) the lever, to which the coil is attached, is made of hard rubber.

In Fig. 26 is shown the most convenient form of case yet devised for holding the exploring coils.

By invitation of Dr. Lyon Hamilton experiments were made with it at his office in New York October 7, 1882, the instruments used being those shown in Figs. 22, 23, 24.

As this was the first successful application of the induction balance to the discovery of a bullet imbedded in the body the position of which was previously unknown, I may be pardoned for entering somewhat into detail.

Hamilton's book contained it.

American Foundry Practice. By Thomas D. Weet. Fully Illustrated. New York: John Wiley and Sons.

The author of this work offers it as the outcome of many years' experience in the foundries of America, in all capacities from apprentice to manager. He writes as a practical man to the members of the trade which he follows, and the impression on reading them that the moulder's art is one that requires considerable thought, and that experience alone can be successful. This indeed is the burden of the book throughout; and the class of every description or explanation the author insists on the necessity of the moulder thinking all the time that he works; thinking before he commences a job, thinking as he proceeds with it, and thinking as he is finishing it off. For the men who follow the rule-of-thumb, and can give no satisfactory reason for the method they adopt, he has a vast contempt, although it is evident he knows that there is a large proportion of them in every shop. When a man has made a bad casting he insists that he should never begin it again until the cause is sought—the cause of the—mishap, and devised a remedy. But this is not one that will help the ignorance under a cloud of advice; from first to last the chapters are full of practical hints, sound and clever notions, and no opportunity is missed of guarding the reader from the disappointments and vexations that beset the moulder, by simple explanation of the conditions that are necessary for the production of good work under the different systems of moulding. Every possible disaster that can be suggested by a long training is set forth, together with the means by which it may be met or can be avoided. But the author by no means confines himself to the humblest of the business: his chapters extend over the whole subject, and include the designing and building of foundries, the erection of ovens and cupolas, the mixing of iron and many other points that are useful both to foreman and manager. His advice to apprentices is summed up in one homely sentence that was short, pointed, and pithy, and as such are likely to be relished at this season, "Learn your business, observe as examples: "He that practises hard manual work will always have the most breathe." "A poor slack turbo when once well do" " A fast-poured muddle should not be continued."

We have not the space to recite the many subjects treated in this book. It is divided into four sections, dealing respectively with (1) the moulder and the foundry, (2) green sand moulding, (3) loam and dry sand moulding, (4) manipulation of patterns, gates, and (5) notes and receipts. In the second and third sections a number of representative objects are taken and the methods of moulding them, with and without patterns, is described. Among these we notice gear wheels, pulleys, kettles, and anvil blocks. Section 3 relates to the construction of castings, learning and moulding of castings, splitting pulleys, mixing loam, and rays of smiling iron, preparing cupolas and the like, while the last section deals principally with blacking, loam, and sand mixtures. In conclusion we can recommend this book to our readers, as we find in it much that is interesting. The moulder's art is not a new one, and no one expects to submit to announce any great discoveries or sudden advances in its practice. If he can give to the public an intelligible account of the best processes in vogue in the country, and can put the experience of a few of the service of the many, he should earn the recognition of the members of his craft.

WIMSHURST'S DUPLEX INDUCTION MACHINE.

In our issue of the 6th of October last,* we described a very interesting electrical plate induction machine, invented by Mr. James Wimshurst, of the Board of Trade, and which possesses several points of superiority over the Holz machine, while at the same time it is of considerably smaller size for a fraction of the cost. Since we published that notice Mr. Wimshurst has made a suggestion theoretic, has substituted a smaller and far less costly form of glass for the original plate machine for producing the initial charge, and has thereby made the apparatus more efficient, reducing at the same time its cost.

Mr. Wimshurst has quite recently again added to his reputation as a scientific inventor, by designing and constructing the very remarkable and interesting machine which we illustrate on the following page, an examination of which would lead one to suppose that simplicity could go no further in the design of a statical induction electric machine capable of producing a continuous and powerful discharge between its terminal electrodes.

The case consists of two circular glass plates discs of ordinary window glass 14¼ inches in diameter, mounted upon a fixed horizontal spindle in such a way as to be rotated in opposite directions at a distance apart of not more than one-eighth of an inch. Each disc is attached to the end of a hollow boss of wood, or of ebonite, upon which is turned a small pulley. This is driven by a cord or belt from a larger pulley, and these are now also attached to a spindle below the machine, and which is rotated by a winch handle in opposite directions in the direction of rotation being obtained by the crossing of one of the belts.

Both discs are well varnished, and, attached by cement to the outer surface of each, are twelve radial sector-shaped plates of thin brass disposed around the discs at equal angular distances apart, and which play a very similar part in the action of the apparatus to the "carriers" of Nicholson's "*revolving doubler*," and those of the "Electrophorus" of Sir William Thomson, but it would

THE INDUCTION VANE.

The induction balance of Professor Hughes was early recognised as a valuable instrument of molecular research; and it is impossible to foresee the great extent of usefulness that may be open to it in the difficult department of study, when a good clue to the interpretation of its results has been obtained.

Up to the present time the most important application of the apparatus has been in metallurgical testing. Its suitability for this kind of work was demonstrated by the extreme sensitiveness to the presence of the minutest particle of metal within the coils, and to the physical nature and condition of the metal. Our readers will remember that when a piece of metal was placed in one pair of coils on "scale-pan" of the balance, as it were, the electric equilibrium was disturbed, and the observer heard the indicating sounds in the telephone. It required an exactly similar piece of the same metal to restore the balance, and produce the corresponding silence in the telephone. It was not enough that this compensating piece of metal was of the same size and substance; but it was necessary, in addition to these properties, that it should be at the same temperature, density, and temper, or to put it briefly, in the same molecular condition. A slight alloy in the compensating metal was at once detected by a residual disturbance in the telephone which showed that the balance was not perfect.

It was pointed out by Professor Hughes that this discriminating power of the induction balance afforded a ready means of detecting counterfeit coins, since if a good coin were placed in one pan of the balance as a standard, a base coin of the same coinage could be at once proved by putting it in the other pan, since it would not quite neutralise the disturbance in the balance created by the genuine coin.

The serviceableness of the induction balance in metallurgical tests of this kind was promptly appreciated by Mr. Chandler Roberts, F.R.S., the chemist of the Mint, who immediately adopted it for the purpose. Availing himself to the fullest extent of the suggestions of Professor Hughes, he at once began a series of experiments which have already afforded results of much interest. Full descriptions of these experiments will be found in his published papers on the subject in the Proceedings of the Royal Society, vol. xxix., page 56, in the *Philosophical Magazine*, vol. viii., page 16, and in the Proceedings of the Physical Society, vol. iii., page 81.

To fit the instrument for giving accurate numerical results in testing the relative effects of different alloys, Professor Hughes divised a graduated zinc scale of a larger form to take the place of the standard coils or metal. It is, of course, clear that a single fixed standard against which to put the metal to be tested could not give a quantitative result. At best it only showed whether there was a disturbance of the balance or not, and did not show how much was the disturbance. It made of the instrument an inductometer; but the zinc scale made of it an inductometer.

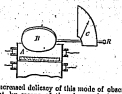
This ingenious device, which we illustrated at the time in Engineering, vol. xxvii., pp. 217 and 457, did not, however, prove sufficiently sensitive for the finer purposes of Mr. Roberts. As will be seen from the annexed Table, taken from an official report of that gentleman, the method is not adapted for accurately equal and similar volumes of gold-copper alloys which vary but slightly in composition.

Standard by Assay.	Readings on Zinc Scale.	Standard by Assay.	Readings on Zinc Scale.
999.0	100	911.7	61
993.6	93	911.3	61
992.8	76	910.8	61
925.0	70	910.2	61
919.1	69	910.2	61
918.1	67	709.2	60
916.9	66		

"But it soon became evident," says Mr. Roberts, "that the instrument was capable of indicating more minute differences of standard, and I at first tried to obtain trustworthy indications by raising or lowering a supplementary horizontal disc by means of a micrometer screw, and this disc was subsequently replaced by an obtuse hollow cone of silver, by which the sensitiveness of the instrument was increased. Professor Hughes, however, who throughout his experiments has afforded me the most generous aid, suggested the following arrangement which has given the best results yet obtained."

Instead of the zinc bar or scale, a disc of gold or other metal A (see the annexed diagram) is placed within one pair of coils as a standard of comparison, and over it is supported a metal vane or damper B, the nature and dimensions of which may be varied to suit particular cases. This vane is attached to a rod or handle H, which can be turned by the fingers so as to set the vane at any angle with respect to the coils beneath. A graduated arc and index to show the angle turned through completes the device.

It will be seen that the vane is an auxiliary to the standard coin. The latter compensates for the greater part of the disturbance due to the insertion of the metal to be tested in the other coils of the balance, and the vane compensates for any difference that may remain. The effect of the vane is minimum when it is in a vertical attitude, and maximum when horizontal. The difference is given by the number of degrees from zero indicated on the scale.



The increased delicacy of this mode of observing over that by means of the zinc scale is readily shown by the annexed Table from the report of Mr. Roberts before cited. It gives the results obtained by the induction vane on a gold-copper series from 901 to 925, which, as has already been shown, is comprised within a range of 24 parts of gravimetrous on the zinc scale. Alloys whose composition lies beyond these limiting values could not be examined by the disc and vane employed, but suitable ones can be selected for any given series of limited extent.

Standard by Assay.	Degrees on graduated Arc.	Standard by Assay.	Degrees on graduated Arc.
925.0	74	914.2	44
920.3	65	911.5	42
916.8	53	901.3	28
915.7	51		

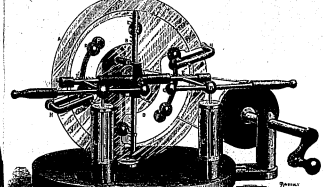
It has been proved by the experiments of Mr. Roberts, Mr. Fleeming, and the mathematical researches of Dr. Lodge and others, that the induction balance effect is mainly, if not quite, dependent on the electrical conductivity of the metals compared, and especially in the gold-silver and gold-copper alloys the effect is greatly influenced by minute differences of composition. Unfortunately, the gold-silver alloys used for coinage are not those which have the most disturbing effect on the balance, a circumstance which adds materially to the difficulty of using the instrument in verifying the standard of this kind for verifying the composition of alloys of the precious metals must in part depend on the distances the accuracy of the results; and the molecular state of an alloy under certain conditions also affects the balance more than small differences of composition." For example, annealing certain alloys of silver, produces changes in their induction-balance effect that are equivalent to considerable variations of standard, and it will, therefore, be necessary, yet to ascertain whether some simple method can be found for bringing any given series of alloys under identical molecular conditions.

The possibility of ascertaining the fineness of alloys by aid of electricity long ago engaged the attention of physicists. In 1820 M. Becquerel suggested that trustworthy indications might be afforded by the electromotive force developed when the alloy is placed in an exciting fluid together with an alloy of known composition. The subject was partially investigated by Oersted in 1825, and, as its practical importance was further influenced by Guy Lussac in 1830, Mr. Roberts made a series of experiments in order to ascertain how far the more delicate appliances in use at the present day could be made serviceable. The results, however, were not entirely satisfactory.

Professor Hughes's induction balance has rendered it possible to attack the problem from a new basis, and though there is, in the opinion of Mr. Roberts, but little hope of finding a more accurate method of assaying than that now in use, it would be so highly advantageous to possess a means of verifying the standard of coins "without damaging their integrity that the capabilities of the induction balance demand careful investigation."

Besides his researches on the gold-copper alloys, Mr. Roberts has also determined the important fact that in the case of the copper-tin alloys the curves of the conductivity for heat corresponds closely with that representing the induction balance effect. He has also pointed out the incomplete character of Matthiessen's curves of electric conductivity, and confirmed the remarkable observations of Mr. Du la Rive, that the conductivity of bismuth is less in the solid than in the molten state. The conductivity of liquid metals is an interesting and probably fruitful branch of research, which has hardly been touched hitherto, and it is satisfactory to know that Mr. Roberts has taken it up. By means of the induction balance, he designs to measure the conductivities of different molten metals contained in small porcelain crucibles enclosed in non-conducting jackets of pumice stone, and we think it highly probable that he will bring to light some unsuspected facts.

VOSS'S INDUCTION ELECTRICAL MACHINE.



We illustrate on the present page an exceedingly well-designed and interesting induction electrical machine which has lately been brought out by Dr. Robert Voss, of Berlin, and which is at the present time being introduced into this country by Mr. Apps and some other English makers. Dr. Voss's machine possesses several points of special interest and value, the most important of which, at all events as regards this country, is its apparent independence to a degree of humidity of the atmosphere. All who are acquainted with the induction machines of Holtz, are aware that when the atmosphere is at all damp, either from meteorological causes or from the presence of a number of people, as is a lecture-theatre, the ordinary Holtz machine is a very often than not practically useless, so that the satisfactory working of such a machine is confined to obtaining some precautions be taken for artificially drying the surrounding air.

Another interesting point in Dr. Voss's machine lies in the fact that it is self-charging, requiring neither friction nor any outside initial charge to start it into action, nor is it necessary to bring the discharging terminals into contact, as in the Holtz machine, before it will commence to work it.

In principle this machine, while being distinctly original, has points of resemblance to the electrostatic multiplier of Mr. Varley, and the electrical replenisher of Sir William Thomson, as well as to the Influence electrical machines of Holtz and Toepler, but it is far simpler and more compact than the last, and is at all times certain in its action.

On reference to the Illustration it will be seen that the apparatus consists, like the Holtz machine, of two glass discs, unequal in diameter, of which the latter, A, is held in a fixed position, while the other is mounted upon a horizontal axis, and can, by means of multiplying gear (seen to the right of the figure) be rotated at a high velocity in front of the fixed disc and in a plane parallel to it. To the front face of the larger plate are attached two pairs of tinfoil discs, F F, F^{1}F^1, each pair being connected together by a strip of tinfoil, and by a second strip to one of the two bent arms H and H^1, by which they are connected to a light metallic brush directed towards the front face of the rotating plate. At the back of the fixed plate are pasted two paper coatings which correspond to what used to be called the paper "armatures" in the Holtz machine. To the face of the rotating plate are attached, at equal angular distances apart of 60 deg., and in a short distance from the circumference, six discs of tinfoil (one of which is marked D in the figure), about an inch in diameter, corresponding in position and size with the tinfoil discs upon the fixed plate, that is to say, if the discs D were numbered in rotation 1, 3, 5, 4, 6, 2, those numbered 1 and 2 would, in a certain position of the rotating plate correspond and be opposite to one connected pair of discs on the fixed plate, Nos. 4 and 6 would similarly correspond to the other pair, and Nos. 3 and 5 would have no discs on the fixed plate opposite to them. To each of the little tinfoil discs there is a metallic point connected, with it is attached a metallic button of the form of a plano-convex lens, and these buttons, to the revolution

* See ENGINEERING, vol. xxii, page 27.

† *Ibid*, vol. xxiii, page 319.

of the plate, pass under and are lightly touched by the metallic brushes F F, which are held by the bent arms H H^1, the brushes being so adjusted as to touch the buttons and not to come in contact with the glass of the rotating plate to which they are attached. E and E are two horizontal collecting combs, connected to one another by being attached to a horizontal bar of ebonite, but connected respectively to the two discharging terminals C and C in the front of the instrument by the metal rods here shown in the figure, and the distance between these terminals can be varied at pleasure by sliding them through the balls which are attached to the outer ends legs of the two cylindrical Leyden jars by which the charge is accumulated and the discharge is effected. B is a vertical bar of brass carrying at each end a comb, directed towards the rotating plate, as well as a pair of metallic brushes, similar to P and P, and which also in their turn make momentary contact with the metallic buttons as they pass beneath them, and at a moment when the latter are under the inductive influence of the metal discs of the fixed plate.

Such is the construction of the machine, and an idea of its general appearance may be formed by reference to the figure. Its principle of action resembles that of Mr. Varley's "multiplier" probably more closely than any other apparatus, but it has points of principle common to the machines of Holtz and Toepler. Assuming in the first instance that a minute initial charge of electricity be given to the tinfoil discs on the fixed plate, or indeed to almost any part of the apparatus, the effect of setting the machine into action will be to build up and accumulate by induction and counter-induction an increasing charge of electricity of opposite signs at the two discharging terminals respectively until their differences of potential is sufficiently raised for sparks to pass between them. The physical process involved in this accumulative action will be better understood by consulting the apparatus with the replenisher of Sir William Thomson figured on page 319 of our twenty-third volume. The paper coverings and the tinfoil discs on the fixed plate correspond to the two fixed inductors in Sir William Thomson's instrument, and the metallic buttons to the carriers, the metallic brushes being omitted, as in the Holtz machine, between the replenisher. The figure of the instrument is, however, more near to Mr. Varley's multiplier, which is very similar in principle to Sir William Thomson's replenisher.

It would be difficult to say at what point in the continuous cycle of operations the first generation of the initial charge takes place, and it is the fact that constitutes the special point of physical interest in the machine; it may occur at the points of contact between the buttons of the rotating plate and the brushes attached to the paper coatings of the fixed plate, or it is possible to be due to a minute difference of potential existing, at the moment of starting, between two conducting parts of the apparatus insulated from one another, causing the electrification of one part of the system to be slightly more positive than another, and such a difference, however minute, would, under the action of the machine, be developed and accumulated by induction into powerful charges. It is probable that the initial action may, in general terms, be attributed to the whole system being in extremely unstable electrical equilibrium, so that the very smallest disturbing influence, such, for instance, as the friction of the contact brushes, or the proximity of some foreign inducting body, will upset the balance, and from the moment that the electrical equilibrium is disturbed the building up of a charge is easily accounted for.

Another very remarkable property of this machine is its independence of moisture. We have made a number of experiments bearing on this point, and have always been able to obtain a continuous stream of sparks between the terminals, although the plates and conductors were bedewed with moisture from having been breathed upon. With a machine, the rotating plate of which is only 200 millimetres (about 10$\frac{1}{2}$ in.), and weighing complete under 7 lb., a series of from 4 in. to 5 in. sparks, accompanied by loud snapping reports, can easily always be obtained; and by placing the terminals a distance apart greater than the striking distance of the sparks, Leyden jars may be charged with great rapidity, and all the ordinary electrostatic experiments may be performed.

Electric Inductive Speech.

The recent experiments of Professor Hughes on electrical tension have been recounted in our columns; and as the subject is just now occupying the attention of several experimenters, we may mention that Mr. C. W. Robinson, Professor of Physics and Mechanical Engineering in the Ohio State University, has made some interesting observations on the electric currents induced in a coil by longitudinally streaming an iron bar passing through it. Professor Robinson was led to these experiments by Joule's result that when a bar of iron is magnetised by means of a helix the bar becomes elongated. He argued that the mere magnifier of the bar by a reversal of the same physical process should produce a current in the helix, and with this aim he fixed a bar of soft iron about $\frac{1}{2}$in. in diameter by its middle point, leaving both ends free to vibrate longitudinally. Upon this bar he caused to slide freely a helix or bobbin of insulated wire in circuit with a telephone, and on striking the bar endwise with a mallet, or rubbing it up and down with a friction cloth, so as to set it into longitudinal vibration, he could hear tolerably loud sounds in the telephone. Strange to say, these sounds were loudest not at the free ends of the bar where the amplitude of the vibrations were greatest, but at the middle where there was a practical node. Sounds produced by the transverse vibrations which mingled with the longitudinal ones were readily distinguished from the latter by their difference of pitch. By a strange oversight Professor Robinson does not state the position of the bar with respect to the magnetic meridian, but it doubtless lay under the influence of the earth's magnetism, and hence the currents were induced by molecular disturbance.

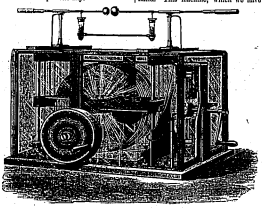
WIMSHURST'S INDUCTION ELECTRICAL MACHINE.

THE history of induction electrical machines, of which perhaps the Holz machine is the best known modern type, dates as far back as about a hundred years ago, when the immortal Volta, the father of electrical science, added the electrophorus to the apparatus of the electrician; and just as the celebrated pile of the same pioneer or the modification of it to which he gave the name of the "*couronne de tasses*" must ever be regarded as the type and precursor of all voltaic batteries, so must the electrophorus be regarded as the origin and germ from which have been developed all the electrostatic induction machines of the present day.

We have from time to time in the pages of this journal, described and referred to the induction machines of Bennett,* Nicholson,† Holtz,‡ Carré,§ Bertsch,‖ Varley,¶ Sir William Thomson,** Töpler,†† and Voss,‡‡ all of which may more or less be regarded as modifications of Volta's electrophorus, and all of which depend for their action, in part or in whole, upon the building up from a small initial charge of electricity, and by a succession of inductions and counter inductions, a far more powerful and accumulated charge capable when desired of producing the most brilliant effects of static electricity.

Up to within a very recent period the most powerful and certainly most widely known machine of this class was that introduced by Mr. Holz, of Berlin, in 1865, and which is to be found in all the important physical laboratories, but the Holz machine has one very serious disadvantage, and that is its dependence upon a favourable state of the atmosphere for successful working; in a climate such as ours in England, there are comparatively few days in the year when a Holz machine can be made to work without great coaxing and difficulty unless means be adopted for artificially drying the air in the immediate neighbourhood of the revolving plates; moreover, the cost of the machines has always been very great. A little more than a year ago Mr. Voss, also of Berlin, introduced an extremely interesting form of Töpler's machine, which we described at the time,§§ this was remarkably independent of atmospheric influence, appearing to work almost as well in damp weather as in dry, but its form did not admit of a number of plates being united to the instrument, as in the compound Holz machines, without very largely and inconveniently increasing its bulk.

We illustrate on the present page a highly interesting and valuable machine, the invention of Mr. James Wimshurst, one of the Consultative Staff of the Board of Trade, which, while possessing all the power of the best Holz machine, is as completely independent of the state of the atmosphere as is the Voss machine, and what is perhaps more important to the majority of scientific men and others requiring a powerful source of static electricity, it can be made and sold at a remarkably small price. Mr. Wimshurst, having himself constructed several experimental machines of the same type, has been enabled to bring the design in a very high degree of perfection, and in its improved form the instrument is now being introduced by Messrs. Peterson and Cooper, of Little Britain. At apparatus of this class has been recently made by Mr. Wimshurst, and is, we believe, the most powerful electrostatic inductive generator in existence; with it all the most brilliant and powerful effects of static electricity may be produced with no more expenditure of power than can comfortably be transmitted by the turning of a wheel by one hand. This machine, which we have had opportunities of seeing at work under atmospheric conditions that would be fatal to the working of a Holz machine, and at a time when all its parts were covered with dust, is capable of giving dense bundles of spark discharges in the open air, upwards of 7 in. long between its terminals, and when small Leyden condensers are attached to its terminals the sound of the discharge is almost deafening. The discharge is capable of piercing all the pages of a Bradshaw's sixpenny railway guide, and most of the brilliant effects of the discharge through vacuum tubes may be exhibited in a most remarkable degree. This machine consists of twelve circular discs of ordinary window glass, 32in. in diameter, mounted upon an insulating spindle, which, by simple multiplying gear, can be rotated at a high velocity by hand. These discs rotate between twenty-four rectangular slips of window glass, twelve above and twelve below the axis, the space between the upper and the lower sets being sufficient to allow the spindle to pass freely between them. These slips are not fixed in any way, but are simply dropped into grooves to receive them, and can in a few minutes be all removed, cleaned, and replaced; they are not coated with varnish or any other insulating substance. The rotating discs rest freely between the plates without touching them, so there is no friction in the working of the apparatus except at the bearings, which is inconsiderable, as the discs, being of thin window glass, are extremely light. It is true there is a series of paper "armatures" or combs on each side of the spindle which rest against the revolving discs, but then contact with them is of the lightest possible character and offers no resisting friction to the working of the machine. Mr. Wimshurst has effectually protected the apparatus against one defect to be found generally in induction machines with several plates; that is, the existence of different potentials in the armatures on the same side. For the successful working of the apparatus all the armatures on one side should be positively electrified and all those on the other side should be of the opposite sign; generally in compound induction machines this is not the case, and a large proportion of the useful effect is lost by neutralisation. To prevent this Mr. Wimshurst connects all the armatures on one side together by a fine wire, which terminates on the outside of the case and serves as a conductor for giving to the apparatus its initial charge, which can be produced by an electrophorus or by an ebonite rod excited by friction.



In the smaller machines which are being made by Messrs. Peterson and Cooper, and which are shown in the illustration, a small frictional plate machine of the ordinary type is fixed at one end of, and within the case, for the purpose of producing the initial charge, but this addition, while making the whole apparatus very complete and self-contained, adds considerably to the expense. If the machine be well insulated the smallest possible charge is sufficient to start the induction, and in our opinion a very much smaller and less costly generator for this purpose might with advantage be substituted for the extra plate machine.

There can be no doubt that Mr. Wimshurst has added a very valuable instrument to the laboratory of the physicist, and we feel sure when it becomes known that powerful electrostatic induction machines can, by carrying out his principle of construction, be made with the simplest possible materials and at remarkably small cost, it can only be a matter of a short time for those interesting machines to take the foremost place among electrostatic generators, and another will at the same time be added to the long list of honoured names who [illegible] science of electricity.

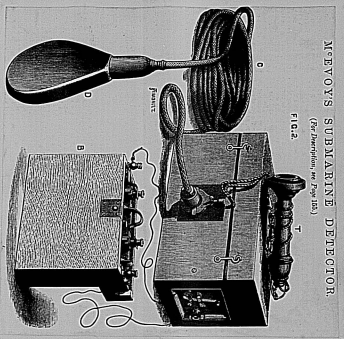
McEVOY'S SUBMARINE DETECTOR.

(For Description, see Page 135.)

FIG. 2.



TANK LOCOMOTIVE; CENTRAL PACIFIC RAILROAD.

CONSTRUCTED AT THE WORKS OF THE COMPANY, SACRAMENTO.

We annex a perspective view of a tank locomotive constructed at the Central Pacific Railroad Works, Sacramento, for working local traffic from San Francisco, or rather from the ferry pier or wharf at Oakland, where the ferry boats from San Francisco land. The company have a large suburban traffic, which is carried across San Francisco Bay, a distance of four miles, by a ferry. The ferry boats discharge at Oakland into a pier which runs into the bay about two miles, and on this pier trains which convey the passengers from the outer end of the pier to the Alameda. In the mornings and evenings the trains are very heavy and make frequent stops; they run from three to eight miles from the end of the wharf.

As will be seen from our illustration the engine is of the six-coupled outside cylinder type, with a two-wheeled truck in front and rear. The chief dimensions are as follows:

Cylinders and Valve Gear:	ft.	in.
Diameter of cylinders	1	2
Stroke of piston	2	0
Distance between centres of cylinders	4	6½
Width of steam ports	0	2
Width of exhaust ports	0	3½
Length of ports	1	0
Maximum travel of valves	0	4
Lap of valves, outside	0	0¾
,, inside	0	0
Lead in full gear	0	5/16
Length of connecting rod between centres	6	0
Wheels		
Diameter of coupled wheels	4	2
,, trucks	2	6
,, journals of coupled axles	0	5½
Length	0	7
Diameter of journals of truck axles	0	4½
Length of journals of truck axles	0	6
Diameter of main crank-pin bearings	0	4
Length	0	4
Diameter of centre coupling rod bearings	0	3
Length	0	3
Diameter of other coupling rod bearings	0	3
Length	0	3
Distance between centres of front and rear coupled wheels	11	0
Total wheel base	22	0
Boiler:		
Diameter of barrel inside smallest ring	4	0
Thickness of barrel plate	0	½
Number of tubes	138	
Diameter ... outside	0	2¼
Length ... over tube plates	10	6
Distance apart of tubes centre to centre	0	3¼
Length of firebox inside	7	0
Width ... at bottom	3	11
... top	3	4½
Height of firebox at tube plate end	6	0
... at back	5	9
Thickness of plates of inside firebox, sides and back	0	5/8
Thickness of crown plate of inside firebox	0	5/8
... tube plates	0	5/8
Diameter of dome	2	0
Height	2	3
Working pressure, 125 lb. per square inch.		
Description of blast nozzle ... Double		
Diameter ...	0	3
Smallest diameter of chimney inside	1	4
Height of top ... above rails	14	11
Grate area	14·7 square feet	
Heating surface: firebox	87	,,
Tubes (inside)	773	,,
Total	860	
Weight, &c.:		
Capacity of tank	1200 gals.	
,, coal box	8000 lb.	
Weight on coupled wheels	60,400 ,,	
Total weight of engine	104,100 ,,	

The boiler shell and inside firebox are constructed of Otis steel, and the tubes of Morris, Tasker, and Co.'s iron, No. 10. The boiler has lap seams, the transverse seams being single, and the longitudinal seams triple riveted; these latter seams are also provided with inside welt straps. The tank is fitted with retaining bituminous coal, the boiler being fitted with rocking grate bars and Ashpan of the usual pattern. In construction we may add, I state that we are indebted to our contemporary, the *Railroad Gazette*, of New York, for our illustration of the engine above described.

McEVOY'S ELECTRIC SUBMARINE DETECTOR.

THE induction balance invented by Professor D. E. Hughes, F.R.S., has had a number of useful applications, and the latest of these is the electric submarine detector of Captain McEvoy, whose name is well known in connexion with torpedo work. In his early

McEVOY'S TORPEDO SYSTEM.

THE part that torpedoes will play in all future wars between maritime powers renders them objects of great interest, not only to naval men, but also to the general public. In the late Russo-Turkish war small, although it had the whole of the Black Sea coast, and both banks of the Danube at its mercy, from the fact that its commanders seamed, very often erroneously, that all the Russian harbours were studded with mines, and that the same appliances were held very far out to sea. Looking further back to the American Civil War, we find evidence not only of the moral, but also of the destructive powers of torpedoes, and see how a nation with numerous harbours and rivers was able by a system of submarine warfare to defend its coast for years against a powerful fleet, and an enemy that lacked neither courage nor resources. Prominent among the officers who derived practical experience from their connexion with torpedo work in the American war was Captain McEvoy, who has since devoted himself to the improvement of submarine coast and harbour defences, and has, perhaps, done as much as any other single experimenter to bring them to their present state of perfection. One of Captain McEvoy's inventions, viz., his "single main system," which has been adopted by several foreign governments, was, until the last few days, on exhibition at the Westminster Aquarium, and forms the subject of the annexed illustration.

In this system of harbour or coast defence the whole of a group of normal torpedoes communicate with the station shown by a single electric conductor. Along this they continually telegraph evidence of their being afloat and in working order, and upon any one being struck by a ship it gives immediate notice of the fact to an observer on the box, any one of these conductors can be separately placed in connexion with the main cable, or the whole may be coupled to it at once. At its other end each conductor enters a torpedo, and passes successively through a telephone coil and a platinum fuse, and thence to earth. Over the telephone, instead of the usual mouthpiece there is placed a bell, or a box containing loose shot, which under the influence of the rolling motion of the waves, continually make a noise that can be heard in a telephone at the central station. The

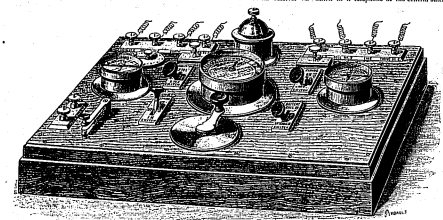


FIG. 1.

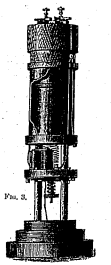

FIG. 3.

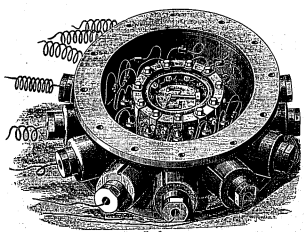

FIG. 2.

above, who can, if he think fit, instantaneously explode the exact mine without any time spent in preliminary adjustments. Further, each torpedo can be electrically isolated from the rest, and can then be tested so that the continuity of the electrical connexions may be determined, or can be exploded without coming in contact with the ship whose destruction is desired.

The single electric cable, which is the modern way by which the currents for producing these various effects are conducted, runs from the signal station on shore to a point in the channel or harbour mouth where the assemblage of torpedoes is situated, and there enters a junction-box. From this box there emerge as many conductors as there are torpedoes to be manipulated, one going to each, and by means of electrically controlled apparatus within this box, any one of these conductors can be separately placed in connexion with the main cable, or the whole may be coupled to it at once. At its other end each conductor enters a torpedo, and passes successively through a telephone coil and a platinum fuse, and thence to earth. Over the telephone, instead of the usual mouthpiece there is placed a bell, or a box containing loose shot, which under the influence of the rolling motion of the waves, continually make a noise that can be heard in a telephone at the central station. The fuse is a piece of platinum wire, through which a current of moderate intensity can be sent without any danger of heating it, but which can be ignited and fed by a more powerful current when desired. The arrangement for effecting explosion by concussion consists of a weight held down in a seat by a spring, but not otherwise secured. When the case is violently struck the weight is displaced, and by its motion brings two contact pieces together, diverting the current from the telephone coil and directing it through an electro-magnet, which maintains the parts in the new position until the exploding current is transmitted, or the current is reversed, when the contact is broken by a spring.

After this general account of the capabilities and mode of action of Captain McEvoy's single main system, we will describe the extremely in-

ulation of the coils B B is connected with the line or earth wire S, and also with the switch lever H; the other terminal is in connection with the battery E. The electro-magnet A is continued in connection to C by wire a, the other end of the coil being in the state J by wire i and to the metal contact screw K. The armature lever D is connected to the upper and lower contact pieces of key S, the lower contact piece of the coil key being also connected to segment R by wire b, the other end of the coil key being connected to the battery E. The lever D is insulated from the frame of the instrument by the ebonite handle L; and with the handful is so arranged that, on the key S being depressed, the lever D is brought into contact with the stop screw K, thus completing the circuit to cause the soft iron armature D to form a temporary magnet, and cause the lever D to attract the said armature, and from this it will be seen that the lever D is insulated from the metal contact screw K, and the stopper N will move away from the contact screw on the dial to each instrument to set in a different position, so that only one instrument can be worked at any other instrument, as the operator at the central office can be working position at a time. The operator at the central office can call any one of the other stations either by means of bells in the case of an ordinary station telegraph or by means of the plan, the central office can call any one of the other stations by means of the plan, the operator at the central office can call any one of the other stations by means of the plan, the operator at the central office can call any one of the other stations by means of the plan, the operator at

Advertisements cannot be received for insertion in the current week later than 5 P.M. on Thursday. The charge for subscriptions is three shillings for the first four lines or under, and eightpence for every additional line. Terms for extensive series made known on application. Payments must accompany all orders for advertisements, otherwise their insertion cannot be guaranteed. Copies of the latest advertisements on the wrapper and on the inside pages may be obtained on application.

The Publishers are prepared to accept subscriptions in the United Kingdom monthly, quarter by post 6 /6, 7s. 6d., or annual, 30s including two double numbers. If credit be taken, the charge is 7s. 6d. extra. No subscriptions being payable in advance.

FOREIGN SUBSCRIPTIONS.

The rates for subscriptions to ENGINEERING from abroad are: 11, 12s. 6d. For Subscriptions to Engineering, Canada, India, Brazil, Canada, Chilwalia, Newfoundland, Germany, Denmark, Egypt, Java, Holland, France, Germany, Greece, Italy, Portugal, Switzerland, and United States of America.

27, 6s. 6d. For Subscriptions to Belgium, China (viâ Suez Canal), Japan, Australia, and New Zealand (viâ Brindisi).

All accounts are payable to the publisher, Mr. CHARLES GILBERT, 35, Bedford-street. Cheques should be crossed "Union Bank of London, Charing Cross." Post Office Orders to be made payable at Charing Cross, London, W.C.

Office for Subscriptions and Advertisements, No. 37, Bedford Street, Strand, W.C.

ENGINEERING is registered for transmission abroad.

READING CASES.—Reading cases for containing twenty-six Numbers of ENGINEERING may be had of the publisher or of any newsagent. Price 2s. each.

NOTICE TO AMERICAN SUBSCRIBERS.

We beg to announce that we have appointed Mr. LEMUEL SMITH, 128, Broadway, New York, the sole agent for ENGINEERING in the United States, and all subscriptions for the United States must be forwarded to him. Mr. LEMUEL SMITH is also prepared to receive advertisements for ENGINEERING, and will afford full information as to terms, &c., on application. The annual subscription for ENGINEERING delivered in any part of the United States is 14 dollars. Gold currency payable in advance.

NOTICES OF MEETINGS.

INSTITUTION OF CIVIL ENGINEERS.—Tuesday, March 18th, at 8 p.m. Discussion upon "Harbour Works," and (time permitting) upon "Breakwaters and Docks." Paper to be read: "Notes on Lighthouse Illumination," by James N. Douglass, M.Inst.C.E.

THE METEOROLOGICAL SOCIETY.—Wednesday, the 19th instant, at 7 p.m., at the Institution of Civil Engineers, the following papers will be read:—"On the Climate of Ceylon," by Dr. Thwaites, F.R.S. "On the Inclination of the Axis of Cyclones," by the Hon. William Clement Ley, M.A., F.M.S. "Contributions to the Meteorology of Australia, No. 2," by Mr. Ferdinand Baron von Mueller, by Robert L. Scott, F.R.S.

PHYSICAL SOCIETY.—Saturday, March 29th, at 3 p.m. "On Solenoidal Distribution of Electricity," by Prof. J. J. S. "On the Fluxions of Colours," by Captain Abney, R.E.

INSTITUTION OF ELECTRICAL ENGINEERS.—Monday evening, March 17th, on "Constructive Value," by Mr. H. J. Smith, Esq. The chair to be taken at 8 o'clock.

ENGINEERING.

FRIDAY, MARCH 14, 1879.

THE NAVY ESTIMATES.

It is hardly to be wondered at that much interest as attaches to the introduction of this year's Navy Estimates centres rather in questions affecting the *personnel* than the *matériel* of the Navy. The vote of credit not only enabled the Admiralty to make good, in the popular view, the accumulated deficiencies of years of sluggish shipbuilding, but it only too *likely* to be made the unconscious excuse for similar defects in the future. Yet the additions to the Navy of a number of masted ironclads, of which only two can be described as of the first class, should form no reason for relaxing the construction of the real fighting ship, the Devastations and Inflexibles, when it is remembered that, except by a not very large party who hold that quite small ironclads should be substituted generally for large ones, it is now almost universally allowed that ships more or less of the Devastation or Inflexible type, whether monsters like the last named, or vessels of comparatively moderate size like the Ajax and Agamemnon, must be relied upon to do the heavy fighting of the future. Yet though it is nearly *ten years* since the Devastation, Thunderer, and *Fury* (now the Dreadnought), were put in hand, and although they have long become obsolete as regards thickness of armour, it is actually the case that the last named of the three has still to make her first cruise, and that *only one* other vessel of the first class—the Inflexible—has been brought to any thing like a forward condition. Two more, the Ajax and Agamemnon, though they have figured for years in the estimates, are little more than on the third part completed, and though they are expected to be launched in a few months, it is not even proposed to get them much more than half finished even by March, 1880. Ten years after putting the pattern ships of the type in hand, and at least four years after their universal acceptance, we have succeeded in nearly giving them one consort, while there is a distant view of two more, and three others are now being seriously talked of! No doubt the public is quite as much to blame as the Admiralty. The intense interest excited by the Devastation—or rather by the charges against her: their triumphant refutation was less noticed—has long since died out, and the certain knowledge that, directly a big ship is nearly built, somebody will find out that she is all wrong, and must be "suspended" for a couple of years' argument, tends to damp public interest in shipbuilding. The days when every Briton, assigning or otherwise, was either a vehement broadsider or a vehement turret-man, produced, no doubt, a great crop of nonsense, and may even have been responsible for Admiral Fishbourne, but they were the days of rapid progress. Now nobody worries the Admiralty seriously, and though it doubtless makes progress as good, in kind, as when most Englishmen were its austere advisers, its progress in quantity is not satisfactory, as we have shown. Part of the public apathy about the building of large ships is perhaps due to a new and not ill-founded conviction that the English Navy has lately given evidence of great power, and, inferentially, of the possession of its old superiority to the fleets of other nations. Considering that we have made it our business for years to defend the Navy against the charge of weakness so often brought against it by ignorance, or worse, it need not be said that we accept fully, up to a certain point, the very respectable note recorded to its efficiency. But though this has satisfactory display of English naval power serves to confirm the arguments frequently urged, and fully illustrated by comparisons with the fleets of other countries, in these columns, it proves nothing beyond the *present superiority* of our Navy. We have urged with equal constancy that that superiority will not be maintained except by a reasonably rapid development of the heaviest fighting class of ships, in which other nations are fast overtaking us, and as years pass without the necessary additions, we can but commence to change sides with our old opponents. They are content, because the Navy has received additions of the kind they believe in, but which we believe to have been sufficiently represented in our fleet already; we are not content, because the additions we consider necessary appear almost as distant as before. If there were the slightest hope that in two years' time the Ajax and the Agamemnon, the Majestic, Colossus, and Conqueror, could be added to the Navy, we should feel satisfied with the fleet of nine great turret ships the country would then possess, backed up by the three rams, Rupert, Hotspur, and Polyphemus. But experience forbids any such hope, and at least four years must be expected to elapse before the fleet is completed, and by that time there will be enough vessels of the class afloat in other countries to inspect our supremacy seriously. Italy, alone, has now two Inflexibles to our one, and whereas all our later vessels are less powerful than the Inflexible, the Italians are building to a design of much greater power. As is well known, they have given up their armour, and limit the plating to the protection of the guns, and of a sort of central trunk connecting them with the lower part of the ship. A thickness of only 2 ft. of armour is thus obtained, upon which a tonnage considerably exceeding that of the Inflexible, and as the case of making all temporary, as well as stability, dependent upon keeping the water out of an unarmoured hull by contrivances more or less resembling those used in the ends of the Inflexible. We entirely agree with Mr. Smith in his refusal to adopt this principle of shipbuilding in the English Navy, but it is obvious that such vessels might go through many actions without paying the penalty of their undoubted weakness in that one particular. He would be a bold man who would attempt to assess the value of a ship carrying 2 ft. of armour, and guns to correspond, against a ship like the Inflexible, or, still more, like the Devastation, whose guns could make no impression on the Italian armour, and whose own plates would yield like sandskin before her guns. With the Italian building, we ought to neglect anything rather than the construction of first-class ships. Praise is due to the present Admiralty for its insistance upon keeping up the repairs of ships; but no repairs to old, and therefore obsolete, ships, can do as much for the strength of the Navy, as regards heavy fighting, as the construction of one or two vessels of the newest type.

The discussion following Mr. Smith's speech was unusually tame. It was the speech of a plain but capable man of business determined to work his important upon common-sense principles, and generally allowed to have worked it with success. There was little criticism, for the gratifying reason that the country places confidence in the present First Lord, while the only weak point in his programme, to which we have adverted, awaks as yet no remark.

PROFESSOR HUGHES'S INDUCTION BALANCE.

From the moment when the electric telegraph ceased from being but a beautiful laboratory experiment, to become a practical application of science, and before it could take its place among the commercial undertakings of the world, it became necessary, from the very exigencies and requirements of its useful application, to multiply the number of conducting wires along the same routes, carrying them one below the other and parallel to one another, for any one route, upon the same line of poles. From the moment that this was done the telegraph engineer found that he had conjured up an enemy in his own camp which has gone on growing and becoming more powerful to constant augment, defying every effort to conquer it, and increasing with the extension of the system and with the greater perfection and sensitiveness of the instruments employed. This enemy is what we now term electro-dynamic induction, and may be generally defined as that property of electricity by which electric currents are produced in conductors by the influence of other currents passing through conductors in their vicinity. Electro-dynamic induction was discovered by Faraday in the year 1831, and his researches in connexion with this subject culminated in his transcendent discovery of magnetoelectricity, the development of which has lately produced so much excitement in the commercial world, and is at the present time rapidly taking a position as one of the most valuable and important applications of science to the comfort and convenience of man.

If a current of electricity be transmitted through one of two wires which run more or less in a parallel direction, a momentary electric current is produced in the other at the moment that the current is started in the first; and the secondary current so produced is in the opposite direction to the primary. Again, at the instant of breaking the circuit of the primary wire, a momentary impulse or current is produced in the secondary wire, but this time in the reverse direction to the former one, that is to say, the current induced in the secondary wire is, on the cessation of the current in the primary wire, in the same direction as the primary current which produced it. The strength of the secondary current in both instances depends, upon the combination of several conditions, such as the degree of parallelism between the two wires, their distance from one another and their length, as well as upon the strength of the primary current, and the resistance of the secondary wire in which the induced current is produced. As the distance between the two wires is diminished, the strength of the induced current is lessened in proportion; and when the directions of the two wires become precisely coincident to one another, inductive energy ceases, no secondary current being produced. The primary current is broken or breaking the circuit in the primary wire. Again, if the distance between the two wires be increased, the inductive action is lessened, and when the circuit is diminished, and *vice versâ*, the maximum effect being produced when the two wires are so placed as possible to one another without their insulation being destroyed, and, as this inductive influence is exerted both by and through the electric impulses of the parallel portions of the two whole wires, it follows that an extension of this length increases the effect of induction by a sort of cumulative process, and for this reason the resistance of the secondary wire does not play so important a part as the other conditions above referred to. The

ELECTRICAL INDUCTION.

Experimental Researches into Its Law of Proceeding Through Space and Time.

By Prof. D. E. Hughes.

The induction of one metallic current wire has of late years been a serious question upon telegraph lines—the constantly increasing number of wires upon the same poles, added to the adoption of high speed and consequent sensitive apparatus, renders the study of these effects of the first importance.

The disturbing effects have become much year more and more troublesome, and it is now found that the duplex, quadruplex, and other multiplex systems of Telegraph have introduced a series of problems of the most complex character, with the view of finding a remedy. I at once perceived that at last I had to deal with a question of a much more complicated nature than was at first supposed. We found that when the full insulation of two or more parallel wires, the line and the grounds—the induction of the lateral wires; that is, the effects of one wire were very different; and whilst it was easy to deal with the ordinary effects of static charge, the same powerful and rapid effect of induction was not so readily dealt with hardly by insulating the wires, and even by using wire cells we could reduce the induced current, but, at the same time, we should reduce the current with which the line was working. The remedy was in most cases (perfectly distant from the probable) worse than the disease. Condensers and polarisation batteries would allow the momentary currents to pass away to earth, but would retard the more prolonged currents of the distant stations. The only remedy we then found was by the introduction of the electro-magnet, with an armature fixed upon its pole—thus being a closed magnetic conductor. This practically answered, and employed all the short momentary currents; but even these at this late the apparatus was working at high speed, and with the most sensitive receivers, we practically only got the best out of the current worked.

In this case, whilst the remedy was practically perfect (for no appreciable effect was noted with momentary reversals, it was useless for those working at high speed requiring shorter contacts, and consequently more sensitive organs of receptive.

The effects I recorded was at that date from following up this line of research. The disturbances on the lines from the same have been on a comparatively rare from the adoption of more rapid, and consequently more sensitive, organs; and in the telephone we have at last met with an organ of such extreme delicacy, which not only reveals the constant induction, but which is the most sensitive test we have. The telephone has not been largely adopted upon the Postal lines.

In a late paper I had the honour to present to the Institution of Civil Engineers, and also to the Royal Institution, I then stated that I had, to possess in the telephone and microphone; and we then put this forward

* Paper read before the Society of Telegraph Engineers, Thursday, December 19, 1878, and the Royal Institution, Friday, December 20, 1878, and January 10, 1879.

all of these we might hope to multiply, theoretically, the cases (and remedy for lateral cellular) to infinity.

The following experiments are to a résumé of the results obtained.

We made use of three separate and distinct means of research. The first consisted of two or more parallel wires, 1, 2, 3, &c.; the one being used as a primary was connected to battery, and the other wires, with check as source of sound through with the battery to earth). The secondary wire, upon which the induced current was observed, was connected to telephone—both ends of this line also being to earth.

The second arrangement was made, in order to study the effects upon a much similar length, and with more accuracy the laws governing the effluent on the longer line.

Two parallel wires—copper—copper wires were strung upon a board. If the ends of these wires were placed 12 in. apart, and a battery of 4 cells of Leclanché with 1 Daniell connected to the one. The condenser was then introduced in the primary circuit in connexion with battery and key, and the secondary end of these wires with the other, or with the telephone circuit. In this case, we could observe the effects of momentary reversals, by examining it with the unprotected induction upon a powerful one felt in vibrating sufficient induction upon a powerful one felt in vibrating sufficient induction upon a powerful one felt in vibrating sufficient

current needed. Magnetic condensers would absorb the induction, but also absorb the first part or the part most needed of the voltaic current.

Secondary or intermediate stations all these would give contrary effects to those of the primary secondary batteries and condensers in deviation; but these would weaken the primary current, and for a line of ten wires would, from a calculation we have made, require 45 such condensers, and even then it would be impossible to fulfil all the necessary requirements.

As to the assembling station ordinary induction coils do not act sufficiently strong for a line of ten wires only.

Deviations from synchronism, as we have required, but a great resistance between the instruments should be introduced, and, moreover, the current would be prolonged beyond the induced current.

Polarisation batteries and condensers would also, if in derivation, require great earth resistance, and would require ten or fifty wire for the same number of conductors as the intermediate system, which is objectionable.

Commutating coils, as arranged in the instrument we have established, fully meets the difficulty, giving perfect compensation for any number of wires, with but one coil in each wire, provided that the lines are used for transmission in one direction only for stated periods, and that they are arranged as in Preston, as already explained.

The Bell telephone, however, itself gains five fresco inductions, and not lacking in clear voice, and therefore requiring no compensating arrangements, as in the instance we have already mentioned, wires both ends are to earth, and its electro-magnet wound differentially.

I have studied this subject with much interest because I believe that the future improvement in telegraphy depends to a great extent on its entire solution, and I hope that a fair discussion on this subject now rests may be brought to light.

MOLECULAR ELECTRO-MAGNETIC INDUCTION.*

By Prof. D. E. Hughes, F.R.S.

(Concluded from page 58.)

THE measurements of electric force mentioned in this paper are all measurements on an arbitrary scale. Their absolute value has not yet been obtained, as we do not, at our present stage, require any exact comparative measures. Thus, if each coil in the 100 mile circuit had 100 ohms resistance, 2 Daniell cells would give by the aid of the key 1 and that the following are the comparable degrees of value:—

Soft iron	59 Tertiary current.
Hard drawn iron	50 " "
Steel	45 " "
Hard tempered steel	30 " "
Copper, 60 cents.	3 " "
Copper balls, 1 centm. diameter, 20 turns in 20 centims.	45 Secondary currents.
Iron, spiral, ditto	45 " "
Glass	65 " "

The tertiary current increases with the diameter of the wire, but not in the same ratio as the secondary determined; thus, an ordinary hard iron wire of 1 millim. diameter giving 50°, one of two millims. diameter gave 100°, and the maximum of force obtained by any degree of torsion is at or near its limit of elasticity, as if in some fibres or wire that point, producing a permanent twist the current disappeared. Thus, for instance, with a wire in the case of a permanent twist, the point of which was 1 millim. hard iron wire was 50° of torsion, but in hard steel it was 60°.

* The substance of a paper read before the Royal Society, March 17.

† 50° successor has the same electromotive force as 0·50 of a Daniell battery.

Longitudinal strains do not produce any current whatever, but a very slight twist to a wire, under a longitudinal strain, produces its maximum effects: thus, 50° of torsion being the critical point of iron wire, the same wire under longitudinal strain, required but 10° of torsion to produce the same effect; however, to produce a perfect longitudinal strain alone. I have, therefore, only been able to try the effect of longitudinal strain on fine wires, not larger than 1 millim. in diameter, but as to all cases not effect whatever manufactured by longitudinal strain alone, a larger case will be found if absolutely perfect. Thus, if a perfectly annealed iron wire under strain are equally under no elastic strain or tension, but the path of their motion is now parallel with its wire, or the axes of electric induction effect, but the compound strain, composed of longitudinal and transverse, react upon each other, producing the increased effect due to the compound strain.

This successor is not only useful for showing the direction of the current and measuring it by the zero method, but it also shows at once if the current measured is secondary or tertiary. If the current is secondary its period of action coincides with that of the successor, and a perfect zero is obtained, but if at any case obtained, and its value in successors is given; but if the current is tertiary, no zero is obtained, and if the value of the tertiary is 60°, we find 120° the nearest approach to zero possible. But by the aid of separate induction coils to convert the secondary into a tertiary, a perfect zero can be obtained, and the value of the secondary and its force corresponding to that which we wish to measure.

If I place a copper wire in the balance, and turn the coils at an angle of 60°, I obtain a current which the successor gives, as in the instance of the copper, as eternal; and, that is secondary. If I now replace the copper by an iron wire, the coil remaining at 60°, I have again exactly the same values for the iron as copper—viz., 60°, and in both cases secondary. Now, it is evident, that in the case of the iron wire there was produced at each passage of the current a double molecular change; but this longitudinal magnetism did not disturb change the character of the current or its value in force.

A most beautiful demonstration of the fact that longitudinal magnetism produces no current, but that natural magnetism can act equally as well, no matter the direction of the longitudinal magnetism, consists in forming an inductive circuit, or taking two parallel but separate wires, bringing electricity at their final ends, the free ends being connected with the circuit, so that the current generated must pass up one wire and down the adjacent one. Or, testly, still better, one of there are no internal strains, complete zero of electro-motive current will be found. Now, giving a slight torsion to one of these wires in a given direction, we find, say 60° positive; twisting the parallel wire in a similar direction produces a perfect zero, thus the current of the second must be 60° also positive of the first. If, instead of twisting it in a similar direction, we twist it in the contrary direction, the zero is increased in value from 60° positive to 120° positive, showing, in this latter case, not only a doubled increase of force, but that the currents in the iron wires travelled up one wire and down the other, corroborating that both were strongly magnetic by molecular action. This beautiful and perfect experiment also proves that its molar magnetism has no effect, as the currents are equally strong in both directions, and both wires can double or efface the currents produced in each. If, instead of two wires, we take four, we can produce a zero, or a current of 120°, and with twenty wires we have a current of 300°, or the maximum power of the apparatus. We have here a means of multiplying the effects by giving an elastic torsion to each separate wire, and joining them electrically in tension. If loops are formed of one iron and one copper wire, we can obtain both currents from the iron wire, positive and negative, but none from the copper wire, as the effect of a conductor upon which tension has no effect.

I have already mentioned that internal strains will give not tertiary currents, without any external elastic strain being put on. In the case of iron wire, these disappear by a few twists in both directions, but in flat bars or forged iron, they are more permanent; evidently, portions of these bars have an elastic strain, whilst other portions are free from it, and, as I have already mentioned in the instrument, however, is so admirably sensitive, and able to point out not only the strain, but its direction, that I have no doubt its application to large forged pieces, such as shafts or cannon, would bring out most interesting results, besides its practical utility; great care is therefore necessary in the manufacture of iron that it should be free from internal strains, or that we know their value.

Magnetising the iron wire by a large steel permanent magnet has no effect whatever. A hard steel wire can likewise become strongly magnetic, but no current is generated, nor has it any influence upon the faults obtained from molecular movement, as in elastic tension. A flat wire iron bar, or a bundle of iron wires, when magnetised by an iron bore produces transversal, instead of longitudinal, but neither shows any trace of the currents produced by molecular magnetism. I have made many experiments with wires and bars thus magnetised; but as the effect in every case was negative when freed from superficial errors, I have not thought it necessary to describe them. In bending round which the instrument gives, that longitudinal magnetism first passes through its successive modifies before and during the discharge, or recomposition of its magnetism. For this purpose, using no battery, I put the terminals and telephone to the coil, the wire having no current passing. I then magnetise the iron wire at one end of the wire. I find by slightly moving the coil, that there is a Faradaic induction of 50° at both poles, but very little or none at the centre of the wire; now fixing the coil at the central or neutral point of the wire, and listening intently, no sounds are heard; but the instant I give a slight twist to the wire, a sound is heard, and a perfect tertiary induction is heard, whose value is 60°. Again, testing this wire by moving the coil, I find only a remaining magnetism of 10, and upon repeating the experiment of elastic torsion, I find a tertiary of 2 thus we go on gradually discharging the wire, but its discharge will be found to be in proportion to the force that has passed through the stage I have mentioned.

Heat has a very great effect upon molecular magnetic effects. Up to 100 it increases the current, but in what the current is diminished. For experimenting on iron wire, which gave a tertiary current of 50° positive (with a torsion of 10°), when heated, but retained its set to cold, with a torsion of 10°, when cold. I very much doubted the experiment at first, but on repeating the experiment with steel several times, I found that on heating it, I had restored the extreme hard (yellow) temper to that of the well-known blue temper. Now, at this temper, the wire, as stated was but 10 to 15°, whilst soft iron of similar size gave 50° of force cold, and 100° at red heat. This fact, so completely shows that the effects I have described depend on molecular elasticity, it proves at least, as far as iron and steel are concerned, that a comparatively perfect elastic body, such as tempered steel, has the greatest molecular elasticity, and that heat reduces it, but that soft iron, having but little molar elasticity, has a molecular elasticity of a very high degree, which is increased by heat.

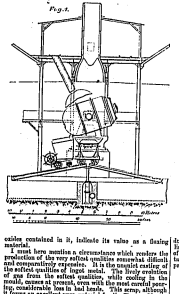
The objects of the present paper being to bring the experimental facts before the notice of the Royal Society, and not to give a theoretical solution of the phenomena, I will simply add, that if we assume with Poisson, that all parts of the molecules of iron are elastic, and that the molecules slightly compressible or elastic, and that they are capable of being polarised, it would sufficiently explain the new effects.

Jenkin has shown that no iron bar is longer and shorter when magnetised than when before, and in the case of the successor we see the extreme portions of the wire are under a force equal to more than three over the centre, and as the polarised ellipse are at an angle with the molecules of the central portions of the wire, its polarisation ceases upon them, producing the comparatively strong electric currents I have described.

Engineering Aug. 5. 1881.

PRESIDENT GARFIELD AND THE HUGHES INDUCTION BALANCE.

One of the most interesting and important applications of electricity that has ever been made, involving as it does the saving of human life and the amelioration of human suffering, has recently been employed with complete success for the localisation of the bullet which so nearly deprived the Republic of the United States of America of their President. On the 16th of July last the following telegram addressed to Mr. W. H. Preece, was transmitted across the Atlantic by Professor Graham Bell. "Bell to Preece—Can Hughes suggest form of induction balance to locate ball in President Garfield? If so telegraph at once at my expense." In reply to this telegram, which was handed to Professor D. E. Hughes, F.R.S., an answer was telegraphed back the same day, in which Professor Hughes gave instructions for the construction of an instrument, a special form of his induction balance which has already been described in these columns,* and Professor Hughes at the same time sent by post to Professor Bell sketches, and a more detailed description of the way to proceed. Professor Hughes's instructions were immediately carried out in Washington, and our readers will have seen by the telegrams which reached this country on Monday last, that the position of the ball within President Garfield's body has been localised with great accuracy by the electrical method devised by Professor Hughes. The method was as simple as it could be; an induction balance was constructed, in which one pair of coils fixed at a definite and invariable distance apart by being wound on a double bobbin or spool, being separated from one another by the thickness of the middle flange, and the four free ends of the two coils were made into a tube by which the two coils or searching apparatus were connected to the battery, telephone, and rheostone, and with a second pair of coils which formed the initiating apparatus. From the construction of the induction balance it follows that by varying the distance of the adjustable coils of the indicating apparatus, until the inductive currents in the apparatus are balanced or neutralised, silence in the telephone is produced so long as there is no outside disturbing metallic body within the induction range of the searching instrument. The moment such is the case the equilibrium is destroyed and the sound is brought back in the telephone, becoming louder or less audible as the disturbing body is nearer or further from the pair of searching coils. By passing such an apparatus over that region of the President's body in which the bullet is known to be, as on are placed at the telephone at the other end can immediately detect by the sounds becoming louder when the foreign body is exercising its maximum inductive effect upon the bobbins, and as it is a fact that for equal distances the maximum disturbance is produced when the metallic body lies in the axis of the coils, it will be seen at once that not only the distance of the bullet from the surface of the body, but also its direction from any one spot can be ascertained with extreme accuracy, and by repeating the operations on different parts of the region under examination, a number of distances from the surface are obtained as well as a number of lines of direction, all of which have a common origin in the bullet, and by this simple arrangement the surgeons attendant on the President of the United States have been able to locate the bullet within his body with unerring exactness.



removed, the liquid is stripped, and finally the cleanup of bullions is effected on the same truck. A small ten-horse power locomotive is employed to do all this work.

The new plant contains other peculiar arrangements and modifications, which we propose to pass over, as they do not appear to us to be worthy of the basic process.

The slag produced in the blast furnaces is held, I have given analyses above, is employed over again in the blast furnaces, since we are thus enabled by means of the phosphorus present in it to raise the content of phosphorus in our pig iron. The small amount of silica and high content of lime in the slag, as well as the iron and manganese lime upon President Garfield, and there was every reason to believe that the position of the bullet had been satisfactorily localised.

III. Although Hughes's induction balance is well known, a brief résumé of its principle will not be out of place. Whenever a current of electricity from through a wire, it converts the neighbourhood of that wire into a magnetic field. A "magnetic field" is a term applied to any space in which a magnetic influence of magnetism, and it is observed by the appearance with lines of magnetic force which have sometimes been called lines of magnetic force that rays of light have to light itself. Whenever a conductor moves through these lines of force or whenever these lines of force are projected through a conductor, a current of electricity is generated in the conductor. Now, if we take our wire and form it into a coil (as at A in the accompanying figure), and pass a current of electricity through

this coil, its neighbourhood becomes a "field;" and if we suddenly start another coil (B), a current of electricity will be induced in this coil for every current that passes through A. If we suddenly stop the current in A, a current is induced in B. The strength and direction of this induced current will depend upon the strength and direction of the primary or inducing current in A, and upon the intensity of the magnetic field and the lines of magnetic force passing through it. Anything that disturbs the field will vary the current in B. Now if a battery of four or five cells is joined to A, and a vibrating contact piece is rapidly and alternately interrupts the flow of the current through A. As B is represented another coil, precisely similar to the first, through which no current can flow at first, and at A and C are represented two coils of wire precisely similar to each other, but so connected that the current induced in the one are in the reverse direction to those induced in the other. If, then, a piece of metal be now applied to the two, before with great sensitiveness any currents, however feeble, that may be flowing. If the instrument is connected up, as shown in the diagram, and the "interrupter" be set going, there will be silence in the telephone, because the current that are induced in the coil are balanced by currents induced in the others. If, however, a piece of metal be brought near enough to affected any wires in the field of A, other currents are induced in this piece of metal, the lines of force are disturbed, and the balance is destroyed, and sounds are heard in the telephone. These sounds can again be destroyed by bringing the coil into the same position of field of A, readjusting the coils at B until perfect silence is obtained, as we have the primary and secondary coils in the same relation to the field of A. Hence, a graduated scale can be used to obtain measurements of the amount of disturbance. The instrument is so sensitive that it can trace the smallest impurity in a sovereign; and Professor Chandler Roberts informs us that it has been utilised in the Mint for the detection of base coinage.

IV. In order to apply this apparatus to the localisation of a bullet in a wound Professor Hughes recommended that the pair of coils C should be made movable and portable, so that they might be moved over the body of the wounded man. He anticipated that if the coils were brought within 30in. of the bullet its presence would be detected. The bullet could readily be brought in close to the axis of the coils by observing the position of maximum sound. It remains when that is done to ascertain its depth, and Professor Hughes suggested by moving a similar bullet in the field of A, and observing in the small receiver B attached to it that the depth of the total bullet could be ascertained. Professor Hughes will shortly devise a practical form which can be placed in the hands of any surgeon.

ELECTRICITY AND GUNSHOT WOUNDS.

*On the Application of Electricity to the Localisation of a Bullet in a Wound.**

By W. H. Preece, F.R.S.

I. Any application of electricity which can aid the practice of surgery and lead to the total suppression of pain must fulfil one of the highest functions of the art of applying the great forces of nature to the wants of man. I purpose to show how an electric current can be made an invisible and immaterial probe, localising the position of a bullet in the human body by the production of a well-known kind of sensation of pain. Electricity has already been used for probing purposes, but only to detect, by the ringing of a bell, the fact that a metal has been touched by the point of the instrument. The operation was performed with all the pain to the wounded sufferer, and electricity was employed only as an agent more sensitive than the finger.

II. The sensation of using electricity alone as the test itself, for this purpose, occurred to Professor Graham Bell in Washington. He telegraphed to me on the subject to consult with Professor Hughes as to the use of his induction balance for the purpose. That gentleman threw his whole heart into the matter. Full directions were sent out to Professor Bell by telegraph, practically corresponding to the subject with Mr. Tainter. Experiments were made by

WIMSHURST'S ELECTRIC MACHINE.

We have from time to time, in the pages of ENGINEERING, described the very interesting electrostatic induction machines * of Mr. James Wimshurst, one of the consulting engineers to the Marine Department of the Board of Trade, and who, combining as he does a remarkable intuitive knowledge of electrical matters with great skill as a mechanician, has designed and constructed a number of new forms of induction, machines of a high order of excellence and originality, and which he has moreover freely given to the world. These several machines form so many advanced links in a most interesting chain of development in the history of electrostatic science, besides placing in the hands of the physicist and science student most valuable additions to high-class apparatus at their command, and which can be made and supplied with a reasonable profit at an exceedingly moderate cost.

We illustrate this week a very large machine which has just been completed by Mr. Wimshurst in his own private workshop, and which, unquestionably, the most powerful and efficient electrostatic machine in existence. This apparatus has been constructed for and presented to the Science and Art Department at South Kensington by Mr. Wimshurst, the cost of the raw material being defrayed by the Department.

On reference to the illustration it will be seen that the form of this machine is nearly identical with the smaller type which we illustrated and described two years ago.† In point of difference lying in its size and in the construction of the supporting parts, which the greater weights have necessitated. Thus, while the diameter of the circular plates of the smaller machine was 14 in., that of those of the great machine is 24 in.; the former being cut out of ordinary window glass, while the latter are discs of plate glass $\frac{1}{8}$ in. in thickness, and weighing 280 lb. each. Each of these discs is pierced at the centre with a hole 6 in. in diameter, and is firmly attached to a gun-metal tube 18 in. in length, carrying the disc at one end and a pulley at the other, and which is let on so as to run freely on an iron tube 3 in. in diameter, this tube being supported at each end by strong oak frames, rising from a firm base, also of oak, and which is fitted with lockers at each end, for holding spare parts and accessory apparatus. The heads of the two frames, A A frames, consist of massive castings of gun-metal which are so shaped as to hold the hollow iron tube, and into the clouts rail rods are attached. The iron tube projects at each end beyond the frames, and to the projecting ends are attached the brass "neutralizing" rods, which terminate in fine wire brushes, shown in the illustrations.

To the discs, which are well varnished with an alcoholic solution of shellac, are attached, at equal angular distances apart, radial sectors of tinfoil, 10 on each disc. These sectors are 19 in. long, and have a mean width of 1.63 in., thus having an area of 31.35 square inches. They is thus on each plate a metallically coated area of 500 square inches, or a thousand square inches in the two discs together.

As we have in the article in our thirty-fifth volume, to which we have before referred, described the principle and action of Mr. Wimshurst's electrical machine, we need not repeat it here, but we may remind our readers that the machine may in principle be regarded as a sort of doubled-up "Nicholson's revolving doubler," the sectors on the one disc acting as inductors on the other, and vice versâ, and that the probably due to the fact that both plates continue charges of electricity to the collecting combs, and that the sectors on the one disc act as inductors and as carriers respectively to those on the other when they approach the best positions for those respective actions to take place.

The collecting combs are attached to the discharging rods, as shown in the engraving, by interchangeable best adjustments in the segment, by interchangeable best their positions with respect to the lines of equal distance of the discs may be varied within a range of 2 in., that is to say, between about 6 in. above and 8 in. below the horizontal diameter. The discharging rods or terminals are constructed of brass tubing 1$\frac{1}{4}$ in. in diameter, and are fitted with terminals of different diameters, which are also interchangeable. The distances of these spark discharges can be varied by the glass handles with which the discharging rods are fitted at their lower ends, and as these handles have their attachment in a hinge-joint, they can be used as levers wherewith to turn the terminal rods around a vertical axis, and thus to vary the distance between their upper ends.

The two discs are rotated in opposite directions by the lower driving gear shown in the figure; this consists of a horizontal spindle fitted with a winch handle at each end, and carrying a pair of cast pulleys which are connected respectively to the two pulleys attached to the discs by endless cords, one of which being crossed, causes one disc to be rotated in the opposite direction to the other; and as the weight of the bearings of the lower spindle is adjustable, the driving cords can always be maintained perfectly tight.

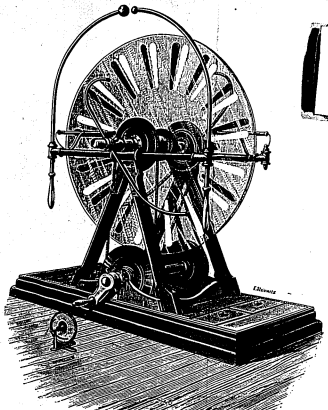
The principal characteristics of this form of electrostatic machine, and to which its exceptionally high values as a laboratory instrument is due, are (1) that it is readily self-exciting in almost every condition of the atmosphere; (2) that the polarity of the opposite inductor charges, as it is so liable to do in other forms of induction machines; (3) that the charge is very large compared with the area of the glass employed in the discs, and (4) the small cost at which the machine may be constructed.

Although the great machine which we illustrate in this notice was constructed in a workshop in which there was a steam engine and boiler at work, and consequently with an unlimited quantity of water in the atmosphere, and although it was closely surrounded with lathes and shafting, the former metallic conducting bodies, into only did it take up its charge even before a stream of discharge sparks between its terminals of over 14 in. in length. The same was always found far more satisfactory than was ever allowed before it was tried, but when it is set to work at South Kensington (where it will be located by the time these words are before our readers), and where it will be under far better conditions for developing its full powers, still higher results may be expected. We may, indeed, congratulate Professor Ayrton and the science schools generally on this new acquisition to the physical laboratory, which must prove a most valuable instrument for experimental research.

Mr. Wimshurst has in his laboratory what is probably the largest collection of the most powerful electrostatic induction machines in existence, having worked for several years in perfecting this class of apparatus. We have in the illustration introduced (partly to serve as a comparison of size and partly to illustrate a very interesting and typical form of the apparatus) a sketch of what is perhaps the simplest and the cheapest electric influence machine ever constructed. This little apparatus consists simply of two discs of varnished glass 12 in. in diameter, fitted with tinfoil sectors, and mounted on a spindle, which can be held in the hands, and the discs can be rotated in opposite directions by turning them with the finger and thumb. When this is done—although there are no collecting combs or discharging terminals—most brilliant effects can be produced, the whole apparatus literally bristling with electric discharges immediately the rotation commences, and one of the most remarkable and not the least valuable features of this beautiful little instrument lies in the fact that it can be constructed in a good saleable and workmanlike manner and sold at a very small charge.

While we would urge Mr. Wimshurst to go on still further in the important experiments, in hope of further discovery, we are bound to admit that we are unable to see how it is possible to get greater simplicity to be reached, or for higher efficiency to be obtained.

THE WIMSHURST 7-FT. DUPLEX ELECTRIC MACHINE.



ECONOMICAL STEAM TRAMWAY.—The Directory, Batley, and Birstal steam tramways, the first ever constructed in England (worked by Merryweather 7-in. engines), show, by the last half-year's working account, that the total cost of the running of the engines was 2.37 pence per mile, and the total expenses of the whole undertaking, including locomotive charges, 5.16 pence per mile. This is one of the most economically worked lines in the country.

Lines of force due to a Small Magnet

I have been recommended by Sir William Thomson to send you the following construction for the lines of force due to a very small magnet.

The equation to the lines of force due to a very small magnet placed at the origin of co-ordinates and lying along the axis of x is—

$$\frac{y^2}{(x^2+y^2)^{\frac{3}{2}}} = \frac{1}{C} \quad \ldots \ldots \quad (1)$$

By varying C we obtain a series of similar curves.

Transforming to polar co-ordinates by putting $x = r\cos\theta$, $y = r\sin\theta$, we get for the equation (1)

$$r = C\sin^2\theta. \quad \ldots \ldots$$

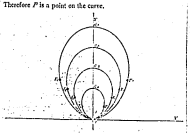
This immediately suggests the following construction:—

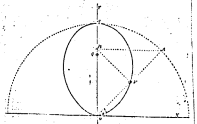
Take $OC = C$, and with this as radius, describe a semicircle. Draw any radius OA, then take AP perpendicular to OY, and DP perpendicular to OA: then P is a point on the required curve. Because

$$OD = OA\cos OAD \qquad \text{where } \theta = \text{angle } AOX.$$
$$= OA\sin\theta,$$

Also $OP = OD\sin\theta$
$= OA\sin^2\theta$,

Therefore P is a point on the curve.





In a similar manner any number of points on the curve may be obtained; and by varying the length OC, we get different curves of the same class.

Near to the point C in the figure, the points on the curve cannot be constructed accurately by the method just given; but if the radius of curvature for the point $(x = a, y = 0)$ be calculated, it will be found that for the point G it is $\frac{OC}{3}$. Q is the centre of curvature. And a large arc of the circle described about Q with radius QC coincides with the curve. Thus the whole curve may be constructed with great accuracy.

From equation (1) radius of curvature at any point (x, y) is given by

$$\rho = \frac{C.y(x^2+y^2)^{\frac{3}{2}}}{3(x^2+y^2)(x^2-y^2)},$$

or, with x eliminated by (1),

$$\rho = \frac{C\sqrt{y}.(y^{\frac{1}{2}}C^{\frac{1}{2}}-y^{\frac{1}{2}})^{\frac{3}{2}}}{3(yC-y^2)}.$$

Thus $y = \cdot 432\,C$ gives the point of maximum radius of curvature.

Lines of force—

$$\frac{x^2}{(x^2+y^2)} = \frac{C}{r}.$$

These curves may be obtained by giving to C the values

$$C = \cdot 05C$$
$$C = \cdot 1C$$
$$C = \cdot 2C$$
$$C = \cdot 3C$$

The points (F) are points of zero curvature.

Glasgow, January 29 JOHN BUCHANAN

ON A NEW ACTION OF THE MAGNET ON ELECTRIC CURRENTS.

THE statement that "the Mechanical Force which urges a conductor, carrying a current across the lines of magnetic force, acts, not on the electric current, but on the conductor which carries it" has often been a puzzle to students of electricity. Experiments have become at various times to prove that the statement is not correct; but have hitherto uniformly resulted in failure. Mr. E. H. Hall, working under the direction of Prof. Rowland, believes himself to have been more fortunate than his predecessors, and describes an experiment which apparently proves a permanent effect of a magnet on the distribution of currents in a system of wires. As Mr. Hall promises a more extended investigation we shall describe his experiment, as much as possible in his own words without comment or criticism.

The following experiment had apparently been formerly tried by Prof. Hochheim, but without success:—

"A disk or strip of metal, forming part of an electric current, was placed between the poles of an electro-magnet, the disk cutting across the lines of force. The two poles of a sensitive galvanometer were then placed in connection with different parts of the disk, through which an electric current was passing until two nearly equipotential points were found. The magnet current was then turned on and the galvanometer was observed, in order to detect any indication of a change in the relative potential of the two points."

No such change could be observed and Mr. Hall now repeated the same experiment substituting a piece of gold leaf, mounted on glass (Chester 23 a decided deflection of the galvanometer needle.

This deflection was much too large to be attributed to the direct action of the magnet on the galvanometer needle, or to any disturbance of the latter. It was moreover a permanent deflection and therefore not to be accounted for by induction.

Some rough quantitative experiments were tried with the result "that with a given form and arrangement of apparatus the action on the Thomson galvanometer is proportional to the product of the magnetic force by the current through the gold leaf. This is not the same as saying that the effect on the Thomson galvanometer is under all circumstances proportional to the current which is passing between the poles of the magnet. If a strip of copper of the same length and breadth as the gold leaf but 1 tenth in thickness is substituted for the latter the galvanometer fails to detect any current arising from the action of the magnet, except an inductive current at the moment of making or breaking the magnet circuit."

MAGNETIC PHENOMENA.

The effects of magnetism, as they are usually pointed out, are far from agreeing with those which practice is revealing at every moment; and, owing to the often inexact data that are possessed, a sometimes happens that we meet with deceptive only in the results expected. The reason is that two kinds of actions which are essentially different are confounded with each other—*static action*, that is, the action revealed by magnetic attraction, and *dynamic action*, which gives rise to the reciprocal mechanical reactions of magnets and currents. These actions are not mutually disposed on each other, although they may have a reciprocal influence, and consequently may be *interpolated*. *Dynamic action* is induced by those magnetic currents which Ampère supposed to envelop the molecules throughout in which entered and perpendicular to its axis, and may be considered as dependent upon a resultant applied to the center of the molecular bar. This resultant, then, represents all the individual actions of the currents constituting the molecular system. From this point of view the magnetic axis is the line of most energetic, exactly according to the neutral line, where, however, no action of attraction takes place. In fact, it is at this point that the effects of induction are most energetic, as said by why MM. Poggendorff, Müller, Faber, and others have advised the selling of the helices of the inductors cell like those of this cell. It is for this reason, too, that when a small (illegible) is caused to revolve on a magnetized bar, the resulting induced currents are direct when the cell moves from the neutral line, and inverse when they approach it. *Static action*, on the contrary, closely approximates to that of the electric cell by induction, which is in play in electrical conductors. Without in any way entering into the theory

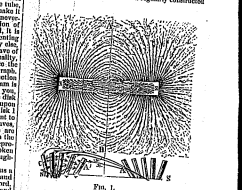

FIG. 1.

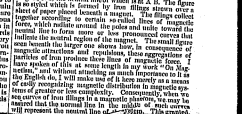
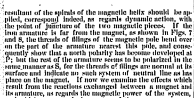
magnet, N S, the neutral line of which is at A B. The figure is so plced which is formed by two rings drawn over a sheet of paper placed beneath a magnet. The particles, brought together according to certain so called lines of magnetic force, which radiate around the poles and tend to extend the neutral line to more or less prominent curves that indicate the neutral region of the magnet. The figure shows more clearly than any one above how, in accordance with magnetic attractions and repulsions, these aggregations of particles of iron produce those fine lines of magnetic force. I have spoken of this at some length in my work "On Magnetism," and without attaching as much importance to it as the English do, I will make use of it here merely as a means of accomplishing magnetic distribution in magnetic systems of greater or less complexity. Consequently, when we say curve of force, we mean a magnetic curve, or, what is the same thing, the curve in the middle of each curve will represent the neutral line. The points *a*, *a'* will be called by their like and unlike poles.—These positions are represented in Figs. 2 and 3. The one in Fig. 2 belongs to



FIGS. 2 AND 3.

the two magnets united by their opposite poles. It is seen that the two series of filaments at the middle of the two magnets seem to have become fused into a single system, which tends to furnish but a single neutral line when the adhesion of the two magnets perfect, but which, by reason of their imperfections, gives rise to two distinct neutral lines. The character of Fig. 3, on the contrary, shows that the distribution of magnetism has been little affected on each of the two magnets, since the two systems of curves are found to merely correspond in the middle of each. When these magnets are separated by a slight space, the filamentous exhibit themselves in the form seen in Figs. 4 and 5, and which show that the magnetic field, in cases where opposite poles are in presence, behaves like a true magnet—conditions which do not exist when like poles are opposed

to each other. When, instead of two magnets, we employ a piece of iron and a magnet, or, in other words, when we employ a magnet provided with an armature (as in Fig. 6), the phantom of this arrangement shows that the neutral line of the magnet has not returned to the point of contact of the two pieces. It has slightly approached it, it is true, but the threads of filings which radiate around the pole, S, and the whole surface of the armature, P, show that, as regards quantity action, this armature forms only an expansion of the magnetic pole with which it is in contact. Consequently, if polarized over its whole surface, and, nevertheless, as we have demonstrated in another article, the effects induced in this case (see Fig. 5) show that this neutral line, where the



FIGS. 4 AND 5.

resultant of the spirals of the magnetic helix should be applied, corresponds indeed, as regards dynamic action, with the point of departure of the two magnetic pieces. If the iron armature is far from the magnet, as shown in Figs. 7 and 8, the threads of filings of the magnetic pole bend over on the part of the armature nearest this pole, and consequently show that a north polarity has become developed at P; but the rest of the armature seems to be polarized in the same manner as the threads of filings are inverted at its surface and indicate no such system of neutral line as has place on the magnet. If now we examine the effects which result from the reactions exchanged between a magnet and its armature, as regards the magnetic power of the system, and which we may do by means of the apparatus represented at Fig. 9, we find:

1. That the attractive force of the pole provided with an iron armature has become considerably weakened, but that,

FIG. 6.

as an offset, the attractive force of the opposite pole has become greatly increased.

2. That the induced currents resulting from the addition of this iron armature have not only increased in a large proportion, but may be super-excited by the simple approach or withdrawal of the armature.

3. That the action is still greater if the magnet is provided, at its two poles, with two armatures.

4. That the magnet is an electro-magnet, the armatures remain firmly attached to the poles, even after the current has been interrupted through the electro-magnet, and that too with the greatest force.

From these effects it follows that magnetism, considered from the standpoint of its polarization, behaves like electricity in a conductor. The polarities which are in presence not kept developed one by the other in a *hidden state*, for their presence cannot be recognized externally; and on the surfaces of the magnetic pieces is created there neutral lines, the magnetism which has ceased condensation, and which is of the same character throughout the whole circumfe-

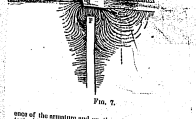


FIG. 7.

rence of the armature and on the pole of the magnet in contact with it. This is why the difference in the effects of magnetic polarity is found to be greatly weakened in comparison with what it was at first, and in fact this weakening corresponds with all the magnetism hidden at the point of contact of the two pieces. But this magnetism is soon the less used up on account of being hidden; it might even be said to become more active when it was originally, since the latter ought to act, however, that the expression "more active" is incorrect, which I recognized at the beginning of my researches in 1838, and which I have developed in the former of these articles, and quite recently, for if suppose an ought to be kept up independently of the phenomena of polarization, but which, in fact, disappears with it, arising the which surrounds the magnetic action, which, in fact, disappears with it, arising the which surrounds the magnetic action, which, in fact, disappears with it, arising the which surrounds the magnetic action,

INDIA-RUBBER.

The composition of India-rubber, as determined by Dumas, is 87·2 per cent. of carbon and 12·8 of hydrogen.

In its natural state it forms part of the milky sap of various species of trees, which are to be met with in tropical regions, its synonym, caoutchouc, being derived from the caoutchouc tree, which is chiefly to be found in Central America, and was for some time the source whence the main supplies of the article were drawn. The trunk of the tree is periodically pierced—in some instances as frequently as once a fortnight—and the sap as it issues is either caught in vessels placed for the purpose, or allowed to accumulate in a hole dug round the foot of the tree. The liquid may be prepared for export in two ways. Either balls of clay are inserted into it, and then poured over a fire, until the India-rubber which they have taken up hardens, re-dipped, and have the evaporation repeated upon them, until a certain thickness is obtained; or a piece of wood is employed, around which the sap accumulates as before, which is in its turn dried after a certain volume has been secured. The purest India-rubber is prepared in the latter way. With the clay-balls, impurities in the shape of sand, pebbles, &c., are unavoidable.

The first process to which the raw material after its importation is subjected has for its object the removal of all the impurities which have become mixed with the natural gum as it ran from the parent tree. This is effected by sawing it up—after being softened by immersion in hot water—into small pieces of about an inch and a-half square, passing these betwixt two horizontal cylinders, and keeping a constant stream of water flowing upon them. The irregular sheets into which they are ultimately formed are then dried by being hung where a free circulation of air can take place.

The sheets are then kneaded and heated for the purpose of rendering them perfectly homogeneous mass. This is done by means of a horizontal cylinder, along the whole length of which some strong knives, with a series of sharp pointed teeth disposed at alternate rows. Into the free space of the cylinder the India-rubber is introduced, and the entire mass assuming a rotary motion, under the influence of these teeth, is manufactured by them until perfect homogeneity is attained. The cylinder was usually formed with a double casing, heated by steam, in order to facilitate the process of manufacture, but this is now being abandoned, as the mechanical heat developed is found of itself to be sufficient for the work. By raising the temperature too much, great danger is incurred of rendering the India-rubber soft and viscous, and thereby lowering its value for electrical purposes to a very material extent.

The last operation in preparing the pure rubber is to melt it betwixt the compressing cylinders, which are hollow, heated internally by steam pipes, and arranged horizontally in couples. From betwixt these it finally issues in the shape of a smooth compressed sheet of close, texture.

Pure India-rubber is colourless and transparent. It

But the difficulty of making a proper joint has not been surmounted.

On the other hand, vulcanized India-rubber, though not affected by temperatures like pure rubber, has a great drawback which the latter does not seem to possess. In contact with copper wire, it in time assumes a friendly useless for insulating purposes. To resist this, the copper wire is tinned before the India-rubber is wrapped around it.

Taken all in all, gutta percha seems destined to hold its own, as the insulating material in underground and submarine telegraphy for many years to come; and in our next number we shall touch briefly on its manufacture and the various properties possessed by it.

Tel. Journal Dec 15 '77

Mr. Hancock has discovered, in the course of some experiments, that vegetable tar, by the addition of the oxides of lead for in a less degree by some other substances, is almost instantly solidified, and that the solid mixture thus obtained has remarkable insulating powers. In some experiments at Silvertown, it was found that a 16 copper wire, covered with a coating of gutta-percha weighing only 40 lbs. to the mile, had its insulation thus increased nearly 200,000 per cent, and that the insulation resistance was no less than 2,800,000,000 units, an insulation sufficient for any lengths possible on the surface of the earth.

CAOUTCHOUC.—In June, 1876, the English Government sent out 50,000 seeds of the Brazilian rubber tree to India, but only 4,200 arrived there in good condition. These were sown together in a plot, and in a few days had put forth shoots eighteen inches high. A number of the best plants have been sent to Ceylon, Singapore, and Burmah, for transplantation at these places.

THE SOCIETY OF TELEGRAPH ENGINEERS.

PROFESSOR ABEL'S INAUGURAL ADDRESS.

(Concluded from page 51)

In addition to his investigations into the deterioration of gutta percha, Dr. Miller carried out a series of exhaustive researches into the manufacture and behaviour of India-rubber for insulating purposes. He pointed out that mastication promoted the oxidation of India-rubber, and further experience has established the fact that in this respect the two gums—gutta-percha and India-rubber are very much alike.

The application of vulcanising to India-rubber was hailed as a most important step in submarine telegraphy; but although many chemists have made this same process of vulcanising a subject for study and investigation, it remains imperfectly understood even, to the present day. The wire manufacturer had no difficulty in most important objection urged against the application of the vulcanising process. Professor Abel then proceeded to give some interesting illustrations drawn from his own personal experience of the uncertainty of our existing knowledge regarding the chemical and other conditions to be fulfilled in the application of vulcanising processes to the preparation of telegraph cables.

A number of half-mile lengths, for instance, of vulcanised telegraph cable, manufactured by Messrs. Siemens, others coated with vulcanised India-rubber, after being immersed in water for several months or three years, a period varying from eighteen months to three years, to have undergone considerable deterioration; the dielectric in some instances had become so porous

Continued.

that even the variations in the hygroscopic condition of the atmosphere on board ship, where the wires were placed between decks, caused decided differences in the results obtained with a particular battery current ; and this circulation was not distributed uniformly over a length, the porosity in some instances exceeding along a few feet only, leaving the adjacent portions in very good condition. Such was found to be the case in a length of the cast of cable which had remained submerged in cases showed precisely similar results.

The uncertainty attaching to this was still further illustrated by the fact that in numerous cables with multiple cores of this description some of the cores remain comparatively good, whilst the insulation of others had fallen off to a very great extent.

Scarcely less conflicting is the experience gained with cables prepared according to Hooper's system. This system consists in maintaining the inner portion of the india-rubber surrounding the conductor in an unvulcanised condition by means of a "separator," which consists a preparation of a metal possessing the power of arresting the passage of the sulphur beyond a certain point, and subsequent to the application of the whole of the india-rubber compound.

The difficulties, due to the alteration of the india-rubber, being caused by oxidation, the question naturally arises as to how the oxygen finds access to it? It must evidently find access to the interior of the dielectric *through the substance of the cable*—a view which is more than confirmed by the researches of Graham. That eminent chemist showed that solid india-rubber absorbed oxygen to an extent which showed the gas to be to'ce as soluble in it as in water at the ordinary temperature, and the comparatively greater porosity of vulcanised india-rubber would favour this absorption. The solubility of unvulcanised India-rubber being once established, the tendency to the absorption of oxygen by the external vulcanised layer, and, through its passage through the latter, more rapidly by the internal, and the tendency to chemical change of, and consequent annihilation of oxygen by, the lower portion, which thus acts like the vacuum by which Graham caused air very slowly to pass in oxygen to filter through a stout vulcanised India-rubber tube.

The efforts made from time to time to improve the insulation of cables, several steps necessary only to clear the ground for future experiments, but of late important success seems to have been achieved in a direction where different experimenters (including Prof. Abel himself) had failed—that direction is towards paraffin, a substance which during the last thirty years had been put from the chemist position of a chemical curiosity to the extreme rank amongst important chemical products. Dr. Frankland Fields, F.R.S., working in conjunction with Mr. Varley, the mineralogist, produced by means of a solvent, and re-crystallizing the substances together, a block chemically compact very favourably with india-rubber and gutta-percha, and would seem likely to prove very valuable for telegraphic purposes in the future.

Prof. Abel could only allude to the importance of chemical science in the proper management of batteries, and concluded after a valuable paper read before the Society by Mr. Partridge, "On Batteries and their Employment in Telegraphy," and the instructive discussions which followed, needed only to be named. Amongst other matters of importance where the telegraph engineer might derive great benefit from the fruits of applied chemistry, were the decay and preservation of telegraph poles, the preservation of fibrous

---

CAOUTCHOUC.

JUST as the world was beginning to be told that the supply of this useful material was about to become short by reason of the destruction of the tree which produced it, and the thriftlessness which failed to keep up the supply by artificial cultivation, we are also informed of the fact that an entirely new source of supply has been discovered in Burmah, in a creeping plant, whose botanical name is *Chavannesia arenderia*, of the doghane tribe, natural order, *Apocynaræ*, Lindley. The plant is very common in Burmese forests, and is cultivated by the natives on a small scale of its fruit, which is said to have an agreeable acid taste, and to mature at a season when tamarinds are scarce. Mr. G. W. Strettel, of Rangoon, has published an interesting descriptive notice on this plant. In 1850, in Mason's "Burma," it was described as yielding an excellent elastic gum, and believed to be *Echites macrophylla*, Wight. Another plant, *Amblenthera tomentosa*, in Pegu produces rubber, but far inferior, and less elastic than *C. ovalenda*. Measurements of the creepers have been made, which show the thickness of the stem at 5 to 7 years old to vary from 9 to 11 inches in circumference. Assuming the trees to be 30 feet apart, the following details given by Mr. Strettel will enable us to form a fair idea of the probable financial results. Area to be cultivated, 400 acres; trees at 30 feet by 30 feet equal per acre 48, or 19,200 creepers on 400 acres. Minimum yield of caoutchouc per annum estimated at one viss (3lbs. nett) per creeper, equal 19,200, or at £20 per 100 viss, £5,760 per annum. The cost of starting this project is trifling in the extreme. All that is necessary ought not to exceed on an average of seven eight shillings per acre per annum. After the first year the creepers will have attained a sufficient height to require little or no further attention beyond, of course, protection from fire, &c. Thus at the end of seven years the cost on 400 acres would represent £1,120. At the expiration of seven years the creepers will attain large proportions, and preparing the caoutchouc, which are estimated at 12½ per cent. of the profit. According to these figures and the present market value of the india-rubber of this creeper, the net assets of the scheme may be approximated at £3,360 per annum. The milk of this creeper appears more readily coagulates than that of the *Ficus elastica*. The leathern vessels are those that yield the inspissated milk, and when packing care should be taken not to crush the sap used. Mr. Strettel says: "The cut I adopt is in the form of an arrow, and the incisions are made on the sides of the stem. The tiers of arrows are about three feet apart, so as to prevent that the cuts do not come in a perpendicular line with those below. At the point of the arrow I attach a funnel, formed of the leaves of the plant *Pandanus*, which readily attaches itself to the tree, from the glutinous nature of the milk. Any other leaves will answer equally well, if sufficiently large and proof against cracking. The season for tapping the trees is about the end of April. Between October and March circulation is slow and milk scarce, but during the rains the milk is more aqueous, and flows more freely. Chemical tests have proved that the rubber of *C. ecalenda* is purer and better suited for purposes than that obtained from the *Ficus elastica*. —*Journal of Applied Science.*

INDIA-RUBBER CONSIDERED IN REFERENCE TO ITS APPLICATION TO TELEGRAPHY.

By THOMAS T. P. BRUCE WARREN,
Analytical Chemist to the India-rubber, Gutta-percha, and Telegraph Works Company, Limited.

(*Continued from page* 189.)

Besides the application of india-rubber as an insulator for submarine cable cores, aerial and land wires, there are many other purposes for which it is used in connection with telegraphy, and principally in its harder forms of vulcanization which are known as ebonite or vulcanite.

Ebonite is now extensively used for battery cells, and for insulating supports. In fact it is now so universally employed by the electrician that there is scarcely a piece of apparatus in which it is not employed.

Formerly it was much used for pole insulators, and covering "pins" for their support. Its use, however, for these purposes has been abandoned to a very great extent, owing to its surface becoming

PAPERS FOR JUNIOR STUDENTS.

The Resistance of Insulators.

The resistance of the dielectric or insulator presents some of the most important problems of electrotelegraphy, and it will be impossible that we can exhaust their application until we have attained to some acquaintance with instrumental work. But there are general principles the knowledge of which will tend to the easier understanding of what we shall presently have to say. The specific resistance of insulators varies with every variation in their composition: and as their composition is necessarily subject to many more variations than are likely

[illegible] as copper, the [illegible] ees would be of [illegible] ution in the re- [illegible] ference of age of [illegible] ivalve or temperature results [illegible] ulators to a very [illegible] tion eliminated [illegible] sources of error [illegible] or much electric [illegible] sulators or dirt [illegible] adhering to the insulator. This conduction by the surface of a body it is very difficult to avoid, and for the following reason:—There is an exceedingly large quantity of common salt (or chloride of sodium) floating about, in fine particles, in the air. The precipitation of such inside contains a large proportion of this ingredient. Now a great deal of this salt is deposited or condensed on the surface of any solid body on those amongst our students who have worked with a spectroscope will be painfully aware), and as salt is, in relation to an insulator, not much a very bad conductor, a large proportion of the electricity escapes over the surface. Glass, when thoroughly warm and dry, is a very perfect insulator, but in ordinary or moist atmospheres much of the electricity finds its way to earth, and is lost. The clumsy or vulgarly insulators of electrical instruments are very quickly covered with such a conducting film, and Mr. Varley, who has studied the subject extensively, recommends the washing of the surface of the clumsy or vulgarly with very dilute sulphuric acid, then with water, rubbing until dry, when the surface may have solid paraffin rubbed over it.

The presence of this conducting film at once explains how preferable it is to reduce the extent of surface of an insulator, on the ground that by reducing the superficial area we reduce the liability of the electricity to escape. The glass insulators of our telegraph posts are constructed on the principle of exposing as little conducting surface as possible.

It should be remembered that, although there is so much difference between what is generally termed a bad conductor and an insulator, the latter does not mean a substance giving infinite resistance, through which no electricity can pass, but simply a very bad conductor. Graphite and gas-coke are bad conductors, for their specific resistance is from 1500 to 20000 times that of pure copper. The resistance of gutta-percha, however, bears very little relation to this, as we may gather from the resistance of a cubic metre of various kinds of gutta-percha employed in the undermentioned cables:—

D. A. Table of Resistance.

Red Sea	...	...	$0{\cdot}363 \times 10^{12}$
Malta-Alexandria	...	...	$1{\cdot}230 \times 10^{12}$
Persian Gulf	...	...	$1{\cdot}800 \times 10^{12}$
Atlantic (end)	...	...	$2{\cdot}280 \times 10^{12}$
Gutta-percha, at 24° C.			$3{\cdot}330 \times 10^{12}$

For the purposes of comparison it may be stated that the British Association unit of resistance would be measured by a conductor of pure mercury, 1 sq. millim. in section and 1048 metres long at 0° C. Of course a cubic metre of copper would have so prerceptible resistance.

The most useful information we can give the student as to the nature and character of the principal insulators is to describe what they are, and, as far as known, the method of preparation.

India-rubber.—This well-known substance, sometimes called caoutchouc, is the dried juice of a tree, the trees yielding the juice being known botanically as of the orders *Urticæ*, *Euphorbiaceæ*, *Apocyneæ*, the greatest of the *Siphonia cahuca* (South America) and of the *Urceola elastica* (East Indies) being known commercially. The native incises the tree and collects the exuding juice in vessels of dried clay, whence the product takes the form known as "bottle" rubber. The juice is solidified by the application either of artificial heat or of that of the sun; in the latter case the product is known as "lard" gum or rubber. In this way we obtain the immense supply of India-rubber for our cables, the purposes of waterproofing, &c.: as much as 120,000 cwts. having been produced in 1870, 60,000 cwts. of which came from the island of Java.

Pure India-rubber is white, and, when in thin sheets, semi-transparent. Its elasticity is perfect. It is non-fibrous, but it possesses the curious property of becoming somewhat fibrous and less translucent when exceedingly stretched. It is not brittle when cold, but becomes hard; but water and steam render it soft, but it suffers no chemical change from their action.

India-rubber is soluble in—

Alcohol-free ether,
Oils of coaltar,
turpentine (with heat),
Sulphide of carbon,
Persian naphtha,
Chloroform,
Benzoline.

It is insoluble in alcohol; is not decomposed by dilute acids or strong alkalies (strong acids readily decompose it). If a piece of India-rubber be stretched and then immersed in cold water it loses some of its elasticity, which it regains when placed in water at 45° C. or 50° C., and when again chilled acts as a gas pervading high illuminating power.

The chemical formula of India-rubber is C_5H_8, and no parts of this substance contain 87·5 parts of carbon and 12·5 of hydrogen.

The electrical resistance of India-rubber decreases with increase of temperature, but not so rapidly as with gutta-percha. Under pressure the resistance increases.

Vulcanite.—India-rubber immersed in molten sulphur becomes softened to several degrees—that is to say, it is vulcanised, and remains elastic (while India-rubber is then wasted, first with a dilute solution of caustic potash, and then with water. In Hancock's method hexachloride of sulphur is substituted for the sulphide of carbon. Many other methods have been advised, but they have not met with extended use.

By THOMAS T. P. BRUCE WARREN,*
Analytical Chemist to the India-Rubber, Gutta-Percha, and Telegraph Works Company.

For all the phenomena connected with insulators, silence is not one which demands more careful consideration than the changes brought about by variation of temperature; yet I am not aware that any writer on telegraphy has devoted more than the bare space required for the enunciation of the fact that the insulation of telegraph cores is increased or diminished by the rise or fall of the thermometer.

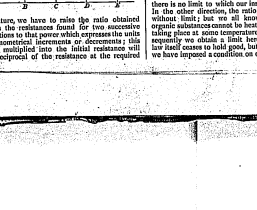
It is with the view of directing the attention of electricians and telegraphists to a few subjects in this department of the science of practical electricity, and which are but scantily dealt with, even in the print and most complete works on the matter, that I have thought the present paper a suitable one for the commencement of a series on the practical bearing which certain physical and chemical facts have upon Telegraphy.

From the circumstance that telegraph cores have a high or lower resistance according as their temperature be low or high, the lengths and thickness of the insulator remaining the same, we are necessitated to refer whatever tests are made for insulation to some fixed temperature, and for this purpose we are supplied with a table of co-efficients for this correction; so that, knowing the value of an insulating covering in megohms per nautical mile, or any similar standard length, we can ascertain what will be the effect of raising the temperature any number of degrees above that at which our observation is made, or conversely if the required temperature is below that at which our test is made.

The temperature which is now by common consent taken for this fixed reference of results is 75° F. The advantage of this temperature is, that it can always in practice be readily obtained, either for the purpose of direct observation, or for the verification of *the modulus of conversion*.

By the term *modulus of conversion*, I mean the root or radical number which expresses the ratio between the insulation resistance of any insulating covering for differences of one degree on the scale of Fahrenheit.

This modulus, from all we can tell at present, is



[illegible] structural conclusions. An extra gutta-percha [illegible] carried out [illegible] certain value, [illegible] conductors [illegible] may more on [illegible] ance of an in- [illegible] I am aware, [illegible] ig Jenkin [see Cables, &c.], [illegible] o actual pre- [illegible] Sir Charles [illegible] adian Govern- [illegible] ndian Gulf. [illegible] xamination of [illegible] mperature on [illegible] Hooper, and [illegible] to meeting of [illegible] n, in the year [illegible] this core, he [illegible] explained that [illegible] pering general [illegible] all insulators, [illegible] pleted for my [illegible] [illegible] mperature, one [illegible] es, measure on [illegible] corresponding [illegible] on the points [illegible] ders increasing [illegible] ng by dividing [illegible] erature by the [illegible] ceding or pre- [illegible] crement; con- [illegible] at any required

temperature. By this process we obtain an expression which plotted out gives a logarithmic curve.

Professor Fleeming Jenkin had before this graphically represented the effects of temperature in curves by a logarithmic curve, so that, although he did not give us a formula which admitted of general application, he at least indicated the method for its mathematical development.

A few words may be said here on the properties of this curve, and the relation of certain of its properties towards the phenomena we are now discussing.

The logarithmic curve—if on an indefinite line, AA, the parts AB, BC, CD, DE, &c., be taken equal to each other, and ordinates AF, BG, CH, &c., be drawn perpendicular to AA, and in length varying in a geometrical progression, the curve FHK, which passes through all their extremities, is called the logarithmic curve. The axis LA produced is an asymptote to the curve; for since the terms of a decreasing geometric series never can become equal to nothing, any ordinate drawn from the origin in the direction AF can never become nothing. Since, however, it becomes less and less, the curve approaches nearer and nearer to the indefinite line.

In the other direction it is also obvious that the curve may be continued *ata limite*.

To apply these considerations to the varying condition of an insulating envelope under the action of variable temperature, the initial ordinate AF may be drawn to represent either the resistance which we obtain on starting, or better still, by representing the value of this as unity make AF equal to 100 mm. if it is required to draw a large diagram. It will be necessary to keep this of small size, as, however, since its successive expansions will give dimensions far too ordinates unmanageable for a graphic illustration. We have then to draw BG, which is to represent the value at a higher temperature point. The resistance at A temperature, divided by that found at B, if this difference 1° F., is the modulus or co-efficient for 1° F., if the interval be 10° F., or any other number of degrees, will obtain the modulus for 10° F. or whatever may have been the difference in the temperatures. Multiply a this ratio into 100, and draw BG in mm. corresponding to the product; in the same way we may proceed with the results of all the observations.

In ballooning whatever low degree of temperature we may take A to represent, we can always conceive of lower ranges of temperature, consequently we can extend the ordinates on the left-hand side of our initial experiment; but however we may carry this temperature the resistance can never become absolutely perfect, for then we should obtain ordinates equal to nothing; these ordinates may become as small as we please to make them, but we can conceive of their being reduced much smaller. In the same way we may get our insulation by reduced temperatures as high as we please, but so long as we can conceive of lower temperatures so we must assume there is no limit to which our insulation can attain. In the other direction, the ratio can be expanded without limit; but we all know for certain that organic substances cannot be tested without change taking place at some temperature or another; consequently we obtain a limit here, not because the law itself ceases to hold good, but from the fact that we have imposed a condition on our insulator which

the ratio obtained between the resistances found for two successive observations to that power which expresses the units of thermometrical increments or decrements; this product multiplied into the initial resistance will be the reciprocal of the resistance at the required

* Taken from Prof. Jenkin's "Cantor Lectures."

592. "Covering Telegraph Wires, &c." Henry Cornish (communicated by R. Weber, Weighton, Russia). Dated February 25, 1878. 2d. This consists in insulating wires, with a covering made from india-rubber or caoutchouc, dissolved by steeping bisulphuret of carbon (C S_2) over it, and is prepared in bottles with large necks, tightly stopped. The metals are sponged with this mixture, and as hone after, they are sponged repeatedly with a second solution. This solution is made by taking gutta-percha, wool, tar, and resin, and pouring bisulphuret of carbon over it, then mixing the result with the first india-rubber solution in the proportion of 4 to 1; then adding more bisulphuret of carbon. *Not proceeded with.*

"Kerite" a kind of artificial caoutchouc, is the invention of Mr. Day of New York, and is made as follows:—To produce 100 parts by weight of Kerite, 50 parts of cotton oil, and 50 parts of oil-clear are heated together in a cauldron for several hours, at a temperature of about 150° C. After this has been done, 50 parts of linseed oil, 15 parts of sulphur, and 5 of ordinary wax or of solid paraffine are added. The whole is then heated for five or six hours, at a temperature under 150° C. to prevent carbonization. It is then allowed to cool, and is moulded into blocks convenient for future purposes. The price is about 2s. 6d. per pound sterling. Mr. Day received honorable mention for Kerite insulated telegraph core, exhibited at the Paris Exhibition.

3730. W. R. Lake, of the firm of Hamilton, Lake, and Co., patent agents, Southampton Buildings, London, *An improved insulating compound for telegraphic purposes.* A communication from Calmon G. Shumway, of Kenosha, Wisconsin, U. S. A. Dated December 9, 1872. This invention relates to a compositional materials producing an insulating compound by means of which a more perfect insulation of telegraphic conductors is obtained than by the ordinary methods; this compound is at the same time cheap and durable, and is not easily affected by the action of the weather. This compound is composed of one part coal-tar or its equivalent and two parts charcoal or saw-dust, tan-bark, or any other organic body having a fibre and being a poor conductor of electricity and which may be ground or cut up to mix with the tar. The coal-tar is brought to a boiling temperature, when the charcoal is introduced and thoroughly combined with it by agitating the entire mass by any mechanical means. The proportions may be varied.

This invention relates to a compositional material, producing an insulating compound by means of which a more perfect insulation of telegraphic conductors is obtained than by the ordinary means; this compound is at the same time cheap and durable, and is not easily affected by the action of the weather. This compound is composed of one part coal-tar or its equivalent and two parts charcoal or saw-dust, tan-bark, or any other organic body having a fibre and being a poor conductor of electricity and which may be ground or cut up to mix with the tar. The coal-tar is brought to a boiling temperature when the charcoal is introduced and thoroughly combined with it by agitating the entire mass by any mechanical means. The proportions may be varied.

Brooks' Patent Insulators not Liable to be Damaged by Lightning.

BROOKS' PATENT INSULATOR WORKS,
No. 22 South Twenty-first street,
PHILADELPHIA, Sept 29.

TO THE EDITOR OF THE TELEGRAPHER.

DEAR SIR—Of the 15th instant contains the following:—"Perhaps the gravest fault with all the wires of the Western Union Company is, that in this city were among the Brooks insulators,' and I am informed by one in an

throughout, which ought to know whereof he affirms, that the wires here never tested so satisfactorily since, from the fact that no repairs recently in the city, the 'Brooks' have not been used, for what reason I have been unable to state. The Kenosha insulators have been introduced recently on repairs here in the city. An intelligent operator of my acquaintance, who has given investigation a good deal of thought, says the Brooks is the best insulator made, that although the first cost is much more than any other insulator its insulating properties are so vastly superior to any other he has used in his fifteen years experience in line building and repairing that they are by far the cheapest insulator extant. In a letter which Mr. Brooks might remedy, an objection is that the way they are now constructed lightning leaves us through them, destroying their insulating properties of course, and it passes through the insulator in such a manner that the defect cannot be noticed by a repairer unless he climbs each pole and examines each insulator. Not being an insulation man I do not suggest a remedy, but give the information for what it is worth. Several of the Burlington and Quincy and some of the Michigan Central insulated wires are strung exclusively on Brooks' screw shank insulators, and give great satisfaction, working well in either wet or dry weather."

Your correspondent says, "The way they (the Brooks' insulators) are constructed lightning leaves us through them, destroying their insulating properties of course, and it passes through in such a manner that the defect cannot be noticed by a repairer unless he climbs each pole and examines each insulator."

THE BROOKS PATENT INSULATOR.

The advantages of this improvement in the insulation of overland lines are:—1st. It is not affected by rain or humid atmosphere; and, As a result of this quality (perfect insulation) large and expensive wire conductors are avoided; For circuits less than 300 miles in length, a wire of No. 12, or 2 B.W.G. is sufficient; For circuits varying from 300 to 500 miles, a No. 9 wire is necessary; and from 500 to 1000 miles, a No. 6, or 4 millimetres diameter—wire answers all the purposes of the larger and more expensive conductors. 2nd. Lines insulated with this Insulator are not affected inductively—a desirable quality where the double transmission system is employed. 3rd. These Insulators resist the most powerful atmospheric discharges. 4th. They are not injured by missiles. 5th. They afford a simple and secure fastening for the conductors. The foregoing qualities guaranteed.

Manufactured and for Sale by the Proprietor,

DAVID BROOKS, 722, South 21st Street, Philadelphia, U.S.A.

SIEMENS, BROS., 12, Queen Anne's Gate, London, S.W.

Le caoutchouc et la chaleur

Nous ne croyons pas sortir de notre spécialité en donnant quelques détails sur une propriété curieuse d'une substance dont l'électricien fait un usage constant.

Le professeur Tait a présenté à la Société royale d'Edimbourg quelques morceaux de caoutchouc dont M. Macfarlan de Milcham s'était servi pour isoler des fils, et qui, ayant été soumis à un allongement élastique prolongé pendant plusieurs années, avaient pris une forme définitive. Mais la faculté de reprendre la forme définitive n'avait été en quelque sorte que suspendue; car M. Maclachlan ayant on l'idée de plonger dans de l'eau chaude ces débris, on les a vus reprendre immédiatement leur forme primitive. On produisit les mêmes effets avec du caoutchouc tendu presque jusqu'à la rupture pendant qu'il était soumis à l'action de l'eau chaude et que l'on conserva ainsi tendu jusqu'à un complet refroidissement.

IMPROVED TELEGRAPH INSULATOR.

ALTHOUGH the production of an efficient form of insulators for aerial wires is a most interesting and important problem, the advances made in this branch of practical telegraphy has by no means been as great as could be wished.

The employment of a liquid repellent of moisture placed in a recess formed around the ordinary cup form of insulator, was believed, attempted some years ago; but either through the imperfect way in which the experiment was made, or in consequence of the utility of a very high standard of insulation being so apparent as it is at the present day, when economical battery power and the employment of the duplex and quadruplex systems of working are points of great importance, the idea was not carried into practice. Messrs. Johnson and Phillips, who have paid considerable attention to the production of an efficient form of insulator on the above principle, have not succeeded as to obtain patterns which have proved effective under conditions which would be fatal to those of the ordinary form.

Although these insulators require the test of continued use under conditions that exist in ordinary aerial telegraph lines, yet the success that has been obtained is so remarkable as to deserve notice.

Fig. 1, 2 and 3 show forms of these insulators.

Fig 1. This insulator is fixed above its arm or support in the manner. The lower edge of the porcelain a is turned up inward so as to form a chamber, shown at b, in which oil or some other insulating fluid is placed.

Fig. 2. In this insulator the porcelain consists of two parts, a, the head, is firmly cemented to the bolt c, which passes freely through the second part e, containing the insulating fluid b. c is held in position by the nut d, when this nut is unscrewed a may be lowered so as to expose the oil chamber b to view for the purpose of examination or for the introduction of the oil.

In both cases the insulators are easily filled with the oil or other insulating fluid by means of a long-necked oil can.

Fig. 3 shows how an ordinary porcelain insulator may have the insulating fluid principle applied to it. The cup-shaped space a is partly filled with the fluid. c is a horizontal cover resting on the insulating fluid. This cover is not fixed, but is free to move round the bolt e; a fan e, attached to the cover, causes it to rotate by the motive fluid of the action of the wind, the object being to break any spiders' webs or filaments which might cause a leakage on the surface of the insulator or its cover. Such ordinary fanning w prevents the rain from entering the oil chamber by means of the hole in the cover through which the bolt passes; it also, when properly placed, prevents the cover c from being tilted up by the wind and touching the porcelain. This form of insulator is especially adapted to districts infested with spiders or other web-spinning insects.

The following tests taken on twenty of the patent insulators and on four ordinary white porcelain insulators with a porcelain tube round each bolt speak for themselves.

The loss obtained on the four ordinary insulators is multiplied by five, to make it comparable with the twenty patent insulators, which are assumed to represent a mile of line.

The tests were taken with eighty cells, and an astatic mirror galvanometer.

The absolutely uniform insulation shown for the patent insulators is not strictly correct, but the detection obtained on them never being more than two divisions, it was impossible to detect small alterations in the insulation.

Date.	Patents.	Resistance in Megohms per mile. Old battery.	Remarks.
January 30,		about	Insulators fixed.
" 31,	4	14,000	23½ Fine morning.
February 1,	4	4	2·03 Fine rain; raining nearly all night.
" 2,	4	4	21·18 Bright morning.
" 5,	4	4	19·82 Fine; frosty.
" 6,	4	"	9·07 Dull; overcast; has rained in night.
" 7,	4	"	17·71 Dull; overcast.
" 9,	4	"	7·21 Fine, but damp, with dew.
" 10,	4	"	8·74 Overcast; windy.
" 12,	4	"	23·26 Dull; overcast.
" 13,	4	"	1·10 Shower of rain.
" 15,	4	"	10·61 Dull; overcast.
" 16,	4	"	9·03 Dull; overcast; damp.
" 17,	4	"	28·16 Overcast.
" 18,	4	"	48·98 Fine.
" 19,	4	"	5·75 Raining yesterday, and during night; snow flies.
" 21,	4	"	3·62 Dull; overcast; has been raining.
" 26,	4	"	·71 Rain and hail; strong wind; insulation was in 45 megohms shortly after rain ceased.
" 28,	4	"	1497 Fine; bright; sharp frost.

The above figures show the great effect which surface leakage has upon the insulation of an ordinary line; the test taken on February 26 when the rain was very marked, when the insulation of the ordinary line was all from 32 megohms to 1·1 megohm in a few minutes after the rain commenced. On the 26th it was equally instructive to see the rise in insulation rise, when the rain and hail ceased, and the strong wind blowing at the time dried the surface of the insulators, the change in this case took place in a few minutes.

The rain on the 26th had cleared the surface of the insulators, hence the high insulation obtained during the sharp frost on the 28th.

The tests were taken at about 7 A. M.

While all these changes were taking place in the ordinary insulators, it will be noticed that the high insulation given by the patent insulators, remained perfectly constant (as far as could be detected).

It should be noted that under the influence of frost the insulation still remained good, although it might have been expected that the coagulation of the oil would have prevented such a favorable result being obtained.—*Telegraph Journal.*

THE Western and Brazilian Telegraph Company (Limited) announce the restoration of their cable between Bahia and Rio de Janeiro, and also of the Transandine Companies' lines between Buenos Ayres and Valparaiso.

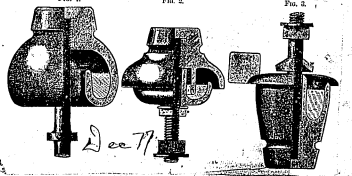

Fig. 1. Fig. 2. Fig. 3.

A NEW INSULATING STAND.

SIR WILLIAM THOMSON has frequently dwelt on the great importance of insulating, with the utmost care, any apparatus intended for researches relating to static electricity; he has shown that the atmosphere and other gases have but little effect in dissipating an electric charge, even when moist, and that it escapes mainly in consequence of the deposition of a layer of moisture upon the insulating supports which renders their surface conducting. In all Sir W. Thomson's electrometers there is an arrangement for drying the insulating surfaces by means of sulphuric acid, either free or absorbed by pumice. This method admits of very general application;—for lately, as for example apparatus constructed for the observation of atmospheric electricity, may be most perfectly insulated by supporting it on glass rods inserted in glass cylinders containing free sulphuric acid or pumice moistened with it. In order to do this the lower end of the rods must be either inserted into cylinders of lead or else fixed to the bottom of the jar by means of a substance not acted upon by sulphuric acid, for example, melted sulphur or paraffin; melted sulphur is liable, on account of its temperature, to crack the jars,

* By H. E. Roscoe, Professor of Physics, Collége de France, Paris.

URE [May 9, 1878

notwithstanding the precaution of previous heating; paraffin, on the other hand, softens in the course of time and the glass rods do not retain their vertical position. Notwithstanding these disadvantages excellent insulators may be thus constructed on occasion may require.

For experiment use it is advantageous to employ insulators specially constructed as shown in the accompanying figure; it consists of a bottle having a narrow neck,

through which passes a tubular continuation of the bottom, about 4 mm. less in diameter than the internal diameter of the neck, so as to leave a space of 2 mm. (about) between them. The top of this hollow rod is closed, in order that a brass tube may be cemented upon it, into which may be screwed any apparatus, as, for an Exner, &c., &c. In the shoulder of the bottle is a sulphuric acid may be poured, in the first instance, and renewed from time to time.

Hollow rod and the neck of the bottle is very small, the air in the bottle does not change very rapidly, and the sulphuric acid remains efficient for a long time. It is only necessary to run off a portion of it occasionally by means of a siphon, and as acid fresh; as this may be be maintained for any length of time. Moreover, for an insulator to be used occasionally, an addition is made of a vulcanized rubber cap, which slides on the glass rod to close the neck of the bottle when not in use.

A double pendulum of pith balls supported by such an apparatus maintains its divergence, after being charged with electricity, for a very long time, even in a chamber filled with an audience. One may show by a simple experiment

the great efficacy of this apparatus in comparison with insulators of glass exposed to the air, even when carefully varnished with shellac, by a pair of pith balls, suspended by a thread of cotton, is hung upon the lattice support, and the metallic foot is placed on an insulator, and connected with a charged conductor, no divergence of the pith balls occurs in the first instance, but little by little the electricity is propagated along the glass rod, and then the threads near the support begin to separate, and soon after the balls diverge and remain at a certain distance from each other.

The electrometers of Sir Wm. Thomson are sometimes so perfectly insulated that the loss of a charge of electricity does not amount to $\frac{1}{10}$th part in twenty-four hours. By means of the insulator described above, one may obtain an insulation of like order for *bodies supported in the free air*, and thus diminish to a great extent one of the chief sources of error usually met with in experimenting with static electricity.

* There may be obtained of various sizes, ree fine, lubrifiers, examiner, fine capacity, by Alvergniat Frères, 20, Rue de la Sorbonne, Paris.

BALATA, A SUBSTITUTE FOR GUTTA-PERCHA.—From a contribution of Dr. W. Riegler, in the *Wochenschrift des niederoesterreichischen Gewerbs-Vereines*, we glean the following facts relating to this new article of commerce, which bids fair to become of great importance, in view of the constantly-increasing demand for elastic gums and the rapid destruction of the trees which furnish rubber and gutta-percha.—Balata, which has only been known for a short time, is inferior in the extent of its uses to caoutchouc, but surpasses gutta-percha, and is said to have already become an important article of commerce. It is the milky sap of the bully tree that flourishes on the banks of the Orinoco and the Amazon, in South America. The operation of winning the gum is similar in every respect to that employed with caoutchouc and gutta-percha, and need not therefore be described. It resembles gutta-percha so closely in its general properties that much of it is shipped from Guiana and sold yearly for gutta-percha, although it has many points of superiority. It is tasteless, gives an agreeable odour on being warmed, may be cut like gutta-percha, is tough and leathery, is remarkably flexible, and far more elastic than gutta-percha. It becomes soft, and may be joined piece to piece, like gutta-percha, at about 120° Fahr., but requires 270° Fahr. before melting (higher than gutta percha). It is completely soluble in benzole and carbon disulphide in the cold. Turpentine dissolves it with the application of heat, while it is only partially soluble in anhydrous alcohol and ether. It becomes strongly electrified by friction, and is a better insulator of heat and electricity than gutta-percha, on which account it may find considerable application for electrical and telegraphic uses. Caustic alkalies and concentrated hydrochloric acid do not attack it, but concentrated sulphuric and nitric acid attack it as they do gutta-percha, which it closely resembles in all other properties. We have in balata, says Dr. Riegler, a body characterized not so much by the possession of new properties, but rather a new member of the group of useful elastic gums, taking rank between caoutchouc and gutta-percha, which may, under many circumstances, be found to be more valuable than either; and it is a matter of congratulation that the world has been supplied with another rapid destruction of these trees threatened to seriously diminish. Aug 78.

Gutta Percha Insulated Wires.

Clinton G. Colgate vs. The Western Union Telegraph Company.

This is an action brought by Clinton G. Colgate, as assignee of George R. Simpson, for infringement of a patent granted to Simpson, May 21, 1867, for telegraph cables insulated with gutta percha. Simpson claims to have made the invention in 1847. His final application for a patent was dated Nov. 22, 1847. This and subsequent applications were rejected, but he prosecuted until 1867, the patent was granted. Simpson assigned the patent before its issue to Dodge and Mann, and Dodge and Mann assigned to Arthur M. Eastman, and Eastman to the plaintiff, by whom the suit was brought.

Although the patent had been granted, its validity was denied by parties interested in making and using gutta-percha insulated wires, and no attempt legally to enforce it was made until the present suit against the Western Union Telegraph Company was commenced.

The case was recently tried before Judge Blatchford, in the Circuit Court of the United States for the Southern District of New York, in this city, who decided it in favor of the complainant, thus establishing the validity of the patent.

From this decision the defendant took an appeal to the Supreme Court of the United States. In the meantime the complainant applied for a perpetual injunction, restraining the defendant from using the invention.

The defendant opposed the granting of the injunction pending the appeal, on the ground that it would prove a great detriment to Government, public and private interests by stopping the transmission of messages through cables now and for many years in use by the company. It was further argued that the defendants were unpecuniarily responsible and able to respond fully for any damages that the complainant should suffer in the meantime if the final decision were in his favor. Numerous affidavits were submitted substantiating the statements of the defendant. On Jan. 5th, Judge Shiedield handed down his decision denying the injunction substantially as follows:

It sufficiently appears that at least before the time when a final decree shall be entered in the case it would not be proper to grant absolutely and unconditionally, a perpetual injunction against the further use of the gutta-percha covered wires, and that any such perpetual injunction to be granted before such final decree ought to be granted conditionally and on terms as to substituting something else for gutta percha covered wires or as to taking a license for the future use of gutta-percha covered wires. The affidavits and papers now before the Court do not enable it to determine satisfactorily what such terms should be, and it is proper that the testimony to be taken on the reference as to profits and damages should be before the Court before the question of a perpetual injunction is passed upon. But the plaintiff is entitled to a perpetual injunction against the sale by the defendant to others of any of the gutta-percha covered wires described and against the manufacture or use by the defendant of any gutta-percha covered wires or cables other than those which it now has. No security from the defendant is required, as the abundant pecuniary ability of the defendant was admitted by the plaintiff on the hearing.

WIRE INSULATING MACHINE FOR THE LATHE.

(13234.)—ALTHOUGH I designed this simple machine some years ago, I have not yet seen its use or even description, as perhaps it may interest your readers. A is a wire to be covered with gutta percha; C, rod, by winding cord with which (shown by arrow), pull, D, I suppose (as the large wheel, H, driven by another hand from the screwhead shaft),

carrying the reel of silk or other insulating material. This reel is mounted on a spindle, with a spring and cord, to regulate the tension. Nearly every part of this machine may be made of wood, and be fitted down to the bed of the lathe by a bolt.

T. D. Dale, M.S.A.

WIRE INSULATING MACHINE.

(14276.)—As some of your correspondents may not have a lathe to use with the machine proposed by E. R. Dale, (page 423, let. 13234,) I send the accompanying rough sketch of a wire insulator, taken from Routledge's "Every Boy's Annual" for 1875, trusting that it may make one they will see. Success to your paper.

Fig. 1 represents the machine. A, A pair to hold the two pulleys, B and C, the sleeve over it turns the tube, D E, through which may be seen

the copper wire C, and the reel, F on which a sufficient quantity of wire has been previously wound and placed. The end of the silk from each bobbin must be passed through the second disc, H, and is joined to the wire, and as the reel, G, gradually winds the wire off it, it pulls it through the hollow tube, D E, over the pulleys, B, and winds it on itself at the same time, the stop motion, I, preventing the bobbin from unwinding, thereby acting a tendency motion, and the silk is wound off the spools on to the wire.

Fig. 2 merely shows the way in which the bobbins are fastened to the disc; a small spiral spring prevents the bobbin turning too fast.

Xenos.

WIRE-INSULATING MACHINE.

(11038.)—In your "Ours" (dated September 25th, page 208) has replied from "Every Boy's Annual," may I warn them that the windings on reel C will not be suitable for this arrangement. The reel C is a mere bobbin, and the wire must be wound on it in a way by combining that the wire may not fall in a heap in the middle. Also, the reel C would have to be exceedingly small in diameter to admit of the first requirement, and as it gradually filled and increased in diameter the feed would accelerate in proportion, and as the revolutions of the spool also had increased in the beginning, a really very important increase would be the result. Only a very limited length of wire was to be covered.

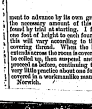
If you, Mr. Editor, think it would be worth the space in "Ours," I shall feel it a pleasure to send detailed drawing of one constructed by me a few years ago, which I think will meet the wants of our readers.

J. E. C.

WIRE-COVERING MACHINE.

(11039.)—Seeing that several notices of wire covering machines, with more inquiries for some further amount of enabling constrom to make instead of buying their insulated wire, I send you a rough-and-ready sketch of a little instrument. A correspondent sufficient for my requirements. A represents a block of wood 2 inches by 1, and 1 inch thick; B shows a piece of brass tube 1in. long; I have, the centre of the block. Right through the centre of the block and end of the tube is a brass wood plug fitting into B with a hole through its centre of each end as well enables it to revolve without shaking about the wire to be covered. Into the centre of the block at A is screwed a brass tube two inches long; this I call hole like the eye of a needle through which the thread from the reel is passed to guide it on to the wire. The reels carrying the thread are each mounted on the block by means of a pin, at which it revolves with a given to the thread by proper degree of tension, and to prevent the reel from unwinding too fast. A slip of tin-plate bent into the form of an arch, and made to press on the end of the reel in the manner shown in the sketch; or by heading these friction-springs more or less the tension can be easily regulated.

The mode of operating is as follows:—Having put the revolution on reel C, and the horizontal thickness on reel D, and fixed the end to the wall, then carry a length to the opposite side of the room, secure it there so that it forms a line stretching across the room, now pass the threads from the reels through the guide-holes and tie them to the wire, steady the wire with the left hand, and with the right turn the handle of the wheel; a couple of turns gives a twisting motion by which a rigid and continuous revolution of the instrument is easily obtained. One of the best features of this instrument is the exceedingly simple means of regulating its feed or rate of traverse along the wire so that the covering shall be even without either doublings or empty places. The rate of feed depends on the connecting rod of the wire shown fine red to which you are progressing, this causes the instru-

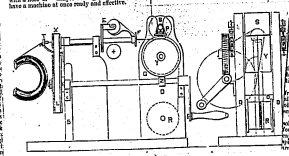


ment to advance by its own gravity as it revolves, the necessary amount of this elevation is easily found by trial at starting. I found it to be about one inch of height to each foot feet of length, but this will depend on the fineness and quality of the covering thread. When the length of wire that can conveniently run the room is covered that portion must be rolled up, then suspend another similar length, proceed as before, continuing till all is done. With very little practice about one foot per minute can be covered in a workmanlike manner.

Norwich. J. H. Cary.

HOW TO MAKE A WIRE INSULATING MACHINE.

(11005.)—By will be evident that in the construction of this machine, a lathe, a vice, and an ordinary stock of tools are necessary. With these, and a little knowledge of their use, any mechanic will find it a pleasure as they gradually advance with their work, seeing everything is so simple and easy. The first, at the finish, instead of being tempted to sell, at the finish, instead of being tempted to sell, with a host of simple mechanical movements they will have a machine at once ready and effective.



The drawing is to a scale of 1in. to the foot, and, I think, is sufficiently plain to require but little explanation. The framework is made of both batch or deal, two feet cracks and knots. Each piece should be planed on both sides, tenoned out, and mortised together, bored, morsed, and glue-pinned. The bearings should be of brass, and well oiled.

To the frame, fair and square. It is a support for standard, on which the driving shaft bracket is also fixed. Supporting the two pulleys. The following scales, S and Y, are made of gunmetal, 20in. and 6in. respectively; the lines for screws are 1in. apart, screws are of 1in. square brass; they slightly taper from the top to the bottom, and accordingly the holes are cut to split the supporting rods; small collars are then turned to proper length and thickness. The disc-spindle, K, is of 1in. hollow brass; the disc is also of brass, and soldered on. The sounds, Y, serves as a guide for the thread, and material on which to fix the speed-springs; this is made of steel, and tempered to a spring temper, should be very delicate and well tempered; they are made to press against the thread on the spool, so that the pressure is reduced as the spool continues winding a uniform drag. The worm-wheel, B, is 12in. pitch line, and has 36 teeth—an ordinary wheel could be made to suit by filing the teeth, if a worm-wheel be not to hand. The worm, A, is of steel, 1in. in length. It is screwed into hand, struck on, 3in. away be driven in to insure concentricity. This worm is keyed on. The crank handle is screwed on. The pulley, L, M, and N, are set in partial spaces, and secured with small wood washers; pulley X is driven tightly on, and fixed with the key in the disc. The pulleys are all of which the two, G, and H, are fixed on the spool, etc. and with the top part of same secured by closed hole pieces of iron, through a hole in the middle of which pass the ends, which are tightened up with thumb-nuts—very little strain is necessary to effect their purpose; they are retained in small grooves turned in the arbors. It is the bobbin which is to be the spool with it is moving round by means of the pulley, P, and the two driven into the spindle, N, and slipped into a short groove in the bobbin. A groove is made in the lower extremity of the hole in the guide, so as to admit of the spindle being drawn out, and the full bobbin removed with an empty one. The guide Y, is a piece of iron 6in. bored, bent to shape with a slot 1in. wide, and 2in. long, and fixed between two pieces of curved steel, 4in. long, the bobbin to rotate springs pressing against each other. W represents a coil of wire which is supported on a similar arrangement to that used by ordinary winding worsted. The wire should be pulled through the tube, turned over three times over the delivering roller, and held in the hand.

The driving pulleys, N and L, are 12in., and the diameter respectively; motion is communicated by a leather belt.

I shall be glad to give any further information that may be required.

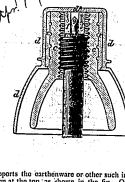
J. E. C.

OPPENHEIMER'S LIGHTNING GUARD INSULATOR.

This invention is designed to obviate the inconvenience which arises in working telegraph lines from the breakage of insulators by lightning, and a consequent making of earth contact by the conducting wires. In order to avoid this kind of fault a lightning discharger is introduced in the interior of the insulator, which is provided with a metallic covering.

The accompanying fig. shows a section of the improved insulator.

At *a* is the metallic insulator pin connected with the post, supposed in this case to be of metal, and having formed or attached thereon a screw *b* which



supports the earthenware or other such insulator *c*, open at the top, as shown in the fig. On the outside of this insulator is a metallic cup *d*, secured by means of cement *e*, and to this metallic cup the telegraph line wire is attached in the ordinary manner.

Upon the top of the insulator pin is placed a ring *f* of insulating material, and the distance to which this ring extends determines the distance between the top of *a* of the cup and an extended part *g* of the pin *a*. This distance may be varied to some extent, but that shown in the fig. which is 1 scale, may be taken as the relative standard.

By this arrangement an effective lightning discharger is obtained within the insulator, the lightning passing through the top of the cup to the pin *g*, and down thence along the pin *a*, as sketch-

(20) J. A. M. asks: Are glass insulators indispensable or not in putting up lightning rods on buildings, or need they separate the electric current? Some parties have been putting up rods here without insulators, using only strips of zinc to fasten them to walls and roofs. Our people are ignorant on the subject, and would be glad to see a full explanation in your valuable scientific journal. A. Insulators will not be needed. The rod should be fastened directly against the wall. The rod should be fastened directly against the building. But the most important precaution is to make sure that the bottom end of the rod has a large conducting surface in contact with the earth. Better have no rod than simply to strike it and a few feet down into dry earth; the proper way is to solder the bottom end of the rod to a metal water pipe or gas pipe in the ground. If there are no pipes, then make a long trench and put in some good conducting material, such as fine coal and put in some good conducting material, such as fine coal and put in some good conducting material, such as fine coal

before you we have samples of the different kinds of insulators used. The first is the cable pyramid which is composed of a very large cement in this country. The two brown earthenware ones on the lower row are also extensively used here; they were, I think, introduced by Mr. Varley about 1868.

Here is an iron-capped white porcelain insulator which is the one now largely used in England by Messrs. Johnson and Phillips. It is peculiar in this way, that between the wire and the bolt the current would have to pass through a cup which is full of oil. Oil is an capital insulator, one of the very best insulators that we have. A current in passing would have to pass through the oil which would considerably retard it, and the whole object of this the insulator is on almost perfect line. But at the present moment the practical experiences of its mechanical properties is not very satisfactory. It is still undergoing a trial, and cannot, therefore, be said yet to have been subjected to the test of time. Then we have very extensively used on the Post-Office lines, for instance, from the figures of the past three years, the average annual number of insulators used by or less here 80,000. The kind that we are now adopting is the one you see on Cochrane's Screw Insulator (Fig. 6). Its principal feature is a screw-thread on the inside of the cup. A moment of electricity has it fine over before there is escape through the bolt and pole to earth. There is its outside cup and another cup inside, inasmuch as it has been found by experience that, to insulate the insulation of a line perfect, you must keep your supports clean. Any of you who are in the habit of using the telegraph instrument will know how essential it is to wipe your pens, and keep your insulating points perfectly clean. And when you erect a line, as between London and Liverpool, and imagine that your insulators are going to keep clean for 100 miles or more, and expect to execute the same, you make a very great mistake.

The insulator is fixed to the pole by the by means of a long screw-bolt passed. It is screwed, can be cleaned, and then simply screwed on to the bolt task again, and is as good as new. So that, while the outer cup, from its large surface, has the power of insulating, the inside cup, from its position has the great advantage of being readily cleaned.

The telegraph lines of the Post-office extend, for occasionally from the breakage of insulators, caused by stone-throwing, and a large portion of the 80,000 I have just mentioned is absorbed in repairing the breakage. Stone-throwing is a thing that we have nothing to do with, and I do not know of anything more ramifying to the mind than the taking a road full of boys that to take up the line and leave a sky at one of these wilful recklessness. The result is that many insulators are broken from stone-throwing. Lightning, again, undoubtedly destroys a considerable number perhaps, not as many in England as in other countries, but, nevertheless, we do suffer to a considerable extent. (Fig. 6) is an iron-covered insulator that has been recently introduced, which also is a lightning protector. It is provided with an iron top, and the bolt screws in, so that it lodges, opposite the iron top, a piece of copper. The object of this is to prevent from insulator passing from bolt to electric worker; when it becomes charged with a little current it puts it on to the electricity which and there you have an insulator and lightning protector. It is one of the most recent inventions in the insulator, and is the invention of Mr. Appold, of the Post-office. While forms of insulators have been used and in large quantities in Australia, where they suffer from the effects of lightning, and I think it is very likely that it will be used not to other countries where similar exists.

To get at once into how essential it is to protect lines with insulators that will withstand the current, I may mention this—that one of the electric tests that we have in this country in the office is the testing of our lines in the to three storms that occur on in the winter from the south-west.

The insulator here is a variety which is said to have a double cup and a villainous climate it fits. The curious cones are also attached by the wires, for the purpose of the. They are drawn upon the rains shields of aqueous vapour. This insulator, you know, is of the kind that is known as the "petticoat" insulator, one of our little friend; it throws down in the form of a petticoat, and it is the petticoat which increases the leakage. Now, I will not for one our island that do not produce rain; but I am prepared to say that our insulators think cooling of moulders, and there are two or two days in nearly every year when the rain falls, as it were, supersaturated with moisture, which, when it comes in contact with any substance from which it is cooler by temperature, deposits the moisture upon it in the form of water, that acts as a conductor and impedes working.

We try to get our insulators to offer a resistance to the passage of the current equivalent to 100,000 miles of copper, and one megohm (or one million, which is the usual expression) is the standard of insulation that we require for a line of wire. Now, I will not for one our island that do not produce rain; but I am prepared to say that our insulators think cooling of moulders, and there are two or two days in nearly every year when the rain falls, as it were, supersaturated with moisture, which, when it comes in contact with any substance from which it is cooler by temperature, deposits the moisture upon it in the form of water, that acts as a conductor and impedes working.

We try to get our insulators to offer a resistance to the passage of the current equivalent to 100,000 miles of copper, and one megohm (or one million, which is the usual expression) is the standard of insulation that we require for a line of wire. Now,

work. In very wet weather, it frequently covers down as low as 300,000m. per mile, but on the 22nd and 23rd Nov., 1877, many of our lines slotting the sea-coast fell down as low as 20,000m. per mile. The result was that there was a positive breakdown throughout the whole country. The reason was that the rain fell in such large drops that it penetrated the shed and soaked in the covering. We could trace the vapour sinking, as it were, in the South Wales district, somewhere in the neighbourhood of Neleist, and gradually proceeding on its way to England. The influence upon our wires was felt during from the central station, right across England, and extended to Ireland, and, in fact, to the Continent. It reached Paris, Berlin, and Vienna, at intervals, but there are two periods in the day at which a similar effect is experienced—viz., that is, at noon and six o'clock. Immediately before sunrise there is always a deposition of dew on our fences, and our lines test very badly, and we have a correspondingly increased number of faults caused. These two periods are manifested, and invariably, by the notice on our wires. You see, in this particular branch of insulation, experience, again, has led us to various improvements, so that, practically, with the gross-result in the days of old, the insulator of the present day stands almost perfection.

As regards the supports of these wires and insulators, experience has pointed out that, on lines of a small number, such as one or two wires, old poles in the main are sufficient. On main lines carrying a number of wires, it is necessary some-

hood of Bristol, and gradually proceeding on its way to Ireland. The influence upon our wires was felt during from the central station, right across England, and extended to Ireland, and, in fact, to the Continent. It reached Paris, Berlin, and Vienna, at intervals, but there are two periods in the day at which a similar effect is experienced—viz., that is, at noon and six o'clock. Immediately before sunrise there is always a deposition of dew on our fences, and our lines test very badly, and we have a correspondingly increased number of faults caused. These two periods are manifested, and invariably, by the notice on our wires. You see, in this particular branch of insulation, experience, again, has led us to various improvements, so that, practically, with the gross-result in the days of old, the insulator of the present day stands almost perfection.

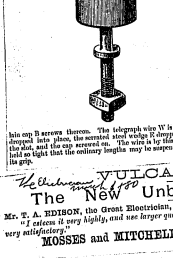
As regards the supports of these wires and insulators, experience has pointed out that, on lines of a small number, such as one or two wires, old poles in the main are sufficient. On main lines carrying a number of wires, it is necessary some-

times to have as many as 21 poles per mile. In the early days the most expensive timber was used for poles. The very best Memel timber that could be procured, and creosoted, and every pole cost a large sum of money. But with experience wiser counsels prevailed, and it was found that it would be unnecessary to use creosote timber than that of the country was used, and continued to be used for many years. But it was found that these poles, in certain very moist climates of ours, very rapidly decayed, and they decayed at what is called the "wind and water mark," that is, the ground line, where the timber was in contact with the earth. There is an abnormal accumulation of moisture, heat, and cold at this point, and the growth and germination of vegetable and animal growth, and gradual decay of the timber. Despite this, wooden poles were produced in very large numbers, and, in fact, were considered the best for the road repeatable timber was used for

CROMPTON'S INSULATOR.

The insulator illustrated in the annexed Fig. 1 is of the form most used by the Postal Telegraph Department. In the porcelain cap is grooved, and the telegraph wire laid by binding wire, firmly attached to it and passing round this groove.

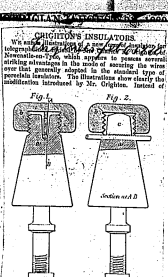
This binding takes some time, and in some districts the binding wire is rapidly corroded and the attachment destroyed. In the new insulator—the invention of Mr. C. E. Crompton of Newcastle—the porcelain cap is made in two parts, A and B, as shown in Fig. 2. The upper part of A is slotted and screwed, as shown by detached sketches, and a strong piece



loin cap B screws thereon. The telegraph wire W is simply dropped into place, the serrated steel wedge E dropped into the slot, and the cap screwed on. The wire is by this means held so tight that the ordinary lengths may be suspended by its grip.

CROMPTON'S INSULATOR

We extract the following account of the invention by Mr. Crompton of a new insulator for telegraph wires from the Newcastle-on-Tyne, which appears to possess several striking advantages in the mode of securing the wires over that generally adopted at the standard type of porcelain insulator. The illustrations show clearly the modifications introduced by Mr. Crompton. Instead of



securing the line wire by a binding wire passing round a groove in the insulator and wrapped around the line as usual, the line wire passes through a slot formed in the top of the insulator, and is held in place by a serrated steel wedge, which is pressed firmly upon the line wire by the cap which is screwed down tightly on the top of the insulator. It is believed that the device has been favourably considered by the Post Office authorities, who have adopted it experimentally on the line between Newcastle and Sunderland, with a view to subsequent extension if the present trials prove satisfactory.

RESISTANCE OF TOUGHENED GLASS.

—M. Decretet finds that toughened glass opposes a much greater resistance to passage of electricity than ordinary glass, and he has employed it in the construction of Leyden jars, which may be more highly charged than the common sort. M. Becquerel points out that this fact may be of some electrical value as leading to the construction of extremely thin condensers, giving great effects. Perhaps the glass will be found suitable to take the place of mica sheets in the construction of fine

ENGINEERING.

FRIDAY, MAY 21, 1880.

THE DURABILITY OF GUTTA PERCHA.

There are not many raw materials which have had a history so curious and important as gutta percha. Light on the English doctor, who while travelling in the Indian Archipelago in 1843, first observed its material to be the gum of an aboriginal axe-handle, dream that in the short space of twenty years it would become the means of enabling the old world to communicate with the new by means of the Atlantic telegraph, that highest triumph of human science.

It is perhaps not generally known that the probable value of gutta percha for telegraphic purposes was first suggested by Dr. C. W. Siemens, who happened to be present at a meeting of the Society of Arts in 1845, when it was first brought to England, and he despatched a sample of it to his brother, Dr. Werner Siemens, of Berlin, to get its electric qualities thoroughly tested by the rude methods then available. About the same time Faraday examined the substance, which as our readers are doubtless aware is the juice or gum of the Isonandra tree. Faraday found it to possess excellent insulating properties, while its readiness to melt at a comparatively low temperature, and its pliability and consistency when cool, marked it out as an insulator for telegraph wires laid either under ground or under water.

It was soon found however that the exposed surface of gutta percha covered wires laid under water became soft and gummy. Moreover, underground wires were subject to decay and consequent loss of insulation, especially in the neighbourhood of oak trees; and a fungus was observed to make its appearance on these defective places, the probability being that the fungus and the decay proceeded from the same cause. The experience of cities showed that wherever the gutta percha covered wire is exposed to the air or moisture, and to changes of temperature, as at the joint-boxes for example, it is liable to decay; and hence it is the practice now to make joint-boxes as hermetically as possible. Lightning, too, is a frequent source of damage in underground wires, connecting aërial lines to offices; and in order to prevent its disastrous lightning guards are inserted at the junction of the overhead and underground wires.

Rats, mice, and "earth small deer" are in the habit of nibbling the gutta percha wires when they get into the pipes containing the latter; but quite recently a far more dangerous enemy, in the person of a minute insect, has been detected by Mr. W. H. Preece, chief electrician to the Post Office, as was recounted by him at a recent meeting of the Society of Telegraph Engineers.

For some time past the underground wires have failed in certain localities, for instance, London, South Wales between Chester and Holyhead, Dublin, and most Manchester. On examining the faulty wire, Mr. Preece found it beset by a small white insect scarcely visible to the naked eye; but which, under the microscope, very closely resembled a tiny white ant. Being provided with a kind of leaping pole or spring under the abdomen, it is able to spring about in the freely manner characteristic of its more civilised congener. Mr. Preece submitted one of these creatures for examination to Sir John Lubbock, an eminent authority in such matters, and he at once pronounced it a Termitoid, or pseudatlus, belonging to the Proderm family. This family is well-known to microscopists; since a black member of it, the water-flea, sometimes seen leaping about on roadway pools after rain, usually furnishes them with the entire which are employed as a test of the magnifying power of the microscope. Indeed the very insect in question, the crystallina variety, is a still more delicate test of microscopic powers. It is found abundantly in Kent, as Mr. Latimer Clark informed the meeting, and ordinarily lives on decaying vegetable matter, such as old leaves.

The fact that the Termitoma's organisms injure the wire at faulty places is not the only reason for believing these insects to be the cause of the faults. Examination of the wire shows it to be all bitten. Examination of the wire shows it to be all bitten and nibbled away wherever it lay exposed to their attack, and on the other hand the interstices of the wire, where it rested on the pipe containing it, is found to be untouched. Moreover, the body of the little animal is quite transparent, and it is, therefore, impossible to see the dark crumbs of gutta percha, or what seems to be gutta percha, lying in its stomach.

Fortunately the places affected by the Termitoma are as yet few and far between, and therefore it will be expedient to provide a means of stopping the ravages of the animal in future; and it may, therefore be necessary to cause the wire in a pipe of lead. Perhaps there is some truth in the suggestion of Mr. Truman that the previous decay of the gutta percha from exposure to the air or other causes incited the insect in the first place to eat it, and that were this primary cause removed the Termitoma would cease to molest the wire.

Gutta percha is so valuable in the arts, especially telegraphy, that, as the supply is ever getting scarcer, it is highly important to find means of preserving it from decay. Why it should decay on exposure to the air is not yet well understood; but it appears to suffer from oxidation. In chemical consolidation it is a hydro-carbon (85 per cent. carbon, 12 per cent. hydrogen) containing very small percentages of oxygen, resin, and impurities. For years past it has been engaged in studying the causes of its deterioration, and he appears to have solved the problem it has, for he hinted in the discussion following Mr. Preece's paper that though not at liberty to reveal the matter then, he would make bold to say that very soon we should know the

wire with clean unspun cotton be put, and insulating it in an iron tube which is kept full of purified paraffine oil by means of reservoirs giving a pressure sufficient to keep out moisture, for the oil alone will not do so. In order to get good insulation the joint should be free from vegetable acids and the oil from moisture. The wire is now largely employed by the Western Union Telegraph Company of America, for telephone and other lines underground, as laid along the road. In the latter case the wires are enclosed in lead pipes, and deposited out of sight, thus obviating the use of unsightly poles and iron wires. The insulation resistance of the wires is about 200 megohms per mile at a temperature of 100 deg. Fahr. These facts were communicated to the meeting by Mr. Brookes himself, who is now in Europe trying his system in Brussels and Paris. In the course of his remarks he mentioned a curious fact which ought not to be omitted. It is that in working these telephonic lines, centring in telephone exchanges, the induction noises so troublesome in telephony, are found to diminish the greater the number of lines in operation. That is to say, if of the total number of lines proceeding from the exchange only two are connected to the earth, and working, the induction will be far greater than if the whole lot were connected to earth for use.

IMPROVED INSULATOR.

This insulator illustrated is of the form most used by the Postal Telegraph Department in England. In this the porcelain cap is grooved, and the telegraph wire held by binding wire firmly attached to it and passing round this groove.

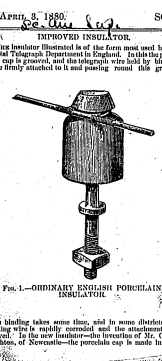

FIG. 1.—ORDINARY ENGLISH PORCELAIN INSULATOR.

This binding takes some time, and in some districts the binding wire is rapidly corroded and the attachment destroyed. In the new insulator—the invention of Mr. C. E. Crichton, of Newcastle—the porcelain cap is made in two

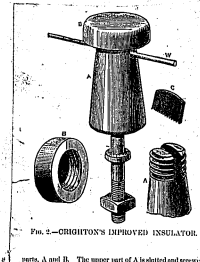

FIG. 2.—CRICHTON'S IMPROVED INSULATOR.

parts, A and B. The upper part of A is slotted and screwed, as shown by detached sketches, and a strong porcelain cap, B, screws thereon. The telegraph wire, W, is simply dropped into place, the central oval wedge, E, dropped into

the slot, and the cap screwed in. The wire is by this means held so tight that the ordinary lengths may be suspended by its grip.

INSULATING MATERIALS.

Aug. 15, 1857. W. Thomson

PERHAPS less progress has been made in the invention of insulating materials than in any other branch of telegraphy. Plenty of skill and science has been brought to bear upon the subject, as numerous patents of wonderful and fearful compounds testify; but the evidence of the work done in this direction has yet to be seen. Certain it is, that of all the products which have been invented, and which their inventors have felt confidence in, not one has been able to compete, with anything like success, with either gutta-percha or india-rubber, especially with the former.

Ever since its first discovery, gutta-percha has continued to prove the very best of all insulating materials in every respect, that is, both mechanically and electrically, whilst its durability for a lengthened period, under ordinary circumstances, is unquestionable.

The enormous quantities of gutta-percha which have been consumed for telegraphic purposes have naturally caused the price to increase considerably, whilst the manner in which the raw material is obtained, without thought of the scarcity which may ensue from the destruction of the trees from which the substance is drawn, is likely to cause the price to go still higher. It is possible that a systematic cultivation of the trees from which the percha is obtained may be attempted at some future date, to the great improvement of the quality of the raw material, but it would take years for all the degruation done to be repaired.

A great question of the day is cheap telegraphy, and the questions involved in enabling this desideratum to be effectually carried out are very numerous. Fast speed telegraphy is one of these. The latter question has been practically solved as regards atrial land lines; there is no difficulty in getting an amount of work out of a single land line which could only be carried on by several cables worked at the ordinary slow speed. In the case of adrial lines inductive embarrassment is but slightly felt; in the case of cables it is the one cause which keeps down the speed, and as far as can be seen, it can only be got over by an increased thickness of dielectric. This latter means greatly increased cost, and the high price of gutta-percha would be a great stumbling-block if the question of manufacturing a cable capable of a high speed of working were considered. The numerous experiments which have been made with the object of finding a cheap substitute for gutta-percha have been so unsuccessful that the public would look with great distrust upon any attempt to construct a long ocean cable of any new and, to a great extent, unproved material, even though the possible advantages were considered to be ever so great. Such an attempt, although possibly a success, would have very great chances of turning out a costly failure, in which most, if not all, of the capital invested would be lost. For underground work some new and cheap insulating material would have very much better chances of success, and, as there is an unquestionable tendency to abandon open in favour of underground wires, a really good and cheap material would prove a very profitable invention to the discoverer.

As regards the insulating property of the material for coating wires, we are inclined to think that a great deal too much importance is attached to the high degree of insulation which the substance is required to have; an insulation of 100 megohms per mile is amply sufficient for cables of a moderate length, provided this comparatively low value is due to the nature of the material and not to a defect in it. A cable with an insulation of 1,000 megohms per knot is, as regards its working capabilities, no better than one which has an insulation resistance of only 100 megohms per knot, but to such a degree of perfection has the manufacture of the insulating material been brought that the fact of the insulation being low is a conclusive proof of a defect. If a durable, sound, and cheap dielectric were discovered whose insulating properties were only a tenth of that possessed by gutta-percha, but yet whose mechanical strength was equal to the latter substance, it would be a very great mistake to reject it because it does not possess the property of very high insulation, since this is really of no practical value.

CANTOR LECTURES.*

13

THE INDIA RUBBER AND GUTTA PERCHA INDUSTRIES.

BY THOMAS DOLAB, F.C.S.

LECTURE I.—DELIVERED FEBRUARY 2, 1880.

Sources of India rubber—Chemical and Physical Properties—Behaviour with Chemical Re-agents—Action of various Solvents—Effects of Heat, Cold, and Light.

India rubber or caoutchouc possesses properties so widely different from those of most other substances, that it became an object of very great interest as soon as it made its appearance in the civilised world, and its industrial importance has rapidly increased as the knowledge of its remarkable characters and manifold applicability has become more extended. At the present time, caoutchouc holds such an important position with to regard the economy of modern arts and manufactures, that were it suddenly to be withdrawn from circulation, many minor industries would in consequence cease to exist; while numerous large and important branches of handicraft would languish until arrangements could be made to adapt their operations to the altered circumstances.

It is, however, during the last forty years that india rubber has enjoyed its greatest triumphs as an industrial agent; that is to say, since the art of vulcanisation was discovered and perfected by the labours of Charles Goodyear, Thomas Hancock, and others.

The earliest rumour of the existence of caoutchouc reached Europe nearly 300 years ago; the first visit of Columbus to Hayti having brought to light the fact that the natives of this island were in the habit of making playing balls of an elastic gum. Nothing more appears to have been heard of india rubber until Torquemada, rather over 200 years ago, described the Mexican Indians as not only making playing balls of india rubber, but also as fabricating helmets, shoes, waterproof fabrics and other articles of elastic gum. This writer gives some details as to the collection of the juice and the making of various articles from it, thus giving us the first view of the india rubber manufacture as a branch of industry. We do not hear, however, of samples of india rubber reaching Europe until long after this, and little more appears to have been learned regarding the substance until the celebrated French naturalist, La Condamine, made a communication to the Academy of Sciences at Paris concerning caoutchouc, he having had ample opportunities of studying the subject in Para. In the memoir in question La Condamine gives very detailed particulars regarding the Para india rubber tree, the collection and treatment of the juice, and the methods made use of by the natives for the production of various articles of caoutchouc. He tells us that the substance in question was used for making torches, these being only an inch and a half in diameter by two feet long, and yet burning for 12 hours. Again, we hear of the use of india rubber for the making of playing balls, and it appears that the natives were in the habit of using enema or injection bottles made of caoutchouc.

Soon after La Condamine's communication to the Academy of Sciences samples of india rubber frequently reached Europe, and scientific men began to make investigations regarding this remarkable body. Between 1760 and 1770 we find Fermond and Macquer studying the subject, and the last-named investigator made tubes and other articles of caoutchouc by dissolving it in ether and coating moulds with the solution, so that a solid skin of caoutchouc should remain adherent to the mould on the evaporation of the solvent.

FIG. 1.

HEVEA GUIANENSIS.

From this time until the end of the eighteenth century the india rubber industry way to considered to have been undergoing its period of gestation, and to have been born with the dawn of the present century. Among the first of the important patents regarding the utilisation of caoutchouc, is that granted in 1823 to Charles Macintosh, for dissolving the substance in coal oil, or coal naphtha, and the use of this solution as a waterproofing agent. I have here a specimen of such a solution, as now manufactured by Messrs. C. Macintosh and Co., of Manchester, together with some examples illustrating its uses.

About the same time elastic webbing was first made with threads, cut from the raw rubber, and other minor applications of caoutchouc to the industrial arts were adopted from time to time, until the great discovery of vulcanisation inaugurated a new epoch in this branch of industry; rendering it possible to so far alter caoutchouc as to make it capable of resisting to a great extent the action of heat on the one hand and cold on the other hand.

The milky sap of many plants contains caoutchouc, suspended in the form of minute transparent globules, these being frequently as small as $\frac{1}{2000}$ to $\frac{1}{4000}$ of an inch in diameter; but comparatively few plants contain sufficient caoutchouc to render them important sources of this body. The trees which yield the largest supply of the best quality of caoutchouc, consist of various species of hevea, which flourish in the northern districts of South America, especially in the province of Para, some portions of the valley of the Amazon being crowded to an extraordinary extent with heveæ. The abundance of the india rubber trees in Para may be judged of by the fact that this province alone exported 7,240 tons of caoutchouc in the year 1877; more than half of this being sent to Liverpool.

Among the heveæ most productive of caoutchouc may be mentioned the *Hevea brasiliensis*, which flourishes in Para, and yields some of the finest caoutchouc, and often attains a height of 50 to 70 feet, with a diameter of nearly three feet; the Hevea

* Reprinted by permission from the *Journal of the Society of Arts*.

As a rubber-producing tree, the *Ficus elastica* stands next in importance of the hevea. The *Ficus elastica* grows abundantly in India and the East Indian Islands, one district in Assam, thirty miles long by eight miles wide, being said to contain 42,000 trees, many of them attaining a height of a hundred feet. This tree also grows freely in Madagascar, and it is well known to us as a greenhouse plant. The slide now projected on the screen represents the *Ficus elastica* in its native regions; and I will next show you one illustrating a *Ficus elastica* now growing out of doors in the Parc Monceau at Paris. (Fig. 4.)

The juice of the *Ficus elastica* contains notably less caoutchouc than that of the American trees, the proportion very often falling as low as 10 per cent. of the juice.

A vine-like plant, the *Urceola elastica*, which grows abundantly in Madagascar, Borneo, Singapore, Sumatra, Penang, and other places, yields a considerable amount of caoutchouc of very good quality, and you will find specimens of the substance from these districts on the table.

Africa yields a considerable quantity of caoutchouc, but generally soft and of inferior quality. It is believed to be yielded by various species of lumolophia, ficus, and toxicophlea. Here are some specimens of African rubber. This specimen, representing the quality known as African ball, being tolerably firm in consistency, while the *African Bake*, which you see here, and the African tongue represent the lowest and most viscous qualities of commercial rubber. In order that you may compare the two extreme of quality, I will hand round a specimen of fine Para together with a piece of African tongue.

The commercial value of the various qualities of rubber may be estimated, to a certain extent, by noting the loss which the samples undergo during the operation of washing, which operation will be described in the next lecture; and also by noticing how far the various samples are softened by a long continued gentle heat. Here are some samples which have been heated for some hours in thin water oven; you will notice that the African tongue has become almost as soft as treacle, while the Para rubber still retains its form, and much of its consistency. The purification of caoutchouc will be considered next week, but your attention will now be called to the properties of pure caoutchouc.

Caoutchouc is nearly colourless, and when in thin leaves tolerably transparent. It, like very many other substances, contains nothing but carbon and hydrogen, but its properties differ very widely from those of other hydro-carbons almost identical in composition. It has been found to contain, in one hundred parts, 12·5 of hydrogen and 87·5 of carbon. Caoutchouc, as might be supposed, burns very readily and leaves no residue; if I set fire to a few ounces, you see how it blazes up. It is soft, and very imperfectly elastic, in the true sense of the term; that is to say, it does not return to its old dimensions after having been considerably stretched. Here is a strip of pure (i.e., unvulcanised) caoutchouc a foot long; you see that I have stretched for seconds, I relax it. It now measures, as you see, several inches over the foot. The elasticity of caoutchouc may be enormously increased by vulcanisation, as I will illustrate to you in future lectures.

(TO BE CONTINUED.)

CANTOR LECTURES.*

THE INDIA RUBBER AND GUTTA PERCHA INDUSTRIES.

BY THOMAS BOLAS, F.C.S.

LECTURE I.—DELIVERED FEBRUARY 2, 1880.

Sources of India rubber—Chemical and Physical Properties—Behaviour with Chemical Re-agents—Action of various Solvents—Effects of Heat, Cold, and Light.

India rubber or caoutchouc possesses properties so widely different from those of most other substances, that it became an object of very great interest as soon as it made its appearance in the civilised world, and its industrial importance has rapidly increased as the knowledge of its remarkable characters and manifold applicability has become more extended. At the present time, enormous trades such an important position with regard to the economy of modern arts and manufactures, that were it suddenly to be withdrawn from circulation, many minor industries would in consequence cease to exist; while numerous large and important branches of handiwork would languish until arrangements could be made to adapt their operations to the altered circumstances.

It is, however, during the last forty years that India rubber has enjoyed its greatest triumphs as an industrial agent; that is to say, since the art of vulcanization was discovered and perfected by the labours of Charles Goodyear, Thomas Hancock, and others.

The earliest rumour of the existence of caoutchouc reached Europe nearly 250 years ago; the first visit of Columbus to Hayti having brought to light the fact that the native of this island were in the habit of making playing balls of an elastic gum. Nothing more appears to have been heard of India rubber until Bouguenaud, rather over 200 years ago, described the Mexican Indians as not only making playing balls of India rubber, but also *as fabricating bottles, shoes, waterproof fabrics and other articles of elastic gum.* This writer gives some details as to the collection of the juice and the making of various articles from it, thus giving us the first view of the India rubber manufacture as a branch of industry. We do not hear, however, of samples of India rubber reaching Europe until long after this, and little more appears to have been learned regarding the substance until the celebrated French naturalist, La Condamine, made a communication to the Academy of Sciences at Paris concerning caoutchouc, *he having had ample opportunities of studying the subject in Para.* In the memoir in question La Condamine gives very detailed particulars regarding the Para India rubber tree, the collection and treatment of the juice, and the methods made use of by the natives for the production of various articles of caoutchouc. He tells us that the substance in question was used for making torches, these being only an inch and a half in diameter by two feet long, and yet burning for 12 hours. Again, we hear of the use of India rubber for the making of playing balls, and it appears that the natives were in the habit of using enema or injection bottles made of caoutchouc.

Soon after La Condamine's communication to the Academy of Sciences samples of India rubber frequently reached Europe, and scientific men began to make investigations regarding this remarkable body. Between 1760 and 1770 we find Fresneau and Macquer studying the subject, and the last-named investigator made tubes and other articles of caoutchouc by *dissolving* it in ether and coating moulds with the solution, so that a solid layer of caoutchouc should remain adherent to the mould on the evaporation of the solvent.

Fig. 1.

HEVEA GUIANENSIS.

From this time until the end of the eighteenth century the India rubber industry may be considered to have been undergoing a period of gestation, and to have been busily engaged in the important patents regarding the dissolution of caoutchouc in that year by Charles Macintosh, for dissolving the substances in coal oil, or coal naphtha, and the use of this solution as a waterproofing agent. I have here a specimen of such a solution, as new manufactured by Messrs. C. Macintosh and Co., of Manchester, together with some examples illustrating its use.

About the same time elastic webbing was first made with threads, cut from the raw rubber, and other minor applications of caoutchouc to the industrial arts were adopted from time to time, until the great discovery of vulcanization inaugurated a new epoch in this branch of industry; rendering it possible to so far alter caoutchouc as to make it capable of resisting to a great extent the action of heat on the one hand and cold on the other hand.

The milky sap of many plants contains caoutchouc, suspended in the form of minute transparent globules, these being frequently as small as 1-5000 to 1-4000 of an inch in diameter; but comparatively few plants contain sufficient caoutchouc to render them important sources of this body. The trees which yield the largest supply of the best quality of caoutchouc are various species of hevea, which flourish in the northern districts of South America, especially in the valley of Para, some portions of the valley of the Amazon being crowded to an extraordinary extent with hevea. The size of the India rubber trees in Para may be judged of by the fact that this province alone exported 7,040 tons of caoutchouc in the year 1877; more than half of this being sent to Liverpool.

Among the hevea most productive of caoutchouc may be named the *Hevea Guaianensis*, which flourishes in Para, yields some of the finest caoutchouc, and often attains a height of 90 to 70 feet, with a diameter of nearly three feet; the

CORRESPONDENCE.

EARTH CURRENTS AND SUN SPOTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR,—One of the most interesting and, perhaps, difficult studies of the present time is that of earth currents. Much attention has been paid upon the subject, but beyond the fact that sun spots are related to the probability that they have the power to affect the earth in a manner as yet unknown, nothing known concerning it. Theories have been started and continually dropped, as in vogue for a time, and then forgotten. Numerous calculations with the varying periods of sun spots, and various instance, meteorological disturbances, magnetic and electric, for to sudden faultless, epidemics, railway accidents, and the price of Consols!

Although unable to express an opinion upon the effect of sun spots upon most of these, some years ago I was regard to earth disturbances, but which I have enjoyed a much regard to earth acquaintance during the last fifteen years, may not be lost. Although I have been suggested by some and accepted by others that in past years earth current forces of considerable power have been themselves during the periods of maximum sun spot periods, as in solenoid during the years of minimum spots, but so far as I am able to trace, we have as yet no sufficiently ascertained facts to settle the question. Nor does there appear to be extant the necessary data for arriving at anything decisive one way or another. Certainly at intervals all along the years 1864-5-6 and 7, and again in 1872 and 73, many earth current storms of greater or less magnitude came directly under my own notice, but in some instances I have found earth current which appeared were proved to be entirely current from other lines, while, in other instances the presumed earth currents were probably of an insane origin; nor will this be surprising to telegraph engineers of the earlier days when the then leaky state of the wires is remembered. There is another feature, however, not to be overlooked as regards earth current data for the past. To many the earth current had no existence until it became strong enough to deflect the comparatively heavy needles of the then in use, and only questionable records of such deflections have been the chief source of information and the basis of conjecture and theory. The general result of the writer's nearly continuous observations over earth currents tends to warrant the presumption that sun spots do exert an influence upon

Waterproofing Boots.—One quart of boiled linseed oil, four ounces of mutton suet, one ounce and a half of beeswax, and one ounce of resin are melted together, and applied while the ingredients are still hot.

A New Method of Insulating Wire.—Preparations have been recently completed by a new concern in this city, the Triplex Insulated Wire and Rubber Company, to manufacture insulated wire for underground and other telegraph, telephone, and other conductors. Samples which we have carefully examined prove that the system comprised avoids the serious drawbacks hastily raised against some of the insulating devices now in use, and gives promise of obtaining a wide field of usefulness. Briefly, the principal troubles experienced in connection with the most popular methods have been that the insulating material becomes too brittle in cold weather, making it liable to flake off, and too soft in hot days. Some kinds also do not adhere to the wire, and so separate from it easily. The Triplex Company ties the wire, covers it with a layer of soft rubber, around which a strip of corked linen is wrapped, and which in turn is covered by an outer layer of thick hard rubber. For underground wires, another layer is added. The process of manufacture of the insulated wire is very simple, all the layers being put on in one operation by means of machinery, thus making it possible to furnish a comparatively cheap article. The wire is fed from a reel into a groove cut upon two steel rollers heated with steam, and simultaneously two strips of soft rubber, each more than covering one half of the wire. The excess of rubber is stripped off. The coated wire is then automatically wrapped with corked linen strips, and is carried to a second set of rolls, where two strips of hard rubber are rolled around it to a third coating. In this the central position of the wire in the insulating material is always secured, a matter in which other methods are not so successful.

GUTTA PERCHA IN TELEGRAPHY.

By W. H. Preece.

...on the ... During the past few years we have been very much dis- ...ences, turbed by a peculiar decay of gutta percha, which has been ...g car- rather difficult to account for. Every one knows that gutta percha is a gum obtained by a tree found in the Indian Archipelago, especially in the Jaconsdra parka. This gum is a compound of carbon and hydrogen, containing about 86 per cent. of the former and 15 per cent. of the latter. But in commerce found in a pure state, and we have the material mixed with oxygen and water, manufacturing processes those impurities are removed, and others are absorbed which tend to its preservation. It is curious to note that water and is a benefit, or identical to its chemical construction, with gum is benzole, or identical to its chemical construction, ...N of the with oil of turpentine and other compounds of that class; ...Ingalls, but well known as it is to the telegraph engineer, it is quite ...ngton a child among the materials applied to science.

...Ghosts ... About 1842 Dr. Montgomerie, in the lands of a ...ed the our- native, in one of the islands of the Indian Archipelago, the ...ch by the results of a very peculiar material, ...become which he was told became plastic in warm water, and cap- ...ed to a able of being moulded to any shape. He brought a speci- ...a few men of it to England, and in 1843 brought it before a meeting of the Society of Arts, at which Dr. Siemens was present. The idea was at once suggested to Dr. Siemens that such material had a commercial value for telegraphic purposes. Experiments were made with it by Dr. Werner Siemens, in Berlin, and Faraday pronounced it as possessing electrical qualities of a high order, and a company was formed for bringing it into the market, since when it has been used in almost every conceivable form for electric and other purposes. I need not dwell on its application; my present object is to bring out its durability and behavior when applied to underground wires.

The gum is soluble in olive oil, benzine, turpentine, and other such spirits; it is attacked by ozone, creosote, and liquids of that kind. In combines with oxygen, and undergoes the ordinary process of rust, which proceeds with great alacrity in air, especially when also subjected to the influence of light. This combination by oxygen is also assisted by intermittent exposure to moisture. In process of manufacture gutta percha becomes mechanically united with water, which evaporates on exposure to variations of temperature, and leaves the gum remaining in a dry and brittle condition. This condition led Mr. Edwin Clark to coat gutta percha with tape saturated with tar, in the belief that the tar would replace the water and keep the gum in its elastic state; but, unfortunately, tar contains creosote, which acts on gutta percha in a deteriorating manner, and so the evil remained.

In the years 1852-3-4, a great quantity of gutta percha core was laid down, and some of the gentlemen now present had the responsibility and management of the work. Those wires deteriorated, and among the many causes of deterioration was one frequently brought forward for discussion before the Institution of Civil Engineers, viz., the growth of fungus upon the gutta percha wires. Mr. Highton, an old telegraph engineer, who is no longer with us, found that the wires speedily decayed between London and Manchester, especially among the coal of salt rock; and in such places a peculiar fungus, the condition of a fungus was always present, and of which I hope to say more as an active agent in the decay of gutta percha. I have reason to believe, and will presently show you why, that Mr. Highton was not quite right in his supposition. In all systems of underground wires it has been found that gutta percha wire decays in the neighborhood of joint boxes. In all cases where attacks the gutta percha core, there also the rust has led to the position, not unnecessarily followed in the streets but as near as possible, so far as possible, hermetically sealing the joint boxes and enclosing the air.

Another agent in the destruction of underground wires is lightning, or the induced currents caused by lightning. The connecting wires between the Central Telegraph Station in London and the various railway stations are laid underground, and, when a current is sent, or by lightning induced, the conventional wire to find "earth," if a weak

CANTOR LECTURES.*

THE INDIA RUBBER AND GUTTA PERCHA INDUSTRIES.

BY THOMAS BOLAS, F.C.S.

(CONTINUED FROM PAGE 231.)

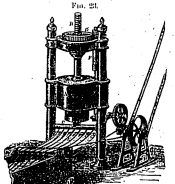
LECTURE IV.—DELIVERED FEBRUARY 23, 1880.

Special applications of Vulcanised India Rubber. Mechanical and Engineering Applications. Surgical Uses. India Rubber Steam or Streetcycles. Vulcanised Caoutchouc in The Dwelling House, the Garden, Children's Play room, and the Printing office.

Few materials have received such numerous applications in the industrial arts as vulcanised caoutchouc; and, in many instances, the applications of india rubber are of considerable commercial importance. So various, indeed, are the uses to which this material is applied, that the mere reading of a list of its applications would occupy much more than the hour allotted for this lecture—as a rough estimate, I should say it would take just about two hours and three-quarters—but I will not do it, but will rather call your attention to a few matters which either are of special interest or happen to present themselves to me to-night.

A pad of india rubber has a remarkable effect in deadening vibration or recoil, and a slab or sheet about an inch thick is a useful thing to place underneath an anvil, in order to reduce the the noise arising from hammering thereon. Again, you know that railway-carriage buffers work against blocks of caoutchouc, these having a remarkable effect in reducing the destructive action arising from the jarring and striking of the carriages against each other. In the case of rubber intended for such purposes, there is, generally, no disadvantage in somewhat hardening the material, by admixture with either one of the inert powders already referred to as being suitable for lowering the quality of vulcanised rubber.

FIG. 23.



APPARATUS FOR MAKING THREADS BY THE PROCESS OF SQUIRTING.

Here, among the articles lent by the Silvertown Company, is an arrangement for breaking the recoil of an ordinary shoulder rubber, and is intended to be attached to that part of the gun which is placed next to the shoulder.

The production of threads of caoutchouc by the process of squirting, is one of considerable interest, and I can be illustrated to you in a very simple manner. Here is a metal squirt, and I will fill it with caoutchouc which has been softened by means of a small proportion of benzole. The beak of the apparatus being placed in the focus of the lantern lens, you see that a magnified image is projected on the screen. The piston being now forced into the cylinder, the softened rubber is driven out in the form of a cord or thread, which easily descends from the mouth of the squirt; but owing to the inverting action of the lens, it appears to ascend on the screen. The threads thus formed must be exposed to the air, in order that all traces of benzole may evaporate, after which they may be cured in any of the usual ways.

The drawing now projected on the screen (Fig. 23) represents an arrangement for the production of threads by the process of squirting. a represents the main cylinder of the apparatus; while r is the rod attached to a piston which fits into this cylinder. The piston is forced down by the gearing represented towards the right of the figure, and in the lower part of the cylinder a series of fine-wire gauze strainers is fitted, in order to remove any solid impurities which may be present in the caoutchouc paste. The pressure of the piston next forces the india rubber into a horizontal tube, marked c, the lower part of which is perforated by a series of holes, out of which the material emulges, forming a row of threads, these being then led forward by an endless band of velvet, E. The threads next pass into a trough, b, which contains running water; whence they are afterwards carried by a long endless band of calico or linen, on which they become sufficiently dry to be wound on bobbins, a little French chalk being made use of to prevent adhesion.

Washers and circular valves are also employed for many purposes, and these may be cut out of the mixed rubber sheet, or they may be moulded out of the mixed rubber. In other cases they can be imbedded in French chalk during the process of curing by steam, or they may be cured in moulds, brass, tinned, or iron, being a very general material for these. The merest trace of oil on the surface of the mould prevents any adhesion to it during the curing process. It may be premised that it is generally necessary to support articles of mixed rubber during the process of curing by heat, as the material softens very considerably before the true curing action steps in. Sheets are generally supported by being wound on a drum together with a cloth, and are then cured in water, while many small articles may be conveniently cured in moulds made of baked clay or shot; these being cheaper and more easily made than metal moulds. It often happens that it is more convenient to cut small washers and discs from the vulcanised sheets, although this course naturally involves some waste of material.

The firms which were mentioned at the last lecture have placed at my disposal the extensive series of specimens illustrating the above-mentioned uses of india rubber, and you can examine them for yourself after the lecture.

FIGS. 24 AND 25.

The manufacture of the various kinds of tubing forms a very important part of the rubber industry. The usual manner of fabricating tubing is to cut the mixed rubber sheet in such a way that, when the edges are put together, no ridge shall be left presenting on the inside or outside of the tube, a matter which is very well illustrated by the diagrams which will be immediately projected on the screen (Figs. 24 and 25.)

A strip of the softened mixed rubber sheet being bent over on itself, the edges are cut off as at A. On now placing the fresh edges together, as represented at B, they fit together, forming a tube, and a loosely-fitting mandril being introduced, the joint is strengthened by being rolled longitudinally with a small roller, resembling a miniature garden roller, only slightly grooved in the middle. The mandril is generally left in during the vulcanising or curing of the tube, the so-called "cobalt cure" being adopted, as already explained. Very often the removal of the mandril presents some difficulty, and, in consequence of this, it is not unusual to employ a spiral wire instead of a solid metal mandril, this being left in the tube when sold. Machines have been constructed for the making of tubes, but with varying degrees of success. In the case of tube machines, a flexible core, or kind of rope, is generally used as a mandril. Tubes are often built up of alternate layers of rubber and frictioned canvas, in very useful in case great strength should be required. Sometimes such canvas is inserted between rubber sheets in a similar manner.

India rubber steam packing is of very great value for making the stuffing boxes of engines steam tight. It is also employed for packing the shaft holes of steamers, and other similar purposes. The steam packing generally takes the form of a cord, built up of india rubber, frictioned canvas, and lubricated or sprinkled cotton. The extraordinary number of patterns or devices into which these materials are occasionally wrought, is well illustrated by the sections which are exhibited by the Silvertown Company, and by Mr. Tuck. This gentleman has made an especial study of the manufacture of rubber packing, and you will be interested in examining the models, which illustrate the method of placing the packing into the stuffing boxes, &c. Generally, packing contains a small square core of rubber, and this is bound round with several layers of frictioned canvas. In such a case, the india rubber core gives the necessary spring or elasticity, while the frictioned canvas endures the hard wear; so tightness is secured in the stuffing box.

The use of gas bags, air pillows, beds, &c., formed of two thicknesses of cloth, separated by a layer of rubber, has now become very general, and can only appreciate the ingenuity exercised in the manufacture of such articles by either seeing them put together, or examining specimens illustrative as to exposition method adopted in building it up. Gas bags have been found very useful for carrying a supply of illuminating gas for the lighting of trains; but the use of them somewhat impoverishes the gas, as the caoutchouc absorbs several of those hydrocarbons which contribute largely towards its illuminating properties. As an insulating material for telegraph and other electrical wires, caoutchouc holds a very high place, and these specimens, kindly supplied by the Silvertown Company, and by Messrs. Rickards and Co., of Derby, will abundantly illustrate this use of india rubber, and the method of coating the wires.

Belting, for the transmission of power, can be very advantageously made of alternate layers of rubber and frictioned canvas, these being built up to the required thickness. Belting is generally cured by dry heat, and in the following manner:—An iron mould, something like a gutter, is provided, this being placed out to the same width of the belting. Into this gutter-like mould, which may be about 20ft. long, a strip of iron fits accurately; so that a piece of belting introduced into the mould is enclosed everywhere excepting at the ends. One end of a length of mould-gas, but not cured, belting being introduced into the iron mould, the necessary heat for curing is applied by means of a massive steam press (Fig. 26), which consists of two cottonguhar cast-iron chests, heated internally by steam. Generally speaking, the chests are heated to a temperature as high as 150° Centigrade, in order that the vulcanisation may proceed quickly.

FIG. 26.—STEAM PRESS FOR VULCANISATION BY DRY HEAT.

In about 20 or 30 minutes, a fresh portion of the belting is exposed to heat in the mould, and so on until the whole length has been vulcanised. The method of vulcanising in question possesses the advantage of yielding belts with very accurately square edges, so that the whole width is available for the transmission of power. The steam press is excellently well adapted for the vulcanisation of figured or patterned sheets of mouldings, intended for ornamental purposes, and the engraving (Fig. 26) represents such a one being made of the apparatus. India rubber belting should, naturally, be protected as far as possible from the action of oil, as the continual motion and consequent very much favours the destructive action of fatty substances upon it.

Caoutchouc has been largely employed in the manufacture of surgical appliances, several specimens of such lines of caoutchouc surgical appliances, several specimens of such lines of caoutchouc being now before you, as they exercise a more continuous and are of considerable value, as they exercise a more continuous and equal strain than would be the case with ordinary bandages. Messrs. Cox and Co. have provided some samples of their extra-Messrs. Cox and Co. have provided some samples of their extra-elastic bandages, made out of spread sheet—a form of rubber elastic bandages, made out of spread sheet—a form of rubber which will be considered less fragile than ordinary vulcanised which will be considered less fragile than ordinary vulcanised appliances—such as infants' feeding gear, injection apparatus, appliances—such as infants' feeding gear, injection apparatus, pessaries, &c.—are represented in the collection before you, but they require no special explanation.

CANTOR LECTURES.*

THE INDIA RUBBER AND GUTTA PERCHA INDUSTRIES.

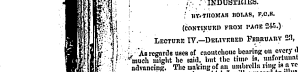
BY THOMAS HOLES, F.C.S.

(CONTINUED FROM PAGE 245.)

LECTURE IV.—DELIVERED FEBRUARY 23, 1880.

As regards uses of caoutchouc bearing on every day life, very much might be said, but the time is unfortunately, rapidly advancing. The sinking of an umbrella ring is a very ingenious and curious operation, which I will proceed to illustrate to you. A strip of the softened and mixed select rubber is cut off obliquely at each end as you see me now cut it (Fig. 27), and after it has been rubbed over with rubber solution to render it adhesive, the

FIG. 27.



obliquely cut ends (A and B) are brought in contact, so that a short tube is formed. This being next placed on a mandrill, one end of the short tube is turned over on itself continuously, so as to convert the tube into a round-rimmed ring. In practice the operation is conducted much more rapidly than I have stated it. Theirings are laid in French chalk and cured by a steam heat; but very often these articles, instead of being made of mixed rubber, are manufactured from cut sheet.

The squeegee is a well-known American origin, and consists of a slootish strip of vulcanised rubber mounted scraper fashion in a piece of wood. The scraper-like edge of the india rubber slides with very great ease over any wet surface, forcing before it any dirt or foreign matter in a manner which is surprisingly complete. No doubt you have all seen the squeegee made use of for cleansing the roads and pavements in rainy weather. The squeegee forms an admirable window cleaner, as I can illustrate to you by applying it to a piece of dirty glass; but it must always be used in conjunction with an abundant supply of water, as the friction between india rubber and dry glass is very great. Considerable use is made of the squeegee in several of the photo-mechanical printing processes, which I had the pleasure of illustrating to you two years ago, as some of you will doubtless remember.

Door mats of vulcanised rubber are now being extensively made use of. The mixture employed for their manufacture is generally of a very low quality; old vulcanised caoutchouc, fibrous materials, and mineral matters, such as whiting, being freely employed. About 20 per cent. is the quality of rubber which finds its African tongue, being often considered sufficient. The material having been calendered to a certain thickness, a very thin tin mat is laid on the sheet by means of French chalk dusted thereon, perforated zinc plate. The mats are next laid in French chalk, and cured by steam. The punchings are worked over again, the slight preliminary curing or setting being insufficient to offer any notable hindrance to this course.

A very excellent manufacturing mat, but one not adopted to any great extent in this country, is to mould them in cast-iron moulds, and then to cure by the dry heat of the steam press (Fig. 26). Other methods, such as building up the mats out of strips, are also occasionally adopted. Nearly all the door-mats are door-stops or buffers, articles of considerable utility in preventing damage to houses by a continued banging of the doors. Small blocks of rubber are often set in the door frames of railway carriages to receive and deaden the fine shock of the blow resulting from a rapid shutting of the doors.

In the manufacture of toys, the applications of caoutchouc are very numerous, and often exceedingly ingenious. Here is a small air ball, or balloon, to which is attached a wooden tube, provided with an india rubber strip, acting as a reed. The reed does not vibrate while the balloon is being distended; and by closing the tube by means of one finger, the air may be retained in the balloon; but on removing the finger, out it goes with a rush, causing an unearthly screak, calculated to delight the infant mind: Hollow playing balls are made of four segments of calendered sheet, put together balloon fashion. Here is one at this stage; it certainly does not look much like a ball, but more like a withered pear, which it would be some time in a square tube rubber too small for it. The next step is to enclose the inelegant ball in a hollow spherical mould, best made of steel, and to expose it to a vulcanising heat. The air inside the india rubber now expands, forcing the material into close contact with the mould, and when the vulcanisation is complete, a perfect counterpart of the interior of the mould is the result. As the included air contracts, the ball, to some extent, collapses, as you see in the case of three samples; but by cutting a small curvilinear hole in one of the balls, as you see, can be made to regain its spherical shape immediately. In some cases it is considered better to tightly distend the cured balls by compressed air; and this may be effected by attaching a small piece of inflated rubber to the interior of the ball, before it is made up, and this lump undergoes no change in the curing process. When the cured ball undergoes no change in the curing process. When the cured ball is taken from the mould, a sharp-pointed or sting-like tube is taken from the mould, a sharp-pointed or sting-like tube is passed through at the point where the lump is situated, and air forced in through this tube. On withdrawing the tube, the hole closes, and the freshly divided surface of the unvulcanised rubber unites again.

I do not think I told you anything about the so-called india rubber sponge, or fresh-like rubber, which may be used for toilet purposes, as pudding, or as rubbers for cleaning shoes or various other articles. It is made by incorporating with the caoutchouc in thin substances which will give off vapour or gas during the process of curing. Among these may be mentioned dewy sawdust, crystallised alum, and carbonate of ammonia. The sponge is vulcanised in moulds, which it fills during the act of expanding. An ingenious application of the sponge rubber is made in the manufacture of certain kind of playing ball. Some of the sponge rubber composition—which, by-the-by, may be compounded as follows:—

20 parts washed rubber of good value.
10 parts red lead or other pigment.
10 parts old vulcanised rubber in a finely divided state.
8 parts sulphur.
8 parts dewy sawdust finely ground.
6 parts oxydised linseed oil

100

is wrapped round a small ball of wood, and the whole is then placed in a spherical mould somewhat larger than the wooden core and the rubber envelope. The heat necessary for curing being now applied, the rubber swells and fills the mould. On taking one of these sponge balls into the hand, its softness would naturally cause one to think it was made of a fine quality of rubber, and to some it is a thing sold at the low price charged; but, on cutting it in two, the mystery is explained,a wooden core and a coating of very low quality sponge rubber being its feature. Very many hollow articles are made in moulds, in the same manner as the hollow balls; not only toys, such as dolls, being produced in this way, but also such goods as injection bottles and analogous articles; the principle of utilising the expansive force of air for forcing the rubber up to the sides of the mould being of widespread application in the rubber industry. Tin or cast iron moulds are often employed, and in such cases a compression of air into the finished article is rendered unnecessary by adopting the expedient of leaving open the article after it is placed in the mould, but before curing; the soft mixed rubber closing immediately on coming into contact with the sides sorry for this purpose.

The use of india rubber for cleansing paper and erasing pencil marks is a well-known application of the material, but its usefulness in this respect has been very much enhanced by incorporating certain gritty materials with it, such as pumice or finely-divided silica. Messrs. Wolff and Sons exhibit a collection of rubber specially prepared for thesecases; and they have adopted the plan of moulding the rubber squeegee form in wooden blocks. By this arrangement contact between the hand and the rubber is avoided. Some people of their evening studies the very dirty envelope much longer than anything yet attempted in metal; but by employing a suitable rubber composition, it is not unlikely that a thorough curing might be effected in so short a time as to offer no friction whatever. The power required to drive these articles, when working with rubber stereotypes, would be comparatively small, while impressions quite as sharp as those from metal ought to be secured. One advantage of the rubber stereotypes would be the ease with which they can be adapted to cylinders of any curvature. As regards ink for stereotypes a few words may be said. A fatty ink naturally injures the rubber; at any rate, if it is not very carefully removed after use; but an ink having glycerine as a basis answers extremely well, and may, as the specimens on the table prove, be left in contact with the stereotypes without in any way injuring them.

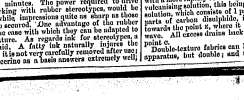
Taking rubber made of india rubber have been occasionally made use of from time to time for some years, but owing to inexperience in their manufacture and use, the results have been, until quite recently, for from satisfactory. You will probably remember that, when lecturing here on photo-mechanical printing, I showed you how a printing roller could be made with a body of the usual soft composition, covered with a thin coat of vulcanised rubber, smoothed by means of glass paper. This circumstance brought to my knowledge the fact that Mr. Robert Lanham had been very successfully labouring in the improvement of india rubber rollers. By the assistance of Mr. Lanham, I was enabled to show you some of his rollers at the lecture immediately following the occasion when I showed you my own. During the two years which have elapsed since that time, Mr. Lanham has still further developed the manufacture of rubber rollers for printing purposes, and I am indebted to him for the opportunity of now showing you the very fine selection of these articles which stand over yonder. Mr. Lanham makes his rollers from red rubber, which is, of necessity, very thoroughly cured in order to enable it to withstand the action of fatty inks; and after the rollers have been turned true by means of self-setting lathes, a fine surface is given to the rubber by means of glass paper. In order to give his rollers the sufficient which is necessary in some cases, Mr. Lanham now introduces a series of perforations parallel to the axis. For lithographic printing, these rollers have very considerable advantages over the usual leather roller, and some excellent samples of work done with them hang on the walls.

India rubber does many services in connection with the art of printing, some of these being of very great interest; but it is impossible to do more than notice the matter this evening.

Waterproof goods, consisting of a thin layer of rubber spread on a textile fabric, are very largely made use of for the fabrication of overcoats, and other waterproof garments. In the manufacture of these goods the first step is to prepare a dough or mixture of the goods as the material. If the vulcanising process is to be carried on in steam heat, as is the case with the cured rubber goods, a composition of the following the case of cotton or linen goods, a composition of the following the case of cotton or linen goods, a composition of the following the case of cotton or linen goods, a composition of the following nature may be spread on the fabric:—30 lbs. rubber, 5 lbs. sulphur, 30 lbs. zinc white, 5 lbs. sulphur, 0 or 8 lbs. of solvent naphtha. When, on the other hand, the curing is to be performed by the cold process, the sulphur is omitted. After the rubber has been softened by the absorption of the solvent naphtha, the materials are thoroughly incorporated by means of a mixing or kneading machine.

A very good illustration of the action of a spreading machine is afforded by the model which is now before you. (Fig. 29) As afforded by the model which is now before you. (Fig. 29) as afforded by the model which is now before you. (Fig. 29) consists of a trackcord, A, which is supported a rule-like

FIG. 29.



MODEL ILLUSTRATIVE OF THE ACTION OF THE SPREADING MACHINE.

bar, B. The material to be coated is placed under the bar, a quantity of the paste or dough is piled up in front of the bar, at the left hand side, and is drawn forwards, so that the rule or bar cuts off an even layer of the soft stuff. In actual use the bar cuts off an even layer of the soft stuff. In actual use the bar cuts off an even layer of the soft stuff. In actual use the composition, is passed over a heated steam chest, in order to dry off the solvent naphtha, and the cured rubber goods about six coats are given—three in each direction. Each coat is about 1-100th of an inch thick, as being about one-hundredth of an inch in thickness.

The method of applying the mixture of carbon disulphide and rubber in the manufacture of the cold vulcanisation of rubber goods, and the process for effecting the same, which would be the india rubber coating when spread on goods, is of some interest. The coated fabric, as it comes from the spreading machine, is passed into a solution (c, Fig. 30) passes round a roller (d), coated also fabric (c, Fig. 30) passes round a roller (d), coated also with a mixture rapidly revolving slate roller, A, which dips in the with a mixture rapidly revolving slate roller, A, which dips in the vulcanising solution, this being contained in a trough, B. The vulcanising solution, this being contained in a trough, B. The solution, which consists of 1 part of chloride of sulphur and 40 parts of carbon disulphide, is led upwards by the roller A, parts of carbon disulphide, is led upwards by the roller A, towards the point e, where it forms a kind of accumulator or towards the point e, where it forms a kind of accumulator or wave. All excess drops back on the fabric travels towards the wave. All excess drops back on the fabric travels towards the point c.

Double-texture fabrics can be produced by employing similar apparatus, but double; and the two textures, which are vul-

FIG. 28.

HOT-PRESS FOR THE VULCANISATION OF INDIA RUBBER CASTS OR STEREOTYPES.

the curing of small flat articles and coats. It consists of a cast-iron fish bottle, upon the bottom of which rests a shift of type, mixed an inch thick. Inside the kettle is placed a small press, like a copying press in miniature. By the side of the press handle is a small iron with a containing glycerine, and in this fluid is immersed the bulb of a thermometer, the stem of which projects through a hole in the cover of the kettle. By means of a small gas stove, heat can be applied to the apparatus, and it is easy to so adjust the gas supply, that the thermometer shall indicate a tolerably constant temperature of, say 140° or 150° Centde. Most qualities of rubber will become fairly well cured by being heated under these circumstances for half to one hour, and any tendency towards a reaction in the mould is obviated by the preparation with oil and blacklead, as described.

The apparatus is extremely well adapted for curing the india rubber stereotypes or stamps, which are now so extensively used for endorsement and other purposes. These rubber stereotypes are a reverse or mould is made from the types, this being taken in plaster of Paris, or better still, in metal. When plaster is employed it is well to harden it, by saturating it with an alcoholic solution of shellac, and again drying. The soft mixed rubber is then forced into the mould, as you now see me doing it, after which the curing may be effected in the hot press (Fig. 28).

Mr. John Leighton introduced rubber stereotypes about eighteen years ago, and since that time their use has become very general for a great variety of purposes. Mr. Leighton has very kindly sent, for your inspection, an interesting collection of specimens, illustrative of the manifold uses to which india rubber stereotypes are applicable. The principle of utilising the swelling which takes place in the rubber when it is heated under pressure in the moulds, for producing the impression, has a worldwide application in the rubber industry. Tin or cast iron moulds are often employed, and in such cases a compression of air into the finished article is rendered unnecessary by adopting the expedient of leaving open the article after it is placed in the mould, but before curing; the soft mixed rubber closing immediately on coming into contact with the sides sorry for this purpose.

The use of india rubber for cleansing paper and erasing pencil marks is a well-known application of the material, but its usefulness in this respect has been very much enhanced by incorporating certain gritty materials with it, such as pumice or finely-divided silica. Messrs. Wolff and Sons exhibit a collection of rubber specially prepared for thesecases; and they have adopted the plan of moulding the rubber squeegee form in wooden blocks. By this arrangement contact between the hand and the rubber is avoided. Some people of their evening studies the very dirty envelope much longer than anything yet attempted in metal; but by employing a suitable rubber composition, it is not unlikely that a thorough curing might be effected in so short a time as to offer no friction whatever. The power required to drive these articles, when working with rubber stereotypes, would be comparatively small, while impressions quite as sharp as those from metal ought to be secured. One advantage of the rubber stereotypes would be the ease with which they can be adapted to cylinders of any curvature. As regards ink for stereotypes a few words may be said. A fatty ink naturally injures the rubber; at any rate, if it is not very carefully removed after use; but an ink having glycerine as a basis answers extremely well,

THE INDIA-RUBBER AND GUTTA-PERCHA INDUSTRIES.—V.

By Thomas Bolas, F.C.S.

(Continued from page 3713.)

THE ringcase laid in French chalk and cased by a sheet metal, but very often three articles, formed of being made of mixed rubber, are manufactured from the start.

The sponge case is an instrument of American origin, and consists of a slender strip of vulcanized rubber into which a sponge is put, in a piece of wood. The sponge is put in dry, and the whole case is put into water for one week or more, and then taken out and dried before being used. The sponge is then ready for use, when a saturated solution of 30 grains to the ounce of water made use of for cleansing the mouth and throat in using weather. The sponge forms an admirable window cleaner, as it will absorb a large quantity of water, and will not drip. Specimens of many articles in daily existence of the finest threads imaginable, all of which as the fabrics themselves introduced—are shown in the exhibition. Threads as fine as hairs of the head, and yet about a very great. Chemicals use 14 marks of the sequence in several of the photo-mechanical printing processes, which I feel the pleasure of illustrating to you, as some of you will doubtless be interested in the formulæ.

Door-cords of vulcanized rubber are now being extensively made use of. The makers employed for their manufactures is generally of a very low quality; all vulcanized constituents, fibrous substances, and mineral matters, such as whiting, being used in their manufacture. The use of a low quality of raw rubber, such as Adriano or Angola, being often considered sufficient. The material is generally calendered to the requisite thickness, a very partial and imperfect curing is generally effected at this stage, the sheets being exposed to a moderate heat between metal plates, these being often considered sufficient. The cords are then cut out and by means of punches and cutters, the discs having been annulled on the edges are passed through cloth coated through a perforated metal plate. The cords are next laid in French chalk, and cured by steam. The gumships are worked over again, the slight preliminary curing or salting being considered to offer any notable hindrance to this course.

A very excellent method of manufacturing mats, but one not adapted to any great extent in this country, is to mould them in cast-iron moulds, and then to cure by the dry heat of the steam-press. Other methods, such as building up the mats out of vulcanized rubber compounds, and then vulcanizing in moulds or drop steam or hydraulic presses, are of considerable utility in preventing the distortion which is continual bugging of the discs. Small blocks of rubber are often set in the door frames of railway carriages to receive and deaden the first effect of the blow resulting from a rapid shutting of the door.

In the manufacture of toys, the application of exceedingly cheap and common materials, and very highly ingenious. Here is a small air-ball or balloon, to which is attached a wooden tube, provided with a valve, and also what acts as a valve. The real does not appear, while the balloon is being distended; and by pressing the tube by means of one finger, the air may be retained in the balloon; but removing the finger, and the valve goes with a rush, causing an assembly attached to delight the latest mind. Indoor pleasures of a very different description to these, and together, are the Indian fashion. Here is one of this stamp: a small ball, which looks like a ball, but more like a silkened purse, which has sealed for some time in a square tube, prepared for it. The real stop is to imitate the instrument but in a better spherical mould, but made of some composition that is a vulcanizing heat. The air-tasks the inflated rubber now appears, forcing the material into close contact with the mould, and when thevulcanization is complete, a true counterpart of the interior of the mould is formed. The ball is then emptied of its contents, the hole, by some means, closed, as you see in the case of these samples; but then, as you see, a small piece is made to fit the hole, and is put in, and then made to regain its spherical shape immediately. Sometimes the ball is examined better to slightly dissect the mould by compressed air; and this may be effected by the ordinary hand-pump of an inflated rubber in the interior of the ball, before it is made up, and this lump undergoes an elaborate forming process. When the cured ball is taken from the mould, a sharp-pointed or sting-like tube is passed through at the point where the lump is situated, and air is forced in through this tube. On withdrawing the tube, the hole closes, and the finely-divided particles of the unvulcanized rubber unite again.

I do not think I told you anything about the so-called indiarubber sponge, or foot-like rubber, which may be used for toilet purposes, as washing, or as rubbers for cleaning shoes or various other articles. It is made by incorporating with the rubber certain substances which will give off gases when heated, such substances as bicarbonate of ammonia, bicarbonate of soda, sesquicarbonate of ammonia, alum, and carbonate of ammonia. The sponge is vulcanized in moulds, which fit the closing the act of imposing. An ingenious application of the sponge rubber is made in the manufacture of the certain kind of playing-ball. Some of the sponge rubber compositions, which, for toys, may be compounded as follows:—

20 parts washed rubber of low quality.
10 parts red lead or other pigments.
10 parts of vulcanized rubber in a finely divided state.
5 parts sulphur.
2 parts each sawdust finely ground.
6 parts of calcined linseed oil.

100

The corrugated round a small ball of wood, and the whole is then placed in a mould of the exact same size, but larger than the wooden one inside. Under carriages, the last necessary for curing being now applied, the rubber swells and fills the mould. On taking the case from sponge balls in the hand, the softness would naturally cause one to think it was of a very low quality of rubber, but the reverse is at all being said as the low sum charged; but on cutting it open, it is found to be composed of wood, corn and a covering of very fine sealing sponge rubber being its factors. Very many hollow articles are made in moulds, in the same manner as the hollow balls; not only toys, such as dolls, being produced in this way, but also such articles as hygienic bottles and analogous articles; the principle of forming the articles in moulds, and for forcing the rubber up to the sides of the mould being of widespread application in the rubber industry. To or canvass manikins are often employed, and, in some cases, a suppression of air into the finished article is rendered unnecessary by adopting the expedient of forcing air into the interior of the article in the mould, but before curing; the soft mixed rubber closing immediately on the minute hole which is necessary for this purpose.

The use of indiarubber for closing paper and paying pencil-marks is a well-known application of this material, but its usefulness in this respect is not, perhaps, much increased by incorporating certain pretty materials with it, such as pumice or finely divided silica, as has been done, and thus exhibit a collection of rubber specially prepared for these uses; and they have adopted the plan of grinding the rubber, sponge fashion, in wooden blocks. By this arrangement, contact between the rubber and the rubber is avoided, and the rubber is left in their coarse-rubber gut very dirty, and then requires hard rubbing to obtain paper.

Very pretty casts or mouldings of phototypic reliefs may be made in vulcanized rubber; and I will next illustrate to you the method of making these, which is as far as the manufacturer of the results, is concerned. Here is an ordinary photographic negative, which is a typical metal cast or mould, produced by electrolytic agencies from the negative. These portions of the negative which are opaque correspond to shallow places in the metal mould, while the depressions of the mould correspond with the transparent portions of the negative.

A writer in the Providence *Journal* predicts a useful future for the milkweed, which has hitherto been considered only a cumberer of the ground. Its seeds yield a finer oil than linseed; its gum can be used in place of India-rubber; and from its fibre a fabric resembling Irish linen is woven; while the young shoots are used in the spring by some people instead of asparagus, which they resemble in flavor. Now, pertinently adds the writer, if cows can be discovered for the thistle and whitewood, they may prove friends in disguise.

WATERPROOFED CLOTH.—Cloth coated with linseed oil to which a little wax and litharge have been added, will be waterproof.

THE INDIA-RUBBER AND GUTTA-PERCHA INDUSTRIES.

By Thomas Bolas, F.C.S.

LECTURE I.

THE SOURCES OF INDIA-RUBBER.

India-rubber, or caoutchouc, possesses properties so widely different from those of most other substances, that it becomes an object of very great interest as soon as it needs its appearance in the civilized world, and its industrial importance has rapidly increased as the knowledge of its remarkable characters and manifold applicability has become more extended. At the present time, caoutchouc holds such an important position with regard to the economy of

FIG. 1.—HEVEA GUIANENSIS, OR RUBBER TREE.

FIG. 2.—FICUS ELASTICUS; A SPECIMEN GROWING IN THE OPEN AIR AT PARIS.

modern arts and manufactures that were it suddenly to be withdrawn from circulation many minor industries would be compelled to cease to exist, while numerous large and important branches of manufacture, such as railway appointments would be made to adapt their operations to the altered circumstances.

It is, however, during the last forty years that India-rubber has become of the greatest importance to mankind; that is to say, since the year 1839, when the discovery was announced by the brothers of Charles Goodyear, Thomas Hancock, and others.

The chief source of the existence of caoutchouc received Europe merely in the shape of the vast tract of Columbia to the United States, in the habit of making playing balls of this solid wood, in the habit of making playing balls of this solid wood, in the habit of making playing balls of this solid wood

CANTOR LECTURES.*

THE INDIA RUBBER AND GUTTA PERCHA INDUSTRIES.

BY THOMAS HOLE, F.C.S.

(CONTINUED FROM PAGE 220.)

LECTURE III.—DELIVERED FEBRUARY 16, 1880.

The powders most extensively employed for thus lowering the quality of rubber are the following:—Clay, chalk or whiting, French chalk or talc, barium sulphate, plaster of Paris, oxide of zinc, sublimate of zinc, sulphate of lead, various oxides of lead, oxy-carbonate of lead or white lead, magnesia, silica, and fuller's earth.

Some of the above-mentioned materials, specially prepared for the rubber manufacturer, are shown in the collection of india rubber chemicals kindly lent to me by Messrs. Forster and Gregory, of Streatham; and these manufacturers also exhibit some qualities of sulphur specially purified for use in the vulcanisation of caoutchouc. It is a matter of considerable importance that the sulphur employed for mixing with caoutchouc should be free from all trace of acid, and also from the moisture which acid samples of sulphur tend to absorb from the atmosphere. Ordinary flowers of sulphur—prepared by passing sulphur vapour into large chambers constructed of masonry, so that this vapour shall condense into minute crystals resembling snow—is almost invariably acid in its reaction, as traces of sulphuric acid are formed by the oxidation of the sulphur. This acid may be removed by washing the flowers of sulphur with an abundant supply of water, and then drying at a gentle heat.

Here is a sample of ordinary commercial flowers of sulphur, and here is some of the same which has been washed and dried. I will put a little of each on a sheet of blue litmus paper, and then moisten them with alcohol. You see that where the unwashed sulphur was placed, the colour of the litmus paper is changed to red, owing to the action of the acid, while the colour of the litmus paper has not been in any way altered by the washed sulphur. All samples of sulphur ought to be tested in this way before being employed for mixing with india rubber. Powdered sulphur is very often in the state of, and it has not so much tendency to be acid as in the case with flowers of sulphur.

The so-called milk of sulphur—or precipitated sulphur—exists in a very fine state of division, and as far as this circumstance is concerned it is especially adapted for mixing with india rubber; but, on the other hand, it is expensive, and is liable to be dampened in manufacture, but in order to ensure perfect vulcanisation it is necessary to employ sulphur uniformly mixed with which actually combines with the caoutchouc. This excess sometimes effloresces out on the surface, becomes acid, and leads to the destruction of the rubber. It appears also sometimes so to overcure the rubber as to make it brittle and useless. In the case of articles presenting no great degree of thickness, the greater part of this injurious excess of sulphur may be removed either by boiling them in a dilute solution of caustic soda or by means of a solution of sodium sulphide. I have found a method of producing vulcanised rubber which shall be free from any such excess of sulphur consists in employing a smaller proportion of the sulphur originally mixed with the caoutchouc by metallic sulphide.

The sulphide of antimony is that which is most extensively employed at the present time, the use of this having been claimed by Charles Hancock in a patent dated January 12, 1846; while in a patent dated February 10, 1847, he fully recognises the fact that free sulphur ought to be employed in connection with the sulphide of antimony. Sulphide of antimony for the rubber manufacturer is prepared by boiling the native sulphide in a solution of caustic soda and precipitating the solution thus obtained with a slight excess of hydrochloric acid. Here is an alkaline solution of the native sulphide, and you see that when I add hydrochloric acid to it, an orange-coloured precipitate is produced. This, when washed and dried, is ready for mixing with the caoutchouc.

The sulphide of antimony thus prepared contains, under ordinary circumstances, a certain proportion of free sulphur, but, in order to obtain the best results with the sulphide of antimony, uncombined state. This can be insured by adding the requisite proportion of sulphur to the caustic soda in which the original native sulphide is dissolved. The well-known red rubber is vulcanised by means of the sulphide of antimony, and the superior qualities of this kind of rubber over the ordinary grey articles are generally recognised by the public. The absence of any considerable excess of free sulphur renders it less liable to decay under the influence of time and light, while it is less subject to destruction by fatty matters than rubber containing an enormous excess of free sulphur. The quality of commercial red rubber is, however, somewhat variable, and I have met with samples which were scarcely vulcanised at all, the sulphide of antimony employed being probably deficient as to the amount of free sulphur present. When the sulphide contains from 20 to 25 per cent. of sulphur, it is generally not necessary to mix more than 15 to 20 per cent. of the sulphide with the rubber; but when a sulphide of antimony containing less free sulphur is employed, it is possible to add a much larger proportion to the rubber with advantage. No manufacturer should ever employ a sample of precipitated sulphide of antimony without first ascertaining that it contains a proportion of free sulphur suited to his work. Extra sulphur may be added in the form of milk of sulphur, but this proceeding is not so satisfactory as taking the right thing to start with. Other sulphides, such as lead sulphide, mercuric sulphide, or zinc sulphide, are occasionally employed as vulcanising agents; but, in order that they may act in the best satisfactory manner, it is necessary for some free sulphur to be present; and the amount of this free sulphur should always be exactly known, in order that the vulcanising may be a matter of certainty, rather than the result of a kind of guesswork process. Sulphide of mercury or vermilion intended for use as a vulcanising agent ought, in most cases, to contain as much as one third of its weight of free sulphur.

The action of these sulphides is peculiar. They have but little vulcanising action themselves, but they enable the free sulphur which may be present to exercise its full force; or, in other words, they take the place of that large excess of sulphur which remains ununited with the rubber in ordinary cases. You will, then, the use of these sulphides renders it possible to avoid the presence of a large excess of ununited sulphur in the finished goods. Some of the sulphides exercise by themselves a powerful vulcanising action; and among these may be mentioned the polysulphides of the alkalis and of the alkaline earths, or articles made of this cut sheet may be very perfectly vulcanised by Gérard's process, which consists in exposing them to the action of a solution of the mixed polysulphides of calcium, at a temperature of about 140 degrees Centigrade.

Among Messrs. Forster and Gregory's specimens are many sulphides adapted for use as vulcanising agents, some of which are mainly intended for use as colouring materials; these latter being, probably, free from any excess of sulphur. The fact of Messrs. Forster and Gregory being so well acquainted with the requirements of the rubber trade enables them to procure sulphides suited for each particular kind of work. Among their specimens may be noticed the antimony vermilion, a very fine colouring matter, but not a vulcanising agent; the golden sulphide of antimony, which is specially prepared as a vulcaniser, and is manufactured in such a way as to ensure uniformity of composition, this being a matter of the greatest importance. Again, we have here yellow orpiment, a bright yellow sulphide, to the extent of 60 per cent. to the rubber; zinc oxysulphide, a white colouring material, which is sometimes used in the best coating compound textures, as it possesses the property of absorbing sulphur, and so prevents sulphuring up, or an efflorescence of sulphur from the more highly sulphuretted layers beneath.

When articles made of thin rubber—as by my cut sheet—are imbedded in powdered sulphur, and exposed to a temperature of about 112° Centigrade for some considerable time, as much as 10 per cent. of sulphur is absorbed by the caoutchouc, and this absorption is facilitated by rubbing the powdered sulphur on the surface of the caoutchouc. This method of sulphuring cut sheets, and articles made from cut sheet, is of considerable practical utility in many cases, and the goods so charged with sulphur may be cured in the ordinary steam vulcaniser.

Parkes' cold curing process, briefly referred to in a previous lecture, is one of the most curious things existing in the whole rubber trade. Here is a piece of cut sheet rubber, which I now dip for an instant in a mixture of one part of chloride of sulphur and 60 parts of carbon disulphide; after which I lay it for a minute on a tray covered with French chalk and heated to about 40° Centigrade. The portion which was dipped is now vulcanised; perhaps not all the way through, but very nearly. This method of articles made from cut sheet rubber. In this case it is probable that the chlorine removes hydrogen from the rubber, and that the sulphur takes the place of the removed hydrogen. A study of the process in question shows us how very nearly is the

40

proportion of sulphur actually concerned in vulcanisation. In Parkes' process we have one of the most perfect vulcanising processes existing, as combined sulphur alone results, and the finished articles are quite free from any trace of sulphur in an uncombined state. An after-treatment with water, or a weak alkaline solution, may be adopted to remove traces of hydrochloric acid. Light perfumes is now often employed in this process instead of carbon disulphide. Some hypo-sulphites, especially the lead salt, are capable of acting as vulcanising agents but are not very extensively made use of. Vulcanisation by hypo-sulphites is, however, interesting, as affording another instance of combined sulphur acting as a curing agent.

Other re-agents besides sulphur exercise a hardening or vulcanising action on india rubber; as, for example, nitric acid and the halogens. Warren claims the use of these latter bodies in his patent dated February 26, 1871, and he has very successfully vulcanised the insulating coating of telegraph wire by means of iodine. A piece of cut sheet rubber dipped into bromine becomes vulcanised instantly. Warren's process has been applied in America to the production of vulcanite bases for artificial teeth.

When sulphur and caoutchouc are mixed, there is a certain tendency for them to unite slowly, especially if exposed to the rays of the sun; a kind of gradual vulcanisation or curing being the result. This is very well exemplified in the case of the cork Piccadilly, to whom I am indebted for this very complete set of specimens illustrative of their manufacture. The segments of cork, out of which these helmets are made, are cemented together by means of a solution of rubber in purified camphine, but a certain proportion of sulphur is added to the solution. During the time that the helmet is in use, the india rubber cementing medium gradually becomes vulcanised, increasing in toughness and hardness by exposure to the heat of the sun. If, on the other hand, no sulphur were present, the rubber would rapidly deteriorate, and the helmet would fall to pieces if used in a tropical climate.

I have to thank several manufacturers for lending me many of the numerous specimens of vulcanised rubber which are before you this evening, Messrs. Macintosh, Hancock, Davis, and Henwood, the Silvertown Company, and others having been most kind in this matter.

The remarkable power which vulcanised caoutchouc possesses of recovering its shape after compression is well illustrated by the fact that a sphere 2½in. in diameter passes between rollers set to a distance of a quarter of an inch without suffering any permanent injury as regards form.

Although vulcanised rubber is insoluble in the ordinary solvents of caoutchouc, boiling oil of turpentine will dissolve it, and solutions of pliable liquid are employed by Dr. Stenhouse, of Rochdale, for making waterproof cloth. Some specimens of this manufacture, which will be referred to in the next lecture.

Oils and fats exercise a very destructive action on india rubber, more especially when the caoutchouc is unvulcanised, and through the kindness of T. S. Speed, engineer to the London Underground Railway Company, I am enabled to show you a very interesting specimen illustrative of this. It consists of a piece of one of the contrivances place employed to lead gas into the trains at the Hammersmith Station, and the pipe from which the specimen has been cut was placed in immediate proximity to the stopping point of the engines. You see how deeply and thoroughly the pipe is corroded and destroyed by the action of oil from the engines, while the other pipes in the station are in excellent condition.

Some of the conditions which are favourable to oil resisting powers, in the case of vulcanised caoutchouc, are as follows:—

1. The use of a high quality of rubber,
2. Thorough mixing,
3. The absence of free sulphur in the finished article.
4. The presence of such pigments as lithrage, red lead, or white lead.
5. The corporation of a trace of glycerine with the materials.
6. Curing in a glycerine bath. (Placed in an ordinary steam vulcaniser.)

On the table you will see some interesting specimens, kindly lent by Mr. Tuck; these illustrate the matter in question, and you will notice how well Mr. Tuck's special oil-resisting rubber has withstood the action of mineral and other oils.

Ordinary vulcanised rubber gradually deteriorates when maintained at a temperature near 150° Centigrade, becoming brittle and evolving sulphuretted hydrogen. This may be principally due to the reaction of the still uncombined sulphur on the caoutchouc. Exposure to the sun's rays will often produce a similar effect on caoutchouc containing free sulphur in considerable excess. Thus we see that, although both heat and exposure

to light have a curing action on mixed rubber, the ever-long continued action of either agency tends towards mischief.

Water-Proof Coverings.

By F. Collingwood, Member of the American Society of Civil Engineers.

Read at the Twelfth Annual Convention, May 25, 1880.

As a contribution to the general subject of the use of asphaltes, bitumens, etc., the writer would offer the following bit of experience:

As it is intended that the arches of the approaches of the East River Bridge shall be roof for mercantile purposes, it became necessary to cover the concrete over the arches with some protecting substance, which should keep out all dampness from the masonry. On inquiry among persons engaged in such work, a great diversity of material was offered, and each lauded as the best for the purpose.

It was accordingly decided to ask bids generally, each bid to be accompanied by samples for testing.

In deciding on the tests, the following requirements were had in view:

1st. That the covering should be impermeable to water at all temperatures, and

2d. That it should be permanent.

It is evident that there is little danger of failure at high temperatures, but at low temperatures cracks may develop from contraction or shocks, allowing water to pass through. The tests on this point were, to make some wooden moulds with grooves about 2 feet long, with enlargements at the ends, so as to give a shape like an ox yoke, and fill them with the mixture. These, with some flat pieces of the material, were exposed to a freezing mixture for 48 hours. Some of the long pieces cracked under this test. After freezing, the pieces were first tested with a loaded point for penetration, and then exposed a short distance to see whether they would break. In this way a fair idea of the respective hardness and brittleness was obtained, and also (by careful measurements) the relative contraction. After this the specimens were exposed to heat, to see their behavior under a high temperature.

The next tests were for durability, and proceeded upon the assumption that in process of time destruction must occur, if at all, in two ways:

1st. By the gradual evaporation at ordinary temperatures of the volatile oils contained in the water-proofing material, and which give plasticity to the mass, thus causing them to be crumbly and absorbent, as witnessed in coal tar roofs. The test for this was to weigh with delicate scales a small mass of the material, and expose it in a small bath to a temperature of 212° for 48 hours, noting the percentage of loss.

The second possible cause of failure was considered to be absorption of water, which by freezing and thawing would eventually cause disintegration. For this test carefully weighed specimens were soaked in water for 48 hours, taken out, wiped carefully, and reweighted to determine increase in weight.

A third possible cause of deterioration would be looseness of structure, causing rapid alternation under passing loads, but this would be determined by the second test above.

The various samples offered may be classified as follows:

1st. Alternate layers of coal tar and felt.

2d. A mixture of concrete, crude petroleum, and resin.

3d. Trinidad bitumen (refined) and coal tar, with an admixture of sand.

4th. Asphaltic mastics consisting of various mixtures of Val de Travers or Limmer asphaltes, with Trinidad bitumen, residuum oil, limestone, sand, etc.

5th. Trinidad bitumen, with paper or felt, in consecutive layers.

6th. Trinidad bitumen (refined), mixed with almost 10 per cent. of residuum oil, put on in consecutive layers.

The tests showed that all of No. 1 were totally unreliable for permanent work.

No. 2 is an admirable fire-proof material for roofs. There was a loss of one-half per cent. by boiling, however, and the price was too great.

No. 3 absorbed 1 per cent. of water, and was evidently poorly prepared.

No. 4. Of these the best samples were excellent, but were rather hard at low temperatures. Of the poorer ones (those most adulterated), some failed by cracking, showing brittleness, others by absorption, taking up as much as 4½ per cent. of water. The best were too expensive.

No. 5 were decided against, on the ground that no paper layers could be made continuous, and threw second as reason for inserting a foreign substance which had no protective power of its own.

No. 6. A mixture of 90 per cent. residuum oil and 80 per cent. Trinidad bitumen was found to be too soft. The residuum oil or petroleum was in that product of the distillation of petroleum which passes over at temperatures between 600° and 700° F. Reducing the oil to 10 per cent. gave a mixture neither too soft when warm nor too brittle when cold, entirely meeting the tests, and being nothing when boiled. It was therefore decided that no other was less than that of any other acceptable sample offered, the bid would be accepted, to put down three layers having a total average thickness of half an inch.

The lesson to be learned from these tests in respect to the use of such materials in road making is this, that it is possible to take a piece of material from a street (a very small piece will do if chemist's scales are used), and determine at once whether there is a reasonable probability of its being of a lasting character. All experience goes to show that compressed asphaltic cement is durable unless well compressed; and the absorption test ought to reveal the physical condition of any specimen as to porosity. A tensile test, by comparison with known mixtures, would reveal something else as to adulteration of the mixture by an excess of grit or earthy material. One bidder put in peat for some purpose best known to himself. Of course, no person would recommend the mixture adopted as suitable for road making; it can only be used where covered from the sun's rays by an external covering of some thickness, for the express purpose of keeping out water.

This experience is given as one method—in the present case a very successful one—of deciding among a lot of bids having apparently few points in common on which to base a decision.

Edward P. Nourse.—The interesting experiments detailed by Mr. Collingwood may be supplemented by a notice of the tensile strength of some samples of asphaltic mastic (No. 4, mentioned above), and of a bituminous mastic known as Filbert's vulcanite.

The asphaltic mastic was made from Val de Travers asphalte, melted in the ordinary refined Trinidad bitumen, with the addition of about 50 per cent. of clean siliceous grit of the size of a pea.

The vulcanite is identical with that tried in Fifth avenue, between Twenty-fourth and Twenty-fifth streets, in August, 1879, and is composed of 141 gallons of refined Trinidad bitumen, 7 cubic feet of fluid sand, both heated to 300° F., and 1 to 1½ gallons of a mixture of cement, limestone dust, and sulphur, all mixed in a horizontal revolving mill.

The test pieces were one inch square, and were broken on a cement testing machine that only registered to 400 pounds.

Four samples of the vulcanite were broken at 120, 140, 185, and 220 pounds. Five samples of the asphalt mastic were broken, one at 352 and one at 400 pounds, the other three stood 400 pounds for over a minute, and broke with an added weight of from 20 to 50 pounds. All the test pieces were immersed for over an hour before the breaking in ice-water; the temperature of the room was 85°.

The asphaltic mastic probably had more than twice the tensile strength of the vulcanite, and would be less liable to crack from change of temperature.

This mastic, without the addition of grit, is largely used in France for covering arches, casemates, and powder magazines, with very satisfactory results, as the mastic yields to the settlement of the masonry without cracking.

It may be doubted if the test proposed by Mr. Collingwood would be a valuable aid in selecting a paving material, as newly laid compressed asphalte would not show as well under it as the mastic, yet experience has shown that it is much more durable than the latter for wheelways—so much so that the Limmer Company, of London, are replacing their mastic pavements with compressed Sicilian asphalte, and it is doubtful if asphaltic mastic will wear better than the best of the bituminous mastics as now laid, particularly under rapid traffic in cold weather, but the asphaltic mastic would be the best absorbent of the two.

F. Collingwood.—In continuation of the discussion of "water-proof coverings," I have a few additional facts to offer.

Our work, as far as it was concreted, was covered during cold weather with the mixtures mentioned above, namely, refined Trinidad bitumen with 10 per cent. of residuum oil. It was thus expected that the stone paving would be laid early in the spring, and a thick layer of sand was spread over it. Instead of this, owing to delays, the pavement has not yet been laid, (July 31, 1880), and the whole has been exposed to the hot weather of the past few months.

The temperature has, under the circumstances, been sufficiently high to cause the bitumen to rise in places through the sand, and to flow to a moderate extent.

This experience shows that it is necessary to attend to the upper limit of temperature as well as the lower. I am now inclined to think that the bitumen would be better without any oil. With the full thickness of paving and sand we expect to put above it, this temperature will probably not be high enough to disturb it. This is, no doubt, the reason for the introduction of felt and paper in its two over roofs and sidewalk vaults.

There is a practical difficulty in applying it to the inside of domes. Where hot enough to insure thorough adhesion to the walls of the dome, the mixture is so thick that the workmen cannot see what they are doing. The warm solution would probably be the best application in such location.

Artificial India-Rubber from Coal Tar.

Referring to Ackersonn's *Caoutchouterie*, pp. 14 genuine, and substitute for India-rubber or gutta-percha, but from which, however, either alkaline or acid solutions will extract the resin, leaving a residue of pure caoutchouc, which, after vulcanization, is found to possess properties for which it is highly valued, being tough, non-sensitive to several influences on which genuine rubber is affected, not affected by pressure or temperature. The base or its compounds would possess remarkable qualities as coal tar oil, or liquid parts of coal tar oil, in quantity equal to a third part of whole mixture. This tar oil is poured into a large kettle, set with an equal quantity of hemp oil, and is heated several hours, either by steam or over an open fire, to a retaure ranging from 225° to 288° Fahr., beyond which it must not go. The mass becomes at length so ductile that it can be cast in long threads, and the remaining thirst portion, consisting of oil which has been thickened by boiling, is then added. This compound from 3 to 10 per cent. of caoutchouc and some sheet should be mixed; after which the mass is heated again one hours at the same temperature as before, and finally from 2 per cent. of sulphur is added. The composition is then cast ouide and worked up the same as India-rubber. By slightly varying the proportion of the three ats of which the substance is chiefly composed, its character may be modified in various ways dong to the practical purposes for which it is required.

Engineering and Mining Journal 1880

New Submarine Cable.

New Submarine Cable.—The cable made at the factory of Berthoud, Borel et Cie, Cortaillod, Switzerland, has a single conductor, composed of a strand of 7 copper wires. The diameter of the strand of the cable is in the insulating material used. The copper conductor is surrounded by three layers of cotton tape, so soon as the weaving of the cotton covering is finished the wire is immersed for an hour in a bath of paraffin, at a temperature of 180° C. Thus all moisture is expelled from the cotton, which then absorbs the melted paraffin. The cable is then passed through a powerful press, which covers it with a leaden tube, the smoothness between the cable and the tube being hermetically filled with caoutchouc (a resin).

Thus the insulating envelope consists of cotton boiled in paraffin and of caoutchouc. Experiments made by Messrs. Schmeckebier and Zeiler, of the polytechnic school at Zurich, show that the cable possesses very considerable electrical advantages over those insulated by other methods.

Engineer Nov 26 1880

It is announced, says the Geneva correspondent of the Times, that the electric cable constructed by Messrs. Berthoud Borel and Co., of Cortaillod in Neuchâtel, have made a highly important discovery in practical telegraphy. After a long and expensive series of experiments they have succeeded in devising a method of laying cables whereby the inductance of the electric current is entirely overcome, and thus the speed of signalling may be increased. This discovery, it is asserted, removes the last obstacle in the way of the widest possible extension of facilities for telegraphic communication. Post 29 Nov 1880

803,—Covering Wire with Insulating Material.

No. 1 J. G. L. Lemiler, London. (1d).—The object of the invention is to provide a covering for electric wires which shall be strong in the direction of the length of the wire, and which is a non-conductor of glue or gelatine is applied to the wire, and a covering of paper is then applied to the wire, which is coated with a solution of gelatine, or such glue or gelatine as may be required, the superfluous glue or gelatine being removed by passing the wire through a gauge. (Dated 1, 1880. Not proceeded with.) Complete specification not supplied to the questioned.

1,886.—Insulating Material for Insulating Electrical Conductors. C. D. de Allen, London. (4. Revised ed *J. L. Knox, Brooklyn, New York.* [Ed. T'rpr].—Consists in making electrical conductors, more especially such as are employed in submarine cables, of a core or centre composed of a fibrous material, as hemp, or of several strands, with a waterproof coating or covering of Trinidad or other natural asphaltes, mixed with resin, drying and softening material, such as paraffine oil, petroleum

Engineering Jan 21 1881

1886

residuum, &c. The properties of native bitumen and asphaltic material depend upon the nature and character of the bitumen and the extent to which the constituent oils have been driven off. A material found to answer well is a mixture of 50 parts of Trinidad asphaltum mixed with 50 parts of petroleum residuum. The ingredients are melted over coals with a continuous covering of thread-like material applied in any convenient manner to the conductor, which is then passed through the mixture, by means of a suitable arrangement of material kept by rest in a liquid condition. In covering a cable between conductors, the core may be covered with hemp, or other fibrous material, and the conductors, or strands, or core, previously covered with the compound, as above, or the core may be covered with the compound, as above.

THE INDIA RUBBER AND GUTTA PERCHA INDUSTRIES.

BY THOMAS HOLMS, F.C.S.

(CONTINUED FROM PAGE 305, VOL. V.)

LECTURE VI.—DELIVERED MARCH 8, 1880.

Gutta percha. Sources. Chemical nature and physical properties. Applications in connection with the industrial arts. Vulcanisation of gutta percha.

Gutta percha is quite secondary to india rubber as regards the number of its industrial uses, but there are cases in which it could be used if replaced by india rubber. It differs from rubber, principally in being more readily softened by heat, in being far less porous, and in lacking that ready extensibility by tension which is especially characteristic of caoutchouc.

The *Isonandra gutta*, a fine tree, which often grows to a height of over 80 feet, and whose stem attains a diameter of three feet or more, is the principal source of the milky juice or sap which, when inspissated, forms the gutta percha of commerce. The *Isonandra gutta* flourishes notably in Singapore, the eastern part of Sumatra, Borneo, and Java. The lantern slide now projected on the screen (Fig. 31), will serve to illustrate to you the appearance of the foliage, flower, and fruit of the tree in question; and next I will show you a slide which represents the operation of collecting the juice or sap (Fig. 32).

The *Isonandra acuminata*, also an East Indian tree, yields some gutta percha; while the *Dejoda walkeri*, or South American bully tree, has of late years afforded a considerable supply of an excellent quality of gutta percha, which passes under the name of "balata."

Gutta percha appears to have been first introduced into this country by Dr. W. Montgomerie, who, in April, 1843, presented some of the raw material, and also a riding-whip made of it, to the Royal Asiatic Society. Some months afterwards, Dr. Montgomerie presented some of the material to this Society, and a man immediately took steps to prove its applicability to various industrial purposes; and the foundation of the gutta percha industry may be said to date to him.

The operation of collecting the sap of the gutta percha trees (Fig. 32) is not very different from the corresponding operation with the juice of the rubber trees. But as the gutta percha juice concreting sap into rough balls or cylinders.

On the table you will find a very interesting collection of samples of raw gutta, some of which are roughly moulded into

THE FOLIAGE, FLOWER, AND FRUIT OF THE ISONANDRA GUTTA.

representations of animals, while others are of interest as enclosing stones, lumps of wood, and other adulterating materials. For the greater part of them I am indebted to the Gutta Percha Company of London.

The essential ingredient of gutta percha is white, and appears to be identical, as regards ultimate composition, with caoutchouc. Faraday gives the following figures as the result of analyses of these bodies:—

	Gutta percha.	India rubber.
Carbon	87·3	87·5
Hydrogen	12·8	12·5
	100·0	100·0

The purification of gutta percha can be readily effected by dissolving the crude material in carbon disulphide, and after filtration, evaporating the solution. Here is some carbon disulphide, and just see how readily these parings of raw gutta dissolve in it. Let us now filter the solution, and pour some on this levelled glass plate. The solvent will soon evaporate and leave a skin or film of gutta percha. Here is such a skin, or sheet of gutta percha, which is now ready to be stripped from another plate, as the solution was poured on this glass about an hour ago. You see that it is nearly white, and when softened by heat it becomes most perfectly plastic. The method of purifying gutta percha just demonstrated was proposed by Parkes, as the foundation of an industrial process for refining gutta percha; but mechanical purifying methods have been generally adopted on a larger scale.

Purified gutta percha as now shows consists of three constituents. The most important is pure gutta, or the plastic principle; and this forms about four-fifths of the whole. Its chemical composition corresponds nearly with the formula $C_{10}H_{16}O$. Albane is valueless in gutta percha, and corresponds in composition to the formula $C_6H_{10}O$. Albane is soluble in hot alcohol, and consists, like the body which is to be next alluded to, a product of oxidation or decay. The third constituent of the purified gutta is called fluavile, and forms a yellow oxidised resin which is soluble in cold alcohol, and has a composition which may be said to correspond with the formula $(C_{10}H_{16})_2O$. It is often present to the extent of 4 to 5 per cent. in gutta percha of good quality; while the amount of albane contained in good commercial gutta often reaches 20 or 25 per cent.

Like caoutchouc, gutta percha is attacked by ozone with great energy, and when exposed to the ordinary conditions of the atmosphere it becomes oxidised and brittle with so much rapidity that old articles made of gutta percha are usually brittle and useless. Most liquids which dissolve caoutchouc also dissolve gutta percha; but in the case of the gutta there can be little doubt that true solutions, rather than starch-like magmas, are formed.

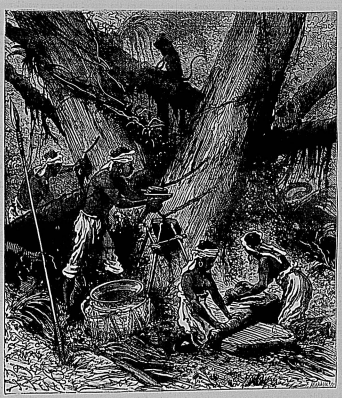
Gutta percha resists the action of alkaline liquids and of dilute acids, but strong and slightly warm sulphuric acid clears it readily, while concentrated nitric acid converts it into a yellow resinous body. Like caoutchouc, gutta percha is an admirable electrical insulator, and also a very useful non-conductor of heat.

When submerged in water, or in any way protected from the action of air and light, gutta percha has little or no tendency to change; while, on the other hand, constant exposure to light, together with alternating conditions of dryness and dampness, is

A temperature of 50 deg. Centigrade serves to soften gutta percha to such an extent that it may be easily moulded into any required form; while at 100 deg. Centigrade, it becomes adhesive and pasty; and at 120 deg. it may be said to fairly melt. The products of the dry distillation of gutta percha are generally similar to those obtained by the distillation of caoutchouc.

In the next place, let me very briefly call your attention to the methods employed for effecting the purification of gutta percha on an industrial scale, those being, in the main, due to Charles Hancock.

The first operation is to chop up the crude gutta into slices o



COLLECTION OF THE JUICE OF THE ISONANDRA GUTTA.

sharings, by means of knives or cutters attached to the face of a revolving wheel. These knives are now often made with saw-like edges, each tooth being sharpened like a lancet; and it is found that the effect of this modification is to reduce the gutta into small fragments, like raspings. The finely-divided gutta is next soaked and boiled in water, in order that particles of earthy matter may sink, while the gutta floats. During this process many particles of woody matter become so far soaked with water as to disengage themselves from the gutta and to sink, while any soluble impurities naturally become pretty thoroughly removed.

45 CANTOR LECTURES.*

THE INDIA RUBBER AND GUTTA PERCHA INDUSTRIES.

BY THOMAS BOLAS, F.C.S.

LECTURE V. DELIVERED FEBRUARY 20, 1880.

(CONTINUED FROM PAGE 293.)

The property of ebonite just illustrated may have a practical application in this way. It is often desirable to obtain suitably a reversed reproduction of a printing block, and this may be done in the following manner:—Make a mould in fusible metal of sheet of ebonite, this being slightly warmed, so as to obtain a sunk impression; and the ebonite plate is next placed off hand or rubbed down by an abrading material, after which it is exposed to a heat of about 140 deg. Centigrade. The compressed lines now rise up and form a printing block, which is an exact reproduction of the original, only it is left-handed or reversed, and to do it for printing it is only necessary to deepen the widely-extended whites by means of the ordinary wood engraver's tools.

Ebonite forms very good printing blocks or stereotypes, there being made just as in the case of the soft rubber stamps (p. 787).

You see before you this evening a very fine collection of articles manufactured from ebonite, these not only serving to illustrate the manifold uses to which this material is applied in connection with the industrial arts, but also to exemplify the variations which may be produced in the material itself; as regards hardness and elasticity, by varying the composition of the original mixture in accordance with the principles already explained. In the case of specimens lent by the Silvertown Company you see a number of small articles of exquisite finish, and you will not fail to notice the colloquial thimble, the pen holders, &c. Messrs. Gow and Co. have lent me two extremely fine specimens of vulcanite work, one being a wheel-and-rounded pinblock shallow chuck, supported by turned columns of the same material, and the other being an inlaid stick, built up of a kind of mosaic, formed out of variously coloured pieces of vulcanite, and you will notice that some of the specimens are nearly white. The conditions under which nearly white and coloured vulcanite can be obtained will be explained further on. Mr. Falkenstein, of the Britannia Rubber and Manufacturing Company, has brought me some admirable specimens. You will notice the thin ebonite sheet, almost like paper, which this firm manufactures, and also the extensive selection of fancy and ornamental articles, these being, for the most part, made after Mr. Falkenstein's own designs. Here is a reproduction of a medal, which has been moulded in vulcanite by Messrs. Mackintosh, of Manchester.

Ebonite works very much like horn or ivory, and can be very readily turned at the lathe, but a high rate of speed is required. A finish can be given to the articles by the use of fine-glass paper, followed by the 000 emery paper used by watchmakers, after which a fine polish can be rapidly given by the arrangement to be described. A number of small pieces of ebonite, such are chessmen, draughtsmen, &c., are finished on a spindle, and this is made to revolve at a very high rate of speed—my about 4,000 revolutions per minute. This polisher being slightly charged with fine brick-dust and water, oil, or powdered pumice, the articles are polished and finished in a few seconds, when they soon receive a high degree of polish. Rotton-stone may also be used on a polisher of this kind; and one considerable advantage attending the use of the polishing apparatus is that in the case with which the ordinary charged with tripoli or rottenstone.

Many metals, especially iron, may be imbedded in soft ebonite and fixed very readily by vulcanisation; and advantages is taken of this circumstance in many cases. Thus, the handles of steel and iron screws may be first advantageously clothed with ebonite, in manner. Again inlaid rubber rollers are usually fixed on to their iron spindles by means of a layer of soft rubber serving as a cement; the ebonite and the soft rubber adhering perfectly, while the somewhat hard rubber fits the iron, especially if the metal is previously tinned before the application of the soft material.

To give anything like a list of the applications of ebonite to the industrial arts would be impracticable, but its more important uses are illustrated by the specimens before you. The characteristic properties on which its usefulness principally depends are its hardness, elasticity, electrical non-conductivity, freedom from porosity, and its inertness towards most chemical products.

Vulcanite may be obtained in a coloured form by incorporating with it a large proportion of certain pigments, such as nitre, marine, vermilion, sulphide of cadmium, sulphide of antimony, or oxide of chromium; while, if it is required in as nearly possible a white state, oxide of zinc and sulphide of zinc may be used. When these pigments are incorporated there is not the same necessity for pushing the vulcanisation to such extremes as when rubber and sulphur alone are employed, as the pigments themselves given a certain degree of hardness. In such cases the proportion of sulphur in relation to the rubber, may be very much reduced, and it is generally sufficient to carry on the curing to a point between the third and fourth stages, as already defined. At this point the rubber has a brownish or dark olive green colour, but the presence of a large proportion of pigment serves to mask this.

Dental rubber, the material used for setting and mounting artificial teeth, consists of a highly pigmented vulcanite, made to imitate the natural colour of the gums. There are on the table some very fine samples of the material in question, and for a position of them I am indebted to Mr. Sangster, the representative of the *New York and Hamburg India Rubber Company.*

Dental rubber forms a very convenient material for the making of various small articles, and is may be readily cured to the small vulcanisers which were shown you on the occasion of the third lecture. (Figs. 26, 27, and 27, p. 299.) When it is desired to have a dental rubber which can be rapidly cured, the following composition will serve:—

Washed Borneo rubber	25
Vermilion containing 25 per cent. of free sulphur	30
Powdered sulphur	5
Sulphide of zinc	30
Sulphate of strontium	20
	100

It is, however, better if colour and quickness of curing are not very primary objects, to approximate more nearly to the composition of ordinary ebonite. As for example :—

Rubber	45
Vermillion, as above	30
Sulphur	15
Sulphate of strontium	10
	100

A small portion of fine gutta percha may be incorporated with the material for dental rubber, the result being advantageous in many cases; and also it is sometimes desirable to use asbestos for ordinary ebonite.

The tensile and heat of ebonite may be compressed in hot moulds, so as to form buttons or other small articles, or these residual products may be mixed with new rubber and subjected to form a second quality of ebonite.

When ordinary vulcanised rubber is heated to 230 deg. Centigrade, or until it melts, a permanently viscous product is obtained, and this substance, if mixed with emery and sulphur to a kind of paste, forms a material out of which the so-called application emery wheels or grinders may be made, these materials being next hardened or cured by the application of steam heat. Emery wheels and bones upon this principle were introduced by Deplanque, about 23 years ago.

Thirty-five parts of old vulcanised caoutchouc having been placed in a kind of still, heat is applied to the mass, the operation being assisted by the gradual addition of about ten parts of heavy coal oil; but this latter is often objectionable, and a reduced caoutchouc is then incorporated with 200 parts of emery of the required degree of fineness, and nine parts of sulphur. These materials having been thoroughly mixed, the hones or wheels are manufactured, and afterwards cured or baked at a heat of 140 deg. Centigrade, during a period of about eight hours. Grinding wheels, made in the above manner, can be worked at a speed of 2,000 revolutions per minute, and are extremely useful for the working of hardened steel or other elaborate manufactures. Some of the wheels, and also some knife sharpeners, are now on the table before you.

The substances for inlaid rubber are of comparatively little importance in relation to caoutchouc itself. Celluloid, however, is occasionally used in the making of flexible tubes for feeding gas or for surgical purposes; indeed, I should refer you, for instances, to the small articles after they have been built up of fibrous material. Such tubes, of which several specimens are before you, are far inferior to rubber tubes in most cases, and are formed by repeatedly varnishing the fibrous hose with a mineral-oil-prepared linseed oil varnish.

Vulcanised oil is, perhaps, of more interest, and many oils, such as linseed and others resembling it, may be vulcanised by being heated for some time to 120 deg. Centigrade with 12 to 20 per cent. of sulphur. The product obtained is soft, and somewhat resembles very bad India rubber. By increasing the proportion of sulphur very much indeed, say to four times the weight of the oil, and vulcanising at a higher temperature, a hard substance, resembling inferior vulcanite, is obtained.

Soft and hard vulcanised oil have been introduced into commerce at various times and under many names, but these materials never seem to have made very much headway.

Various products, having properties or suitable application as their basis, have been introduced as substitutes for hardened caoutchouc. Parkesine, a substance made by incorporating pyroxyline and linseed oil, forms a material well fitted for the manufacture of knife handles or similar articles, and I will now hand round a very beautiful specimen, which is well worthy of your notice.

The substance now known as celluloid, which consists essentially of pyroxyline and camphor, appears, however, to have characteristic properties which will enable it to fulfil certain purposes for which vulcanite is ill-adapted.

A solution, containing about equal parts of camphor and tetrachloride of carbon, preserves or softens pyroxyline very readily, and if such a solution is incorporated with a sufficient proportion of the soluble nitro-cellulose, a dough-like mass is obtained, which hardens on the evaporation of the tetrachloride by means of alcohol, and forming the product into sheets. This substance is exceedingly tough, while it has the advantage of being free from exudation, and is capable of resisting the action of heat to a considerable extent.

Celluloid and analogous products have the disadvantage of being very inflammable, and instances have been known of these bodies igniting by spontaneous combustion.

Bottons, combs, billiard balls, and other similar articles are made of celluloid, the soft material being usually forced in iron or steel moulds. More wonderfully perfect stereotypes may also be made of the material in question. Celluloid is also coming much into use for making artificial gums or bases for teeth.

THE ELECTRIC RESISTANCE OF GLASS.*

Mr. Thomas Gray, Demonstrator of Physics and Instructor in Telegraphy at the Imperial Engineering College of Yedo, Japan, has made a series of careful experiments on the electric resistance of glass at different temperatures, with a view of finding whether the variation of resistance with temperature followed a law sufficiently definite to allow the resistance at low temperatures of highly insulating glass to be approximately calculated from its resistance at higher temperatures. The chief object was to use the law of with results obtained by the galvanometric method of measuring the resistance, for the comparison of specific resistance of different kinds of glass.

Published observations on the resistance of substances, such as glass, porcelain, marble, slate, coke, &c., as well as experiments on good conductors, have generally led him to express the law of variation of resistance with temperature by an equation of the form

$$R = \frac{1}{a + bt + ct^2}$$

where R is the resistance at the temperature t, and the constants a, b, and c are quantities depending on the material. The fact of opinion that some such law as this will be found to hold good in all dielectrics when the effects of the permanent changes produced in the glass by heating are eliminated. These changes are, however, of considerable magnitude in the case of glass, so that it is to them especially he especially calls attention in the paper we quote from, which appeared in the *Philosophical Magazine* for October.

With the exception of one experiment, in which a Thomson quadrant electrometer jar was used, the results were obtained from ordinary glass test tubes which had lain in store for years at the College. The resistances were measured by direct deflection of the needle of a Thomson reflecting galvanometer, produced by the current through the glass. The battery used was composed of ten Daniell cells; but a low temperature a battery of fifty Daniell cells was sometimes employed. Mr. Gray was thus able to measure a resistance equal to 5 × 10⁹ ohms per cubic centimetre in his test tube experiments, and equal to 16 × 10¹² in the electrometer jar experiments. The test tube glass had a greater resistance considerably below the temperature of boiling water, than the electrometer jar reached the latter fluid at a temperature of about 100° C.

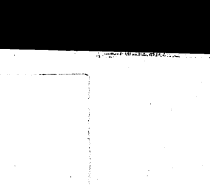
One advantage in these experiments of using this galvanometric method of measuring the resistances, rather than the method with electrometer and condenser of great capacity, was the case with which the temperature and resistance could be simultaneously observed.

In determining the resistances two methods of observation were employed. One consisted in passing the current through the glass first in one direction and then in the opposite direction, and taking the deflection in each case half a minute after the battery had been applied. The mean of these deflections was then taken as the deflection corresponding to the resistance to be measured; and the mean of the temperature was taken as the temperatures of that particular determination.

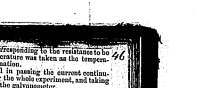
The second method consisted in passing the current continuously through the glass during the whole experiment, and taking deflections by short circuiting the galvanometer.

The first method gives the resistance before any very great amount of polarisation has taken place, at least before more than is proper to that temperature has taken place. The second method gives during the heating pretty nearly what is believed by some to be true resistance, but it also shows whether more or less polarisation takes place when the temperature is high than when it is low. It therefore gives some indication of the effect of the current flowing constantly through the glass while its temperature is being changed.

The results which Mr. Gray has obtained agree with the well-known result that the resistance of a piece of glass diminishes as the temperature is raised; but they also show that the resistance varies more slowly when the glass is cooling than when it is being heated, and that a piece of glass may have its resistance greatly increased by being slowly raised to a high temperature and slowly cooled. There seems, therefore, to be what may be called a permanent change in the quality of the glass, which takes place coincidently with a quasi-elastic change in the quality; and a comparison of the results obtained when the glass was cooling with those obtained when it was being heated, showed that some such opposition as that which has been stated above probably expresses this latter change. Whether the former change is really permanent or not (that is, whether the glass retains this increase of specific resistance at low temperatures) Mr. Gray is not yet in a position to say with certainty; but from observations which he has made Mr. Gray is inclined to think that slow changes take place in glass, tending to raise its conductivity and also its specific inductive capacity. He is not aware that any considerable deterioration in the insulating power of glass stems and electrometer jars has been detected; but in such cases the experiments start to at least a temporary cure, namely, *heating the glass at a high temperature for a considerable time.* This accords with the treatment sometimes adopted for badly-insulating ebonite.



1859.* Insulators: G. Wells, London, and A. Gibbons, Worcester Park, Surrey, &c. 2 Fig.—Our object is to secure telegraph wire, so that in the event of its being broken by any accident, it shall not fall to the ground. In the ordinary mode of fixing the wire round the insulator has hitherto had to be wound in a screw bolt *d*. The wire after being severed, is held in the groove *g* for its reception in the porcelain and the cap *c*, which has a corresponding groove, is placed thereon, and the bolt *d* screwed down, thus holding the wire in the groove. Between the two grooves is a narrow chink. The



bolt *d* is not to allow of the wire being really unplaced or removed. (April 13, 1860.

Mowbay, Rammond Simons, and Co., Cortaillod, Switzerland, write with regard to the recently announced discovery of a way of laying cables whereby the induction of electric current from one wire to another, although the wires are in juxtaposition, is prevented, and say that the fact is that it is not by laying cables in more difficult positions that we can overcome the difficulty of induction, but by the means which we have employed. We may be gratified to hear of such efforts to lower telegraphic rates made with some of the best telephonic appointed provided, and able to be facilitous as regards industries; as that, several conducting yet into one cable, some of them may be used for telephonic and the others for telephonic purposes at the same time without any disturbance whatever in one of the lines.

FIRM CAUGHT BY AN ELECTRIC BATTERY.

From the Tilbotts Herald, Aug. 9, 1871

Shortly after 5 o'clock last evening the cry of fire was heard on Spitalfields street, and as usual the different hose companies responded to the alarm, running to the old Exchange. Another item, that last their hose and were ready for business, but fortunately their services were not required, for the flames had been already extinguished by a few pails of water, which was all that was necessary to do so. An examination of the premises showed that in the battery room of the West. Union Telegraph Company's office, on the second floor, the fire started, and, strange to say, the origin of fires never occurred. The room is about 10 by 12 feet, and when the alarm was given it was filled with dense smoke, so much so that it was impossible to enter the room without the use of water. Upon entering the room it was found that the fire originated in the battery, and from there had communicated to the woodwork of the room, and the entire ceiling was on fire. The battery used here came from Worcester, and the only possible explanation of the fire is that the battery had become heated by a defect in the battery, which is the wonder is that more serious damage did not occur from the alarm of the fire was not discovered by one of the office boys, and by the prompt use of the water from the pails and a few pails of water the fire was extinguished. Much credit is due the office boys for their prompt action in thus saving the wires and apparatus from destruction.

APPARATUS FOR MAKING INSULATED TELEGRAPH WIRES.

The interesting apparatus for the manufacture of insulated telegraph wires, which we herewith illustrate, is the invention of Mr. Thomas J. Nygall, Reading, Mass. Without going into wearisome detail, its object and method of operation may be briefly described as follows: The strips of rubber and graphite compound are wound each on a separate drum, with a layer of muslin between the layers, to prevent sticking. From these drums the two layers are led to a pair of pressure-rollers, where they meet and inclose between them a number of wires that are drawn off from a series of reels. The two strips and the wires inclosed are pressed by the rollers into a compact band, which passes out between cutting-rollers, which trim off its edges, then through a box of powdered talc, and to a receiving roller, whereon it is wound with an interposed layer of tin-foil. An automatic mechanism stops the machine when a wire breaks.

The main features of the apparatus are, a supporting frame, driving-pulley, shaft and gears, pressure-rollers, spools, guide-bar, and guide-rollers for the wire, trimming-roll and cutters, box for powdered talc, and condensing-rolls, with levers, weights, and arms, and automatic arrangement for stopping the movement.

The Electric Light Wires.

TO THE EDITOR OF THE SUN.—SIR: In an article entitled "Fun in my Electric Light Wires" published to-day, I notice that City Electricians Smith has made some very remarkable discoveries relating to the action of electric light currents. The current under his manipulation seems endowed with many novel and wonderful powers. He makes telephone tremble that we had supposed to be quiescent, and he has found that a telephone wire, when not in use, is a receptacle of electricity, and will receive and transmit it to the end of the line. Indeed, he has found that the electricity will pass from one wire to another, and that a current will flow in a reverse direction to that which is passing through the wire. The first and only point at which the insulating covering of the wire is destroyed is at the dynamo engine, where, after the light itself is created, and then and then only can the current be properly utilized and the forces of the current allowed to act.

Electric Light Wires in Underground.

Mr. Thomas A. Edison addressed a letter recently to the New York Board of Water Commissioners, which he wrote:

"I have now that the system of electric lighting of the Edison Electric Light Company is absolutely free from any possible destruction from the operation of the Gas Company, Water Company, Steam Heating Company, or the Fire Department, unless something should occur to destroy all the buildings covered by the mains, and even in such a case the wires would be found in good order after the ruins had been cleared away. From the nature of the system it is impossible for the wires to become crossed with other wires, or to be in contact with gas, water, or steam pipes, or with the earth, and consequently serious accidents cannot occur."

Evening Mail, May 6. 1871.

LIGHT VS. DEATH.

ALLEGED INJURIES ARISING FROM THE USE OF ELECTRIC LIGHTS—THE EDISON INSULATED SYSTEM—ALL CAUSE OF APPREHENSION DISPELLED.

An article which appeared in last evening's *Post* and another which was published in the *Sun* of to-day, bearing upon the alleged perils of running the wires of electric light over houses, have produced a decidedly unfavorable impression, especially as the Board of Underwriters have considered the matter and have decided to rate all buildings into which the electric wires are run as extra hazardous, and have further decided to require the proper authorities to see that the electric wires are properly insulated.

This is understood to refer to the wires of the electric insulated conductors (subscribed for by the Fire Department) of the Edison Electric Light Company, and satisfactorily tested as to their perfect insulation. Under these circumstances, all of whom interested in the matter are applied to their wires. In conversation upon the subject the following information was had of the manner in which the wires are constructed and the precautions which are taken to prevent accidents to the operators.

"In the first place," said one of Mr. Edison's electricians, "our wires themselves are thoroughly insulated, being completely covered with a rubber coating, and then they are laid in pipes which are subjected to the constant passage through the circuit, which, should there be any more than the ordinary force of current, would open and prevent any such damage as is said to have taken place in the case already published. Another thing of great importance is the manner in which we connect instead of running our wires over the tops of houses or on poles, as our contemporary complains about, therefore we are enabled to run to lay our wires under ground next to the curb, and then connect with the houses by means of insulated rubber, and, bordering silently through the eaves of the house, to the electric current, thus causing the double covering of the wires themselves to any means should become broken or otherwise injured.

In front of the building the wires into which the current is to be conducted there will be a junction box, by means of which another and smaller tube, also thoroughly insulated on the inside, will be connected with the main tube, through which the branch wires will be conducted, into the building. You must bear

"If running our electric light wires through the air may be required in the vicinity of any inhabited street may be required in the vicinity of any inhabited street may be required in the vicinity of any inhabited street

DANGER FROM ELECTRIC LIGHT WIRES.

The best means for the distribution of powerful electrical currents is a question of constantly increasing importance. The numerous accidents which have occurred have naturally drawn the attention of all interested persons to the matter, and given rise to the query, how far such currents are likely to cause fires. The burning of the Randolph Mills, in Philadelphia, which doubtless was caused by sparks from the electric lamps falling upon combustible material, has directed attention to another cause of danger, and one which must be speedily remedied if the electric light is to find any employment in interior lighting.

While it is very important to fully realize all possible sources of danger, and to take every means to avoid accidents, it is unwise to magnify the evil, and circulate reports and statements which are not in strict accordance with facts.

We have noticed many statements in print, in which the writers seemed to have no knowledge of the difference in properties between frictional and dynamical electricity.

It certainly is very essential that wires conveying these strong currents should be properly insulated; and we hope the time will soon come when wires for electric lighting, telegraphic, and other similar purposes, shall be placed under ground.

The wires employed in distributing the current for the arc lights in this city are of such size that there is no heating effect produced, and consequently no fire could occur from the simple contact of these wires with combustible material. When the wire is too small for the current it becomes heated, and, under certain circumstances, would become incandescent.

If a wire conveying a strong current should come in contact with a smaller wire, as those employed in constructing telephone lines, the latter would become greatly heated, and produce serious results. This has happened in this city several times, and some instances has caused considerable damage. This heating effect would also be produced in case the larger wire should be nearly severed, thereby diminishing its power to convey the current.

At the recent meeting of the National Association of Fire Engineers, at Richmond, the following resolutions were passed, relating to the construction of lines of wire, for electric lighting: "First—That the wires shall be distinct from all others, and protected in such a manner that firemen can recognize them at all times. Second—That they shall be thoroughly insulated. Third—That there shall be, upon the exterior of all buildings where the wires are introduced, an absolute cut-out (not to be shunt), so that, in case the firemen are called upon by cause of fire to enter there, the danger of instant death—the inevitable result sometimes of coming in contact with improperly insulated or broken wires—may be in a great measure avoided."

Electrical machines, with alternating currents, especially when of high electro-motive force, are very liable to give shocks producing death; but in the case of machines with continuous currents there is less danger of so serious results.

Engineering Jan 5, 1884

Electric Resistance of Insulators.

M. Foussereau, who recently devised the method of measuring high resistances of insulators by the time necessary to charge a condenser through them to a given difference of potential has applied the method to determining the resistance of different insulators, and his results were communicated to the last meeting of the French Academy of Sciences by M. Jamin. The resistance of porcelain is then found to be 781 million megohms at 60 deg. Cent., and 0.602 million megohms at 160 deg. Cent. per cubic centimetre. Were a cross of resistance at different temperatures thus prepared a useful pyrometer might be the result. Sulphur gave a resistance of 7.39 million megohms at 142.1 deg. Cent.; and 2030 million megohms at 49 deg. Cent. per cubic centimetre of substance. Below the last temperature its conductivity ceases to be measurable. Left to itself the sulphur takes a vitreous texture on cooling, and on cooling to an average temperature of say 17 deg. Cent. the resistance becomes 1170 million megohms after one day, and 766 million megohms after two days. An octahedral crystal of sulphur at ordinary temperature gave no sign of conductivity; but at 80 deg. Cent. conductivity begins to appear. Crystallization, therefore, seems to render sulphur more insulating. A fact which is worth bearing in mind. In passing to the liquid state sulphur becomes at once four times more conducting. Ordinary phosphorus has a resistance much lower than the above substances. Solid phosphorus has a resistance of 84,000 megohms at 15 deg. Cent. per cubic centimetre, and 15,000 megohms at 42 deg. Cent. This great fall materializes it to sulphur. The specific resistance of liquid phosphorus is 2.30 megohms at 25 deg. Cent. and 0.34 megohms at 100 deg. Cent.

Electric Resistance of Glass.

Messrs. T. Gray, A. Gray, and J. J. Dobbie, of Glasgow University, have been investigating the electrical resistance of various kinds of flint glass, as made by different makers. The object was to find out the relations existing between the resistance and the chemical constitution of the glass. The experiments made by immersing flasks of the glass in mercury and filling up the interior with mercury. The resistance was measured electrodes to convey the current through the glass cells through the glass, and the resistance measured by a bath, resistance=resistance of the glass increased with the percentage of lead in the glass, and also with the temperature. Not disdeleted as the percentage of alkali in the glass increased. The best specimen tried contained 54.46 per cent. of lead oxide, and had a density of 3.713. Its resistance, at a temperature of 15deg; Cent. was 4,000,000 ohms between two opposite faces of a centimetre cube. The experiments show that the resistance of glass is reduced by an increase of about 8deg; Cent. This may be taken for a considerable range of temperature, but for approximate resistance of glass of a certain composition may be estimated. In taking the temperature observations, the glass flasks were heated by means of a sand bath.

Underground Conductors for Electric Lighting.

The Brush Electric Company in Philadelphia, made a thorough trial with buried conductors in the portion of the circuit lighting Delaware Avenue. The circuit proved unsatisfactory, and in time became open. On examination it was found that the wires had become attenuated in parts, as if subjected to electrolysis, and even wasted entirely away in places. The sand around these wires had become at intervals fused into short rods a few inches in length, similar to the fulgurites produced when a thunderbolt strikes dry sand. Gas from the street mains leaked into the conduit around a short underground system on Chestnut-street and produced a violent explosion. Whether any are formed at a poor contact was the cause, or whether it was produced by some other means, will probably never be known.

Terrestrial Magnetism in Russia.

General de Tillo has completed his researches on the intensity and distribution of terrestrial magnetism in Russia. He finds that the secular variation of the intensity is a function of the latitude and longitude of the place, and has compiled tables showing how much the horizontal intensity varies annually with the latitude and longitude. The annual variation of total intensity is always the same for latitudes from 30 deg. to 80 deg. N. on the meridian of 29 deg. E. from Greenwich; but it is different for different longitudes, diminishing as the longitude increases. Thus:

Annual Variations of Total Intensity.

Longitude E. of Greenwich. deg. deg.	
15 — 30	+ 0.0015
30 — 45	+ 0.0010
45 — 60	+ 0.0005
60 — 75	+ 0.0000

Recrushing Copper Matte.

We recently reproduced some information from the *Engineering and Mining Journal*, concerning the successful starting of a Manhès plant at Butte City, Montana. It was stated that the creation and starting of this plant were carried out by a Mr. E. D. Peters, but it now appears that this was a mistake made by the *Engineering and Mining Journal*, and that the work was really done by three French gentlemen who came over from France specially for the purpose, and who, apparently, represented the "Société anonyme de Metallurgie du Cuivre," which company we infer to be the proprietors of the patents connected with Manhès' process. As this is, so far as we are aware, the first instance of the adoption of the process out of France, the facts connected with it are of considerable interest and importance. It is also now stated that the matte which was so successfully converted into copper of 98.9 per cent. pure copper, assayed 63 per cent.

The New York Elevated Railroads.

The elevated railroads in New York present greater advantages for the use of electricity as a motive power than any other combined, and the company has approached the question in a manner as cool, energetic and businesslike. The representatives of the company in electric matters owned by Edison, Field, Daft, Brush, and Siemens, are to form a company of 1,000,000 dols. capital. Half of this amount is to be paid to the patentees in accordance with a valuation ascend by a Board, consisting of Sir William Thomson; George B. Roberts, ecting of Sir William Thomson; George B. Roberts, President of the Pennsylvania Railroad; J. H. Ralfer, President of the New York Central and Hudson River Railroad; Robert Harris, President of the Northern Pacific Railroad; and Professor Charles R. Cross, of the Institute of Technology. Experiments are to begin at once, and a third rail, weighing about 60 lb. to the yard, has been laid between the tracks of the Second Avenue Elevated Railroad to serve as an electrical conductor. It is expected that the Board will report early in March.

Engineering - Jan. 2, 1885.

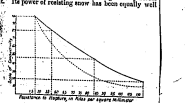
SILICIOUS BRONZE CONDUCTORS.

From time to time, articles have been published in Engineering upon the various properties of silicious bronzes. Since the subject was last mentioned in these columns, the application of wires made from this alloy has been greatly extended, while on the other hand, the method of manufacture has been considerably improved. The two types of wires employed until recently possess the following characteristics:

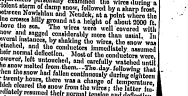
1. Telegraph wires. { Conductivity 97 per cent. Resistance to rupture, 45 kilos. per sq. mill. (28.57 tons per sq. in). Conductivity 22 per cent.

2. Telephone wires. { Resistance to rupture, 75 kilos. per sq. mill. (47.62 tons per sq. in.

Quite recently, at the request of the Eastern of France Railway Company, M. Lucien Werdin has developed a new type of telegraph wire, possessing less conductivity than the former, but having considerably higher tensile strength, which allows the wire to be more lightly suspended, so that posts may be placed at greater distances apart. This new wire has a conductivity of 30 per cent., and a tensile strength ranging from 65 kilos. to 70 kilos. per sq. mill. (41.26 tons per square inch). At the same time M. Werdin has considerably modified the characteristics of his silicious bronze telephone wire, raising the conductivity to 42 per cent., and the tensile strength to 52 kilos. (33.66 tons per square inch). He now also manufactures a special type for wire-spans with a conductivity of 24 per cent., and a tensile strength of 110 kilos. to 115 kilos. (69.84 to 85.70 tons per square inch). The annexed diagram shows graphically the different properties of these wires. By connecting the points referring to each wire with a continuous curve it will be seen how the relations of conductivity to rupture vary. The dotted lines refer to the old, and the full line to the new wires. The extensive use of silicious bronze for telegraph and telephone systems affords further experience as to its



behaviour in practice, especially as to the manner in which it resists the effects of wind and snow. The Consolidated Telephone Company has several stages in Prague, Trieste, Lemberg, Gratz, Crucovic, Cracow, Pilsen, Reichenberg, and Budin, in all of which silicious bronze is wholly used. That at Trieste has especially been subjected to the test of wind, during the frequent and violent storms known as "Bora," and which habitually levies tribute in the shape of uprooted posts and broken wires. Thanks to the small diameter of the silicious bronze conductors no damage has been sustained by them on account of these storms. A similar experience has been made at Rahon, where a very violent tempest, and where in one case the wire was subject to more than 1000 lbs. was exposed to the action of a wind blowing directly across it. No power of resisting snow has been equally well



established. Thus on the Cisalpine-Nasdale Railway, belonging to the Austrian Local Eisenbahn Gesellschaft, the engineer at the head of the telegraph department personally observed the wires during a violent storm of damp snow, followed by a sharp frost, between Newbildau and Neuhaus, at a point where the line crosses hilly ground, at a height of about 2000 ft. above the sea. The wires were well covered with snow and ragged considerably more than usual, and in several instances, by shaking the wires, the snow was detached, and the conductors immediately assumed their normal deflection. Most of the conductors were, however, left untouched, and carefully watched until the snow melted from them. The day following that when the snow had fallen continuously during eighteen or twenty hours, there was a change of temperature, which loosened the snow from the wires; the latter immediately resumed their normal location and deflection. Resistance to the effects of cold has been carefully observed on silicious bronze conductors in Hungary, Scotland, Sweden, Norway, &c. The Austrian company of local railways above mentioned has a telegraph circuit, in which the distances between the posts vary from 328 ft. to 720 ft. across flat country, but in hilly countries these distances range from 200 ft. to 1312 ft. During the last four years the Dallas General Telephone Company has employed silicious bronze wires, and spans as large as 1000 ft., without any accident having occurred. In Vienna telephone posts are frequently placed at the same distance apart, and carry as many as seventy-eight parallel wires. Those important advantages explain clearly the reason of the rapid extension in the use of silicious bronze as conductors for telegraph and telephone systems.

The Engineer - Nov. 5, 1886

HOWARD'S ELECTRIC LEAD MOULDINGS.

The accompanying engravings illustrate in section and elevation a few of the forms of simple and special mouldings, made by Mr. Charles Howard, at the Cleveland Works, Cleveland-street, Fitzroy-square, for carrying and housing electric lighting leads and wires in buildings and ships. They are all of elastic design, and are made in many sizes and of different woods, as

Fig. 1.

Fig. 3.

may be best suited to their situations in use. Figs. 1, 2, and 3 are simple mouldings, the base half of which is fixed to the wall, and is provided with a couple of grooves, in which the leads or wires are placed. The face of the moulding is fixed by a few tenon pins. Fig. 4 shows a form in which the cover-strip, forming part of the face of the moulding, is let into the bat-

Fig. 2.

Fig. 4.

strip, as seen in the section. There is, however, not much advantage in this arrangement, as pin points or heads of some kind, more or less, after all, be used, but the cover-strip on the base, with which there is the disadvantage, that with the same width of moulding the wires cannot very well be quite so far apart. Fig. 5 shows a section of a moulding for fixing round a room

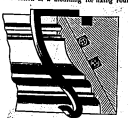


Fig. 5.

immediately below the lowest member of a cornice, if one exists. The groove along the top is made to take the end of a hook, which is of neat and good form, not quite as shown in our engraving, from which pictures may be hung, thus dispensing with picture-rods or nails, the hooks being movable in any required position.

The Engineer - Nov. 19/86

ON PERSONAL SAFETY WITH ELECTRIC CURRENTS.

By Professor A. E. DOLBEAR.

The serious accidents which have occurred within the past four or five years from the contact of persons with wires carrying strong electric currents have served to call attention to the necessity of providing safeguards against such accidents. It is probable that carelessness has been the cause of most of the accidents reported, and it is true that if weak currents only were used nobody could be hurt. It is, however, worth while to consider the conditions of illness of the human body in order to learn where danger lies. I have noted in various places the opinions of different persons as to what constitutes a safe current. In one of the old books it is stated that a spark from a Leyden jar is not dangerous, and in another place one says that a difference of potential of 600 volts is too high an electro-motive force for individual safety.

Now a difference of potential of 1000 volts will not give a jumping spark the hundredth of an inch long. The electro-motive force developed by the Holtz electric machine may be as high as 50,000 volts, and the spark from it will at most give a spasmodic jerk to the hand. The current which passes through the body depends not upon it, so that more than difference of potential must be considered in determining what is dangerous about electricity. The ability of electricity to do work of any kind, destructive physiological work as well as any other, depends upon both difference of potential and current strength, and the amount of work is proportional to the time also. Now the discharge from a Holtz machine through a short wire may give a very strong current

for example, let $E = 50{,}000$ volts, $R = 001$ ohm, then $\frac{E}{R} = 50{,}000{,}000$—fifty millions of amperes but the very short time so size of being injured, for the time of the current passage was very short, probably less than the millionth of a second. If the discharge had continued for an appreciable part of a second the wire would have been vaporized. The discharge is probably equally quick when taken by the human body, and the body can receive energy in just anything. Again, the amount that will traverse the conductor, with a given difference of potential between its ends, will vary between its extremes, and for the human body it may only roughly be calculated. The resistance of the body is very great. Many measurements, made with different individuals and with the fingers and hands, gives a resistance varying between 5000 and 50,000 ohms, and it is quite safe to assume that upon the moistened skin of the skin when under water. Mr. Preece says ordinarily dry have a high resistance; the same hands moist, perspiration or purposely wetted may lose half their resistance. Dr. Stone, of London, has made many experiments, and finds that the resistance of the body may be reduced to 500 ohms or less, by leaving the skin soaked.

If we take 1000 ohms with forty lamps the difference of potentials will be about 2000 volts. If a man with a dry, thick skin were to grasp the terminals at the dynamo, the amount that would go through his body would be $2000 \div 2 = 1$ ampere, and in one second two-tenths of a coulomb would have traversed his arms. If the same hands were soaked, the current might be $\frac{2000}{500} = 4$ amperes, or 4 coulombs per second. In the first case there would be $1 \times 2000 = 2000$ units or joules of energy equal to $2000 \div 7 = 286$ watts, or more than half a horse-power, and in the second case $2000 \times 4 = 8000$ joules, or $8000 \div 7 = 1143$ watts, or 1½ horse-power second. Now, any electro-motive force above about 1·5 volts is sufficient to decompose water, and it has been shown that the fluids of the body are better conductors of electricity than any of the tissue, even the nerves; it may fairly be inferred that such a current will such an electro-motive force might produce a notable quantity of the fluids of the body into their constituents.

To determine the highest limit of safety would require experiments which no human beings would be willing to submit to. Animals might be employed perhaps; but if 600 volts have at any time proved to be dangerous, one may set a lower limit to the resistance of the body and determine the current strength $\frac{600}{1000} = \frac{6}{10}$ amperes. That result looks threateningly large, but it is probable that the resistance of the body is rarely as low as 1000 ohms, then $\frac{600}{1000} = \frac{6}{10}$ amperes. But that represents 1123 watts—a quantity of energy no one would care to have exert in him. After all, what would be safe for one would be entirely unsafe for another, so that each individual would have his own factor of safety, or the difference of potential which he could work with, with impunity. From what we now know it would seem that 100 volts is a safe limit, and that 200 volts is not safe. One could safely have tungsten lit body for one second. But, for fear his resistance, the product of the two will give him the electro-motive force which is very feel terribly safe with. Thus, if one's resistance with wet hands is found to be 6000 ohms, then $6000 \times 1 = 600$ volts; while if his resistance was only 1000 ohms, he could only venture to touch wires having a difference of potential of $1000 \times 1 = 100$ volts. The ordinary incandescent light circuit would be on his limit.

originally intended to be an underground line; and it was actually so laid, along the side of the Baltimore & Ohio Railroad from Baltimore, as far as the viaduct over the Patapsco River—about one-fourth of the entire distance. The insulation in this case also was so imperfect that the wire failed to work satisfactorily, and the plan was abandoned in favor of the wire carried on poles.

Besides the difficulties of insulation, which were finally overcome by the successful application of gutta percha to this purpose, underground conductors have to be provided with a covering that will protect them from damage and breakage, and the insulation from destruction by chemical action or otherwise. Wooden troughs or boxes were early employed for this purpose, but were soon abandoned on account of their liability to decay, and because they afforded no protection against the attacks of rats. Pipes and tubes of various materials—such as glass, earthenware, lead, brass and iron—have also been tried both in this country and abroad. Some of these have continued in use, while others have been rejected for lack of durability, or other defect. When lead pipes, for instance, are laid in a soil in which much decayed organic matter is present, as is generally the case with soil of cities, the lead is acted upon by the carbonic acid, which converts it into carbonate of lead, causing the pipes to disintegrate and perish, and leave the wires exposed.

In England glazed earthenware pipes have been largely used where underground wires are laid, but at road crossings and other places where there is heavy traffic, or where the earthenware pipes would be liable to breakage from any cause, iron pipes have been substituted. Whenever it is possible, advantage is taken of a railway tunnel, and protection by wooden boxing, which can be readily opened for making repairs. After the pipes are laid, the wires, which for underground service are of copper and separately insulated, are carefully arranged in bundles and drawn into the pipes, in lengths of about 400 yards, by means of a coarse wire which is threaded through the pipes for this purpose as the latter are laid. The separate bundles are then carefully soldered wire by wire, and the places of junction covered with insulating material.

This plan of laying wires is attended with several inconveniences. It is difficult, in making so many soldered joints, to have them all perfect and thoroughly insulated. And when it becomes necessary to increase the number of wires in a pipe, or to withdraw and replace one that is broken or faulty, all the wires in the pipe have to be drawn out, as the dragging of a single wire over the others apart from the difficulty of threading it through, is sure to result in damage to the insulation of the wires already in. The pipes, too, are liable to occasional breakage and leakage, from which faults in the wires result, and though means of gaining access to the wires is provided at every 100 yards, the pipes have sometimes to be broken for the purpose of reaching faults and making repairs.

On account of these inconveniences the German engineers, after a trial of pipes of various materials, abandoned them all in favor of an underground cable, which was adopted by the German Government a number of years ago. The cables are made of seven wires, containing from one to seven conductors. On account of the impossibility of obtaining great lengths of copper wire entirely free from flaws and defects, each conductor is composed of several fine wires twisted together. The conductors are separately insulated by means of Chatterton's compound and gutta percha, but then bound together so as to form a single core, which, after being wrapped with tarred hemp, is incased in an outer covering of thick galvanized iron wire, twisted round in the form of a rope. The cable is then completed by a coating of asphalt, followed by a wrapping of yarn and a layer of Clark's compound. The laying of the cable is accomplished by paying it off from a reel into a trench, about one metre deep, prepared to receive it, and filled as fast as the reel with the cable is drawn over. The cable is laid in a depth averaging about five-eighths of a mile (one kilometre) in length, which, like the separate wires drawn into pipes, are united by carefully soldered joints.

In France wires have been laid for short distances, as in cities, between the main office and the exchanges, directly in a bed of asphalt, placed at a convenient depth beneath the pavement.

Dr. Schellen, whose account of the construction of the cable used in Germany has served as a guide in the description here given above, quotes from Dr. Stephan the following particulars in relation to the underground systems in that country. [*See Zietschrauppeteleks Telegraph*, p. 208.] Two hundred and twenty-one German cities, the writer states, are now connected by means of 3,400 miles of underground cable, containing 32,000 miles of wire. All the large rivers in Germany are traversed by river-cables, which number seventy in all, and have a collective length of 12,000 yards. The entire work of constructing this system was accomplished in a little less than five years, at a cost of about $7,000,000.

Experience has shown, since the underground cables have been used in Germany, that they last nearly most with accidents or interruptions; so that, apart from the convenience to the general public in getting rid of poles and wires from the thoroughfares, the underground system possesses several other advantages. It is free from many special sources of damage, such as breakage from

armored, and of sufficient tensile strength to guarantee successful wear and long service.

THE Gold and Stock Telegraph Company threatened some time ago to remove a "ticker" from the office of Ellis Morris, No. 47 Montgomery street, Jersey City. Morris obtained in the Supreme Court here a preliminary injunction restraining its removal. The company sought to have this injunction dissolved on affidavits setting forth that it had leased the "ticker" to Morris on condition that he would use it only for his own business; that he kept it in a room in Jersey City occupied only by a telegraph operator, and that from this room a private wire ran to New York. The inference from these facts was that Morris furnished to "bucket shops" in New York the stock quotations, etc., received by him in Jersey City. The company's attorney also claimed that it had a right to take the "ticker" because Morris had not paid the rent for it. Judge Van Hoesen decided that there was no legal evidence of a violation by Morris of his contract, but only a mere suspicion, on which a legal judgment could not be founded. He therefore denied the motion to dissolve the preliminary injunction on the first ground, but said he would dissolve it on the second ground unless Morris paid the overdue rent of the "ticker" within five days.

Burying the Wires.

Next January, according to Councils' mandates, the overhead telegraph wires come down. Next January, and a good many Januarys afterward, according to the telegraph men, the wires will stay exactly where they are. There is no such bitter war as that between the municipal authorities and the telegraph companies. The councilmen are merely anxious to keep their promises to perform an impossibility, while the telegraph men are equally anxious to demonstrate the axiom that an impossibility cannot be done. The telegraphers, so far, seem to have the best of the argument.

The impending conflict is the result of Councils' diligent effort to abolish the nuisance of wires overhead. They commenced it away back in 1876, when householders and business men grew vigorous in the protests they had been making for years, and as the plans developed up till 1882 an ordinance was at last put upon which it was thought would give complete and equitable remedy. The idea was to give nearly three years' notice that the wires must come down, and then enforce the law to the letter. The presumption, of course, was that, in the three years of grace allowed, underground conduits would be perfected, and the changes from above to below made practicable. Whether they have been or not is the second question which is worrying Councils and which the telegraph men are willing to argue in the negative. The city wires, which should have been given the same place in the ordinance as the others, were thoroughly omitted, and consequently the Police and Fire departments are now troubling themselves about them. If they had been instructed, Superintendent Walker says, it would be impossible to make the change as matters stand at present.

COUNTING THE COST OF THE CHANGE.

The whole subject of taking down the wires, since it has been so thoroughly discussed, has developed some phases that Councilmen thought nothing of when getting the ordinance readied. The heavy cost was wonderfully under-estimated. For the city wires alone almost the whole value of the present poles would have to be abandoned, and other telegraph companies would nearly equal loses in proportion to the amount of their material that could be re-used for service in other places. After that heavy direct loss, and then connections and fixtures and necessary changes in the approach to buildings would run up the amount to a remarkable sum. None of the present wires could be used for the conduits, and poles and cross-arms, equally useless within the limits of the prescribed by the ordinance, from 35 to 50 feet. Superintendent Walker estimated that the removal of the city telegraph property at 1,000,000, and President Henry Bentley, of the local companies, which own a large proportion of the wires, thinks that

Systems of Underground Conductors for Telegraph Lines.

BY CLAYTON C. HALL.

The many inconveniences occasioned in large and crowded cities by the mass of overhead telegraph wires, which, with their numerous poles, encumber the streets, and the hindrances which they frequently present to firemen in the discharge of their duties, have aroused the attention of the public to the necessity of some less cumbersome and dangerous plan being adopted for the overhead location of telegraphic systems. Chicago has led the way in this country in requiring telegraph wires to be placed under ground, and more recently the Legislature of New York has enacted a law bearing upon the same subject. The time is not for distant when, in all our large cities at least, underground telegraphic systems will be generally adopted.

In anticipation of this event it may not be without interest to examine some of the forms of underground conductors that have been tried and are now in use in the older countries where underground systems have been adopted.

In England and Germany, where the telegraph is conducted by the Government as a part of the Post-Office Department, there is not the same multiplication of poles and wires as in this country, where the business, being in the hands of spasmodic and competing companies, involves the construction of an ever-increasing number of parallel and duplicate lines. But even in those countries the necessity of putting the wires under ground in the cities was long ago recognized; and in Germany the wires connecting different cities are in many instances laid in the same manner.

Experiments with underground conductors were begun many years ago, and as early as 1847 the Prussian Government undertook to introduce the system on an extended scale. But the methods used for insulating the wires at that time were very imperfect, and the political disturbances of the period interfered with the work, and so the project failed of success. It was not until many years afterward that the system now in use in the German Empire was successfully established.

It is noteworthy in connection with this subject that the first telegraph wire in this country, that constructed by Professor Morse between Baltimore and Washington, was

portion. These machines require very delicate adjustments of vibration of sieve, and strength of air current.

Countering machines are now very largely used instead of the old hexagonal reels, which simply allowed the fiber to sift out through the silk meshes as it rolled, of its own weight, down the sieveling silk cover. The centrifugal machine is formed of a slowly revolving cylinder, covered with silk gauze. Within it revolves at a faster speed, in the same direction, a number of beaters, which, striking the material being dressed against the silk, evenly and speedily dressed fiber.

At the conclusion of the paper a cordial vote of thanks was accorded to Mr. Corbett, and a long and interesting discussion took place, in which Messrs. Stannard, Sexton, Bennett, Bell, Hamilton, W. Schlesinger, Muir, F. J. Bucklow, and Jones, took part. Mr. Stannard, a practical miller, spoke in favour of the roller system, and Mr. Sorsey took exception to the remarks which roller milling was making in this country, and quoted statistics to show that if as much material still were ground by milling by stones as was given to rollers the former would be the richer sum of extraction. It was also stated that the American milling papers were declaring that the stone gave better and produced it cheaper. A stone miller of the Midlands said that the stone milling was being overwhelmed by the roller milling, and he stated that it was within his knowledge that 500 sacks of flour were produced on by roller system with the same steam power which only produced 250 sacks on the stone system. Mr. Muir spoke in favour of both systems, and said that the stone milling had no advantage in producing a good character of flour, and he was in favour of roller milling.

ELECTRICAL CONDUCTORS.

At the meeting of the Institution of Civil Engineers, on December 4, Mr. Sreenford Newbould, in the chair, a paper was read on "Electrical Conductors," by W. H. Preece, C.B., F.R.S. The author stated that the first aerial conductors were made of iron wire, and the first gutta-percha-covered wires of copper, and in both the positions were soon abandoned, the one universally used for aerial conductors, and, until lately, for overland lines, Sir William Thomson determined great velocities in the working of copper, and Mattheissen detected the causes, and established a standard of purity. Such improvements have been made in the quality that copper wire was now twice as good as it was in 1858. Increased speed of working, improved efficiency of apparatus, and reduced waste of energy had followed the substitution of steel wire for copper. Tarnishing was a disturbing agent in the conductivity of the wire. Resistance increased more than 20 per cent. between winter and summer temperatures. Copper had recently been much used for aerial lines, it was less affected by wind, and had great durability. Hard-drawn wire was now produced which, while had a breaking strain of 28 tons on the square inch, was wire giving only quality, one did not appear to be influenced by the currents of electricity employed for telegraphic purposes. The conductors of all cables contained steel wires. Lightning was supposed to rather it latterly. The ultimate strength of the proposed composite conductor for electric lights was 20 tons per square inch. The size of conductors was controlled by mechanical considerations. Sir William Thomson had laid down the law that should control the size of leads for electric lighting, that the cable shall allow of electricity flowing at cost to waste. The best copper for electrical purposes came from Japan, Chili, Australia, and from Lake Superior; but until now the copper was obtained by electro-deposition, either directly from the ore, or by using impure copper cast into plates for a depositing bath. Electro-deposited copper had not the electrical conductivity of rolled copper. The electrical resistance of commercial iron was from six to seven times that of copper, and variable, due to the presence of impurities. Steel was greater. The weight of a cylindrical wire one mile long, and giving one ohm resistance at 0° fahr., was found called an ohm-mile. While the first iron wire was found to give only an ohm-mile 5,000 lbs., it was now obtained as low as 1,320 lbs., and the maximum resistance was specified at 1,760 lbs. The ordinary best publish, was specified at 1,760 lbs. Bronze used only for fencing purposes, but a very flexible conductor was supplied used for railway telegraphs and for stays; however, the resistance was very high, and in the presence of impurities.

The wire used by the Post Office was made from Swedish charcoal iron, with an ohm-mile resistance of about 1,320 lbs. Bessemer, or a specially prepared basic carbon English, Bessemer, or a specially prepared basic Government, with ores selected by the Indian 1,000 lbs. Cast-iron-silicide resistance of about about 90 lbs. Make up with a breaking-weight of Continent for telephone currents, with an ohm-mile resistance of 2,000 lbs., while in England, where speed of wires was not so important, and length of lines not so long, 1,000 lbs. was considered sufficient. The breaking-strain of 22 tons on the square inch was specified with a view to wires long spans were essential, and speed of working was not so important, the specification of 20 tons on the square inch was considered sufficient. The wires were harmonised with the percentage of pure iron, except where the percentage of manganese was high, as increase in the percentage of manganese augmented the electrical resistance considerably and then an increase in the percentage of silicon or phosphorus. The durability of iron wire was to be measured by galvanising. When the galvanised wire was to be suspended in smoky districts it was advisable to protect it by a bright coat of tin, and in those districts where the atmosphere contained sulphuretted hydrogen, this precaution was placed on simple lines, resorted to, by Siemens. Such a wire was erected in North Belfast and London and Crewe, but the result was very unsatisfactory. More recently (1883) the experiment had been repeated with a similar result. In this climate galvanisation was unsatisfactory. But it was not alone in smoky districts that iron wire decayed. It suffered much along the seashore. The salt spray decomposed the zinc coating, and the chemicals, which were washed away and left the iron exposed, and this was specially noticeable on telegraph lines. Where external decay was not evident there seemed to have no apparent effect on iron wire. Thirty-one years of incessant service in conveying currents for telegraphy had not apparently altered the molecular structure of the iron wires in the open country, as instanced by the North-Western Railway. Swedish charcoal iron was found either in blister or in rods, principally in rods. Each rod was a rolled down to about 0·25 inch in diameter, and weighed on the average about 56 lbs. Each rod was then rolled and drawn into 0·172 inch in diameter, weighing 30 lbs. and measuring 1 mile; less 10% was allowed for the test piece left for transport and use. The Swedish iron owed its purity to the low phosphorus purity, but to the fact that it was smelted and puddled entirely with charcoal. The best-conducting iron stations of various ores, and they were known by various brands, the numbers corresponding to the brands being accurate.

The operation of testing was a most important one, and included not only for the user, but for the manufacturer. Flaws, impurities, faults, notwithstanding the greatest care, would occasionally be found in the material by the most rigid examination and tests. Tests were mechanical and electrical. The mechanical tests embraced one for breaking strain, another for elongation, and a third for resistance to torsion. For hard steel wire, in place of the tension test, it was usual to specify that the wire should bear wrapping round its own diameter and unwrapping again without breaking. The electrical test was simply that for resistance—that a mile of the wire to be examined was wound round a dry wooden drum, and its electrical resistance was taken in ohms by means of a Wheatstone's bridge. Galvanisation was tested by dipping in sulphate of copper, and by bending or rolling round a cylinder of a given diameter, according to the size of the wire. Special machines were constructed for the mechanical tests, the condition to be fulfilled being that the breaking-strain the increasing load or stress should be applied uniformly, without jerks or vibration. For hard steel wire machine should correctly register the actual breaking-weight of the wire slightly. The resistance of the wire was determined by an ink spark set in motion by a weight on the wire, and recording the number of spires indicating the number of tricks taken before breaking. The perfection to which the manufacture of iron had been brought was very much due to the care bestowed on the selection of the charcoal varieties of Dr. Percy, C.B., F.R.S. The standard had been gradually raised, until it had attained a very high size. Great improvements adopted in the expense of thorough inspection, with the result that the wire did rightly inspect. The best results of this wire did rightly inspect. One break in the wire cost for the men in the field, and last one extra per mile effected in the carding capacity of the wire in inverse proportion to the size. It was necessary to remark that the mechanical quality of electrical-wire sometimes changed without any change in the quality rendering unaffected. Tests repeated at some subsequent period might therefore be valueless. Similar allowance were made for the effect of temperature. Homogeneous iron wire as a rule improved in the mechanical properties by being kept in stock. The Post Office authorities had decided to abandon a gauge in favour as applied to conductors, and to define size by diameter and weight. In future, all copper wires would be known by their diameters in "mils," A mil was a thousandth, and all iron wires by their weight in ft. per mile. Steel wire was used for long spans, where its greater tensile strength was needed; but it was for the external strengthening of cables. Steel wire cables that steel was originally adopted, and was first employed in the Atlantic cable of 1858 for the purpose of strengthening the conductor, and for deep-sea cables. The usual diameter was 0·099 in., and it was specified to have a breaking-strain of 1,000 lbs., which was equivalent to 81 tons on the square inch. Steel wire had been produced having a much higher tensile strength. A compound wire of steel and copper was introduced in America about 1874, and it had been extensively used in both hemispheres, but without success. Iron-silicide wire had been tried, but without success. Clark and Chirgin, a discovery of 1,000 miles, giving only 17 ohm resistance per mile. It had a steel core of 0·125 inch in diameter, and was coated with copper electrolytically to a diameter of 0·25 inch. It weighed 700 lbs. per mile, had a breaking-strain of 4 tons, and was of a much lighter diameter, would be equally efficient.

Copper, Bessemer, the hard insulating qualities and their resisting powers of which were well known, was introduced for telegraph purposes about five years ago. Several lines were erected by the Post Office. Two of these crossed the channel that separated the Scottish Highlands from the mainland near Seamens. The object of view was to obtain great tensile strength with a low resistance, especially active where the wire was to be used to span. This was done in 1870, and in 1874 and for 1883 and the highest strength was noticeable in the wire. But phosphor-bronze was considerable in the high electrical resistance, though exceptionally soft, but per cent. that of copper. The conductivity was only 20 supplied was irregular in dimensions and brittle in character. It would not bear knocking about. A new phosphor-bronze, had recently been introduced to remedy these disadvantages. Phosphor-bronze and phosphorised copper wire, and had been much improved by silicious made material, and was specified at such a size that it was strength all equal to that of copper, but its mechanical qualities rendered it eminently adapted for telegraphic purposes. If overhead wire was erected of such a material, upon slightly supports, and with some method, there would be an end to the meaningless crowds now made in

A NEW INSULATING MATERIAL.—The immense strides which have been made in electrical discovery, particularly in practical applications, have created deficiencies in very far new and cheaper insulating materials than those already in use. Hitherto they have been limited in glass, porcelain, stoneware, gutta-percha, indiarubber, and ebonite. Owing to the greatly increased demand, the price of the last three named has risen very much, and is likely to rise still more, and, while the quality has deteriorated, it is found that in the existing sources to supply what is required, not only for telegraph and telephone work, but for the immense field opening in electric light work. Now, everything, safety in the use of electricity, and there is a correspondingly demand for a cheap insulating material, the qualities of which shall be equal to the demand likely to arise. This desideratum has been met by the invention of a material called Insulite, which, instead has been discovered by which wood, sawdust, cotton waste, paper pulp, and other fibrous materials can be converted into a material perfectly impervious to moisture, acids, easily moulded under pressure into any shape, and capable of being worked or cut after solidifying. This material is a excellent non-conductor of electricity, and can be used for all forms of battery-cells, telegraph insulators, supports for electric light leads, and telephone work. It obtains the name of being perfect insulation at a very much less cost than obtained by gutta-percha. As it is perfectly impervious to moisture, it can be made of it cannot oxidise or warp. It supplies exactly what it is wanted in practical work, in which ordinary wood cannot be used because it absorbs moisture and electric is inhibited on account of its cost.—Engineer.

THE IRON AGE

Underground Electrical Conductors.

The attention now being given to the important question of the conveyance of wires underground in large cities, is illustrated by the number of devices for this purpose which are displayed at the Electrical Exhibition in Philadelphia. The *Public Ledger* of that city refers to them as follows:

"The question of underground conduction depends upon the use of of an air insulator of the kind used on telegraph wires it is proposed to place underground. An iron tube like a gas-pipe is laid, with proper manholes and branches, within which are run the telegraph and telegraph wires, each separated from its neighbors by a covering of cotton. When the system is completed, a heavy hydrocarbon prepared from petroleum by a special process is pumped into the line. Every precaution is taken to exclude moisture or foreign substances from the pipes, and the system is kept constantly under pressure, to make sure of no leakage. In the exhibition the system is shown in active operation, the lines being under the hill down, by the Pennsylvania Railroad, and connecting 50 telegraph circuits in such operation, besides the telephone wire used.

The American recitational underground system is exhibited in active operation. This system consists of a cast-iron conduit laid underground, with arrangements for carrying wires through them without endangering insulation. At intersections and other convenient places manholes are arranged, and there are large enough for a man to descend and arrange wires and make connections without difficulty. Where a large number of wires are to be carried the conduit is arranged with a series of trays, one above another, on which may be arranged any number of wires. This system has been in actual operation on Chestnut street, from Third to Broad, for about six months, and is stated to have been so far perfectly successful.

The Edison system of underground conduction, shown at the present entrance, is adapted not merely to the Edison system of incandescent lighting, but to all purposes of electrical conduction. For the purpose of system of lighting, a large number of wires are necessary, on account of the very large currents which are employed. It consists of a rectangular iron gas-pipe of ordinary character, through which is run the necessary copper. Inside the pipe it is built special insulating material, which hardens on the outside into a very hard compound by the action of the air. The pipes so prepared are laid under the ground, and are screwed together like ordinary gas-pipe.

One novel feature of this system is the method of the throwing off of the wires from the conductor. In this system the current is carried from the lamps of equal power in parallel circuits, rather than in series, instead of four. The positive wire passes through a dynamo to connection with the negative pole of the other, and from the centre of the dynamo to the middle wire, as it is termed, of the system. The remaining negative and positive wires pass from the dynamo to the two ends. If the wires are working equally, there will be no current over the middle wire, the two opposing currents exactly neutralising each other.

The current over the two outer wires, if they were connected, would be doubled in quantity—that is, it would be carried on volume instead of one, as is usually carried. Connection is however, made with the middle wire from each side wire, and then the current is reduced to half its volume, so that the current is higher in intensity a smaller wire can be used. In practice, the upper wires were the current of the normal four-sixty volts, with a danger of about 120 volts. The insulation the wires seem to inside one-fifth of an inch, and the total wiring is represented to be 6,000 miles.

The Continental Underground Cable Company have a system of their own. The system consists of a tube from the use of dry 2 p as an insulator—that is, it would be useful to valve single insulation and connections" and by means of a steam engine and a pump a current of dry air is forced into the tubes. A proper system of protection from induction is provided for telephone wires. In the interior of the conduit is arranged a small railway with an arrangement by which a small electric motor may be used if every wire down the conduit. It is pointed out that the arrangement of conduits was sufficiently extensive that a branch line would make an efficient perch pipe in addition to its principal one. Nassi Fed Continental is shown Woodward's combination curb conduit. This is a conduit arranged along the curb, where it can be more easily examined than under the street. Arrangements are made by which steam-heating pipes may be arranged with the conduit, so that the wires may not freeze. The Philadelphia and Reinhard Telegraph and Cable Company exhibits a system which consists of a number of square tools in suitable lengths in which the underground wires are placed and covered by a special insulating compound.

The Orion Electric Underground Company exhibits in the annex a sample of their conduits, which consist of iron tubes, together with their method of insulating the wires as they are passed through them. The National Underground Conduit Company exhibit their conduit and a manhole. The conduit of the latter is embedded in an artificial stone. Examples of terra-cotta, asphalt, and artificial-stone tubes are also shown. The Electrical Conduit Wire Underground Telegraph, Telephone and Electric Light Company also exhibit a system for laying their underground conduits. It consists of a terra-cotta pipe, along which is set at suitable intervals a series of perforated plates of some non-conducting material, and through these holes are drawn the wires it is designed to protect. Models of manholes are shown in the gallery, labelled respectively the Anderson conduit and the Dudley conduit, built of W. Hewitt, Washington, D. C. The models are of wood, and no description of their design or use are submitted."

Underground Electric Wires.

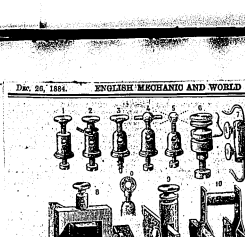
The rapid multiplication in all of our cities of overhead wires for all descriptions of service, constitutes what all parties agree in pronouncing a nuisance, and in a number of localities has called into existence municipal ordinances looking to its suppression. Chicago, we believe, was the first among American cities to take a decided stand on this question, and some years since decreed that all electric wires located after the 1st of January, 1883, should be placed under ground. Other cities have followed this example; but the outcome has apparently been, up to the present, an almost absolute failure to comply with the law. The alleged reason urged by the various corporations affected by the laws in question, is that thus far no satisfactory system has been devised which could be relied upon to warrant them in risking the disturbance of their business.

Meantime, likewise, there have been announced a host of inventions for underground conduits, each professing to fully meet all the requirements of the various forms of electric service.

We have always advocated the underground system for electric wires on general principles, and on the strength of the very general adoption in foreign countries of some system of this character not only in the streets of cities, but in some notable cases also even hundreds of miles of country have affirmed the entire feasibility of the underground system.

The extensive introduction of private telephone lines, and of electric lighting wires in all our cities, to say nothing of the constant increase in the number of telegraph wires, complicates the situation very materially by adding largely to the difficulties in the way of placing the wires for all these forms of service in one and the same conduit. It seems to be necessary to keep the electric light wires separate from the rest, in a special conduit, so as not to interfere with the practical working of the telegraph and telephone wires. The provision of separate conduits means, of course, additional first cost in the adoption of the underground system; but the indefinite increase of overhead wires in our cities simply cannot be tolerated, for reasons that all are familiar with, and sooner or later the change from overhead to underground must be made, either with or without the assent of the companies.

The difficulties of the situation may hasten the adoption of the system of subways in all our large cities, which would solve the problem completely.



ELECTRICAL CONNECTIONS.

THE collection of electrical connections shown in the annexed illustrations is very portable, and may be found useful by those who are superseded with the more cumbersome terminals. Fig. 1 shows an ordinary terminal to be fixed to the base of a galvanometer. Fig. 2 shows a modification of the former that allows the wire to be either in the position shown in the figure, or between two screws when it is more convenient. Fig. 3 shows a terminal screw, with a milled head for the purpose of connecting wires when under test as it is accessible and does not permit of slips. Fig. 4 and 5 show a terminal for the connection of a secure fastening long wires. The latter consists of a small brass screw, with a hole in the head of the screw (fig. 4), or a small brass screw, with a hole in the head of the screw (fig. 5). This is especially adapted to cases where the space is limited, and where there is no way of changing the wire attachments often. Fig. 10 shows a fish terminal used for the purpose of a screw fastening for the galvanometer. Fig. 6 represents a terminal with flat head, and a hole through the centre of the screw. It is fixed to the galvanometer by means of screws. In terminals 7 and 8, and is prevented from turning by means of a screw at the lower part. When two wires are to be united, the clamp shown in Fig. 7 is used. The extension of a brass cylinder contains a set screw that runs altogether through it, and by means of this the wires to be connected are secured, and may be changed at two thirds of a minute. Fig. 9 shows a terminal for the connection of a wire to the galvanometer. Fig. 11 represents a terminal with flat head, and a hole through the centre of the screw. It is fixed to the galvanometer by means of screws. In terminals 7 and 8, and is prevented from turning by means of a screw at the lower part. When two wires are to be united, the clamp shown in Fig. 7 is used. The extension of a brass cylinder contains a set screw that runs altogether through it, and by means of this the wires to be connected are secured, and may be changed at two thirds of a minute. Fig. 9 shows a terminal for the connection of a wire to the galvanometer. Fig. 11 represents a terminal with flat head, and a hole through the centre of the screw. It is fixed to the galvanometer by means of screws. Figs. 8 and 11 represent clamps that are used on those cases for connecting the cabinet with the copper plate. Fig. 11 shows an ordinary clamp, and Fig. 8 a terminator for a slip plate. Fig. 12 shows a key clamp employed by Mr. G. Preece in his telegraphic instruments for testing and signalling purposes. In many cases there is need of often substituting one apparatus for another, and of establishing two continuous cabinets. Fig. 10 shows a fish terminal for the connection of a wire to the galvanometer. Fig. 13 represents a terminal with flat head, and a hole through the centre of the screw. It is fixed to the galvanometer by means of screws. In terminals 7 and 8, and is prevented from turning by means of a screw at the lower part. When two wires are to be united, the clamp shown in Fig. 7 is used. The extension of a brass cylinder contains a set screw that runs altogether through it, and by means of this the wires to be connected are secured, and may be changed at two thirds of a minute. Fig. 9 shows a terminal for the connection of a wire to the galvanometer. Fig. 11

MIDLAND ASSOCIATION OF GAS MANAGERS.

At the Sixth Quarterly Meeting of this Association, held at Birmingham on Thursday, the 1st inst.—Mr. CHARLES HUNT, of Birmingham, in the chair—a paper was read by Mr. C. E. MEDHURST (Chesterfield)

ON PUBLIC LIGHTING, WITH SPECIAL REFERENCE TO STREETS, ETC.

The paper commenced with a few remarks on the use of artificial light in the past ages. It then proceeds: But we pass on to treat more particularly the branch of our industry selected for the author's consideration—viz., public lighting, the discussion of which I hope may interest and benefit each one of us. It is a subject that calls for careful consideration at much attention, and perhaps its discussion at the present time may lead to the adoption of some improvements in the development; but even this consideration is not deep or keen enough to lead to perfection in the answer to every branch of our profession.

The chief requirements of public lights are—(a) steadiness of flame, not susceptible to atmospheric commotion; (b) uniformity of intensity; (c) great penetrating power; (d) great economy per unit of cost, with the least preparation, and easily lighted; (e) non-liability to any sudden or subconflagrations; and (f) great durability and strength.

The first of these I consider to be that of burner used, and the form of glass employed to shield the light. Upon the selection of the one or the other in a measure the light depends, as, of course, the question of interruption in supply or mechanical defect, prefers to the form of support and the attention of the lantern; I we will consider collectively.

In the wide range of materials from which artificial light can be produced, that which fulfils most of the above requirements is undoubtedly coal gas, hence public lighting in most towns becomes a question of the cost of coal gas in each locality. Having assumed this, the light-givers may be briefly separated into those which require a shelter compartment, being reflectors—i.e., Candles and all have been tried over and over again, both economically and usefully, with the result of leaving coal gas the leader of the situation. To coal gas, then, the public returns, being won back to the old time by the very many excellent and unique qualifications; and if we this day advance the just claims of coal gas, and bring out more prominently the claims hitherto unsettled and specific features of, we have every cause to think that, however imperfectly the subject may have been put forward,

To consider a successful realisation of the above conditions may be considered by some to be practically impossible, the nature of the service demanded being of such a varying character, depending upon the nature of circumstances exceedingly difficult to effect; but if we cannot ensure thereabouts, we must strive to secure a position as near to it as it is possible in our particular and individual cases.

By the diversity of the forms of burners which I have submitted in your consideration, and carried through in a series of daily applications, the question of steadiness can be effected in public lighting without any very great outlay. Some may be found better adapted than others on the ground of ignorance; but that cannot apply to ourselves in the present day, when knowledge is universal. The ancients cry out, "Where shall wisdom be found?" Now the answer is, "It rests on the housetops," and knowledge, and consequent strength," so that if any one burner be found strong, the increase of our knowledge makes us stronger, so far forward as the application of the burner is concerned. The strength of knowledge," let us repeat, makes the foundation of our practical facts to be carried out public which is the right path to tread, the right way to use the light they yield, and if they refuse to follow our advice or to accept our direction, we shall still possess the consciousness of having done our duty.

Before the introduction of gas lighting, very little sound knowledge existed generally of the extraordinary power of the atmosphere in its action upon flames, and much of the extraordinary power of the atmosphere in its action upon flames, and much of the extraordinary power of the atmosphere in its action upon flames, and much

emphatic in the expression of an opinion that Local Authorities could do just as they please with roadways under their own jurisdiction; but these are, we think, decisions against him, which are not completely answered by the cases that he quoted. His evidence, however, was a triumphant defence of the rights of Gas Companies, and as such we receive it with much pleasure. It was a fortunate thing that such an important witness was kept back till the last, so as to leave an impression on the minds of the Committee, which, however, we fear, will be swayed by the opinions of the Chairman.

But what, after all, has been done as regards the real points at issue? Mr. Michael showed that Corporations and Gas Companies alike have power to break up the streets for the supply of illuminating agents. This, we think, is indisputable; but it only touches the threshold of the question. How, in the case of Independent Electric Light Companies, shall their capital be limited? How can the illuminating power of the light they are to supply be fixed? How are the charges to be made? And what are to be the limits on profits? These are questions which ought to have been put before the Committee, but which were not, although coming within the scope of the inquiry they were directed to make. To Mr. Michael's evidence, of course, we must return when it is published. In the meantime, we have to thank him for his able vindication of the rights of Gas Companies, and all concerned in the supply of the commodity. As we have said before, this inquiry is happily coming fast to an end. It has, we believe, been utterly abortive, and what report the Committee can make is at present to us quite a mystery. A writer like Dr. Lyon Playfair can, no doubt, make much of it; but what practical ends may be suggested, it is very hard to guess. Most certainly the inquiry has been wide of the mark. It is not, perhaps, the fault of the Committee, for really so little is known at the present moment about the electric light, as regards its application to street and domestic illumination, that we cannot blame them for their meanderings.

At the last meeting of the Metropolitan Board of Works a report submitted stated that the Committee of the Board had, in reply to the communication from the Board of Trade, written to the effect that they entertained certain objections to the scheme for the amalgamation of the South Metropolitan and the Surrey Consumers Gas Companies; but it does not appear that any active opposition will be raised. The fact is that the amalgamation promises to be so beneficial to the consumers in the Surrey district, that we fail to see what objections can possibly be urged against the combination. That the Company affiliated to the South Metropolitan Company will be subjected, after twelve months, to all the pains and penalties imposed by recent legislation, ought to be sufficient to satisfy the most exacting member of the Metropolitan Board, and we are astonished that any remonstrance should be made against a scheme which involves so many benefits to a large section of the consumers of of gas on the south of the Thames.

There is, we are happy to know, a possibility of a much larger combination, into which the Phœnix Gas Company will enter. It is unfortunate that this Company has not been more prompt in responding to popular demands. A few years ago they might have taken the lead in a scheme intended to consolidate the interests of all the Companies south of the Thames; but they followed the opportunity to slip, and now have to take what may be called a secondary position. Nevertheless, the combination cannot, if elected, prove of great value to the Shareholders. The undertakings worked together would yield profits which would fall short of the sum of a reduction of price, and consequently an increase of dividend. The fact is gratifying to both Consumers and Shareholders. The combination we speak of is only in posse; but we entertain an opinion that it is certain to be effected, sooner or later. Every kind of amalgamation we regard with favour. We have had no hesitation in expressing an opinion that it would benefit all if the gas supply of the Metropolis were under one management, and we have constantly urged that if this could not be effected, the northern Companies might all be consolidated, and the southern Companies be in a similar manner constituted into one united body. The objections of the Board of Works will probably have no weight with the Board of Trade, who favour amalgamation, and therefore we take it that the scheme is certain to receive their approbation. As to the Phœnix combination, we shall probably soon hear more. We only hope that it will be proceeded with and soon carried out. A meeting of the Shareholders of the Surrey Consumers Company is called for to-day, to sanction the arrangement for amalgamation. We cannot suppose that any one would be so stupid as to raise an objection. The Company urgently require new works, and the infusion of new blood. They have not, at the present moment, any opportunity of increasing their storage, although they have facilities for the erection of new carbonizing apparatus and the reception of coals. The combination, as we have said, will assist them in both particulars, and we cannot believe that any Shareholder will be led into the folly of opposing an amalgamation so desirable.

Mr. Thomas Bridge Simpson, the late Chairman of the Directors of the South Metropolitan Gas Company, who died on the 18th inst., deserves a passing notice. He joined the directorate of the Company thirty-two years ago, and for the last twenty-two years was the Chairman. Before the districting arrangements in the Metropolis were made in 1855–60, Mr. Simpson rendered essential service to the Company by inducing the Authorities of Southwark to admit the mains of the Company within their limits. Under the arrangements made by Mr. Sotheron Estcourt's Committee, the South Metropolitan Company lost the Borough district, but the temporary possession of it was of much value. Mr. Simpson was of a kindly disposition, and on disputed points loyally accepted the decision of the majority of his co-Directors, and earnestly endeavoured to carry them out. His mode him a great favourite with his colleagues, and it is to be regretted that he has died at the juncture at which the South Metropolitan Company have now arrived. At the great age of ninety, Mr. Simpson, after a short interval of rest, consequent upon an attack of paralysis, has quietly passed away; but his memory will be long cherished by those with whom he was associated.

The sixteenth annual meeting of the British Association of Gas Managers will be commenced, at Newcastle-on-Tyne, on Tuesday, June 10, and the proceedings and festivities will be continued over four days. The programme is of a somewhat attractive character, the papers to be read embracing matters which are of extreme interest to Gas Managers, and which will command the attention of all the members. It would be invidious to select for special reference here any of the communications which will be presented; but we may speak of them in their entirety as all well worthy of notice. Under the able presidency of Mr. J. J. Warner, of South Shields, everything is certain to go well, and we anticipate a most agreeable and instructive occasion. The lecture will be delivered by Mr. C. A. Lebour, F.G.S., and his topic will be "Practical Notes on Coal and Coal Getting." The North of England Association of Gas Managers display great hospitality on this occasion, and we are perfectly certain that the parent Association will derive much enjoyment from the liberality of their descendants.

In another column we publish a paper contributed by Mr. C. E. Jones, of Chesterfield, to the proceedings of the Midland Association of Gas Managers, who held their sixth quarterly meeting at Birmingham on the 1st inst. Mr. Jones's topic was "Public Lighting, with special reference to Streets, &c." There is no matter which deserves more important consideration from Gas Companies than the lighting of public streets. As a matter of fact, it may be said that the reputation of a Gas Company largely depends on the efficiency with which public lighting is performed. Unfortunately, the supply of public lights is not very profitable—indeed, in some instances, it involves a Gas Company in a positive loss; but it must be borne in mind that public lights, after all, constitute a sort of advertisement. The ratepayer who sees a brilliant illumination in the streets, and notices how small is the impost he has to pay for it, naturally concludes that to have gas in the house would be comfortable and economical. Mr. Jones goes into full details of the various requirements for effective lighting, and even the ornamentation of the pillars, and the exact position of the burner. On all these points we perfectly agree with Mr. Jones, and so also with respect to the use of more than twenty-candle gas, which he very properly says is of no advantage to the public. It only blackens ceilings, and causes careful housekeepers, at all events in the South, to anathematize the gas as impure. We wish, with the author, that Parliament would decide on some universal standard of quality. We have for many years insisted that fourteen-candle gas fulfils with efficiency all necessary requirements, and we are happy to see that, year by year, parliamentary sanction is given to this quality. The consumption of six feet per hour per lamp, recommended by Mr. Jones, is unnecessary, and it would not, we think, meet with the approval of many Local Authorities, who would consider it excessive. Inasmuch as the Gas Company would have to add to their charges. We are sorry to find that Mr. Jones is not in favour of the "average" meter system," the adoption of which we strongly advocate. It is not that extra profit results to the Gas Company when it is employed, but, as a Member of the Association very pertinently remarked, it saves squabbles. But we have remarked on this above, and need say nothing more here. We have no doubt that Mr. Jones's paper will be perused with much interest, and we are certain with considerable profit.

PARIS GAS COMPANY.
The Annual General Meeting of the above Company was held in Paris [illegible] the following report on the Company's affairs.

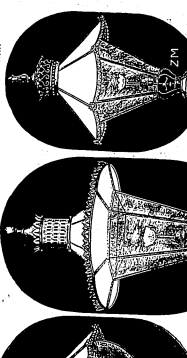
602 THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT. [May 6, 1879.

IMPROVED REFLECTING STREET-LAMPS.

D. HULETT having had numerous inquiries for an Improved Street-Lamp, has to call the attention of Gas Engineers, Local Authorities, and others to his Improved Reflecting Lamps, which are constructed to give the greatest illumination with the smallest consumption of gas.

They are strongly recommended for Railway Platforms and large open spaces, or any places requiring a good light without the use of large burners.

The 14-inch square Lamp is made to fit the ordinary Lamp-Cradle now in use, and is fitted with a 24-inch Reflector.



Special attention is called to our Diaphragm Governor, by the use of which the Governor-by his arrangement-is placed in the most convenient position of the gas consumed is obtained.

They are made in various sizes and also with Governor, Lamp-cock, or square.

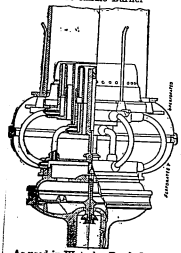
Further Particulars upon application to

D. HULETT, 55 and 56, HIGH HOLBORN, LONDON.

WILLIAM SUGG'S
IMPROVED SYSTEM OF STREET LIGHTING,

SUITABLE FOR EITHER CANNEL OR COMMON GAS.

SECTIONAL ELEVATION of 80-candle Burner

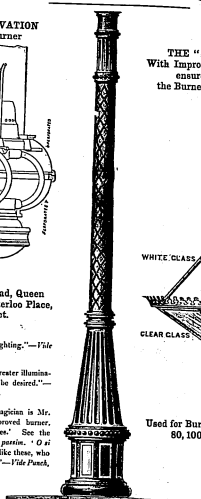


As used in Waterloo Road, Queen Victoria Street, City, Waterloo Place, and Regent Street.

"The perfection of street gas lighting."—*Vide "Times," Feb.* 1, 1879.

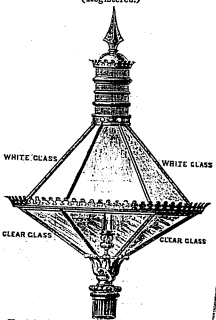
"For all practical purposes no greater illumination than is hereby supplied could be desired."—*Vide "Daily News," Jan.* 13, 1879.

"The real modern Aladdin's magician is Mr. Sugg, who, by means of his improved burner, gives us 'new lamps for old ones.' See the Waterloo Road and Waterloo Place *passim*. '*O si sic omnia!*' If all gas light were like these, who would ask for Edison and electricity?"—*Vide Punch, Feb.* 15, 1879.



THE "WESTMINSTER" LAMP-COLUMN,
Of Improved construction,
8 feet and 9 feet from ground to top of Column.

THE "SHADOWLESS" LANTERN,
With Improved System of Ventilation, which ensures steadiness of the flame of the Burner, even in very windy weather.
(Registered.)



Used for Burners giving the light of either 80, 100, 150, or 200 Spermaceti Candles.

Other Patterns of Lanterns and Columns are in course of construction, and will be shortly Published in this JOURNAL.

WILLIAM SUGG,
GAS ENGINEER,
VINCENT WORKS, VINCENT STREET, WESTMINSTER, S.W.

gases all the information they may require as to the price of the apparatus, the cost of fitting them up, the economy resulting from their employment, the cost of fitting them up, the economy resulting from their employment, and so forth. The show-room continues to be visited by large numbers of persons, and the service they render is found to be fully as great as was anticipated.

Principal Results of Working.—The following table gives the quantity of gas manufactured from Jan. 1, 1855, to Dec. 31, 1878. It shows that during the first 23 years of the Company's existence, the annual consumption, starting from 1,435,150,000 cubic metres (51,435,150,000 cubic feet), or from 1855 was 49,771,000 cubic metres (1,910,101,000 cubic feet), or 4·19 per cent. With regard to the average annual increase, from 1855 to 1878 it has not been strictly constant at about 2,060,000 cubic metres (72,810,000 cubic feet); but from 1871 it has advanced considerably, reaching 12,750,000 cubic metres (450,375,000 cubic feet):—

Year.	Annual Consumption. Cubic Metres. (1 c. m. = 35·315 c. ft.)	Annual Increase. Cubic Metres. (1 c. m. = 35·315 c. ft.)	Annual Increase. Per Cent.
1855	49,771,493		
1856	47,345,470	6,561,975	13·01
1857	52,907,445	5,561,975	11·75
1858	58,043,000	5,135,555	9·70
1859	67,938,185	9,895,185	17·05
1860	75,518,922	7,580,737	11·16
1861	82,730,070	7,211,148	9·55
1862	94,670,220	8,941,150	10·81
1863	100,813,215	6,142,995	6·49
1864	102,930,963	2,117,748	2·10
1865	116,171,727	13,240,764	12·86
1866	122,345,782	6,174,055	5·31
1867	128,587,701	6,241,919	5·10
1868	145,195,421	16,607,720	12·91
1869	154,470,969	9,275,548	6·38
1870	147,491,316	16,979,653	12·99
1871	167,471,316	20,000,000	13·56
1872	177,221,316	9,750,000	5·82
1873	184,221,316	7,000,000	3·95
1874	194,221,316	10,000,000	5·43
1875	207,221,316	13,000,000	6·69
1876	220,221,316	13,000,000	6·27
1877	234,221,316	14,000,000	6·36
1878	251,315,577	20,752,260	8·86

Manufacturing Power.—The manufacturing powers of our works, which, on Dec. 31, 1877, was 228,500,000 cubic metres (8066 million cubic feet), or 8·86 per cent. more than in the previous year, were sufficient to meet the demand, including that of the reserve plant intended to meet cases of accident, or of any unexpected increase in the consumption, was raised during the year 1878 to 250,000,000 cubic metres (8831 million cubic feet). The total capacity of the works is provided for by the end of the current year, upon the completion of the works in progress at the various stations, the manufacturing power will be raised to close at the various stations (9611 million cubic feet), and be capable of 272,500,000 cubic metres (9611 million cubic feet), and be capable of supplying, for the consumption, after deducting reserve, about 225 million cubic metres (7750 million cubic feet) of gas, thus giving every security cubic metres (7750 million cubic feet) of gas, thus giving every security for a supply during next winter.

Localization.—During the past year our main-laying operations have not been so extensive as in previous years. Our mains establishes have, however, increased by 26,250 metres, apportioned as follows:—

	Metres.	Yards.
In Paris and its environs	23,852	26,250
In the outskirts	22,998	24,997
Total	46,850	50,997

Or nearly 29 miles. Consequently, the total length of mains laid under the public roadways has been increased to 1,925,072 metres, apportioned as follows:—

	Metres.	Yards.
In Paris and its environs	1,278,867	1,391,741
In the outskirts	629,717	679,190
Total	1,925,012	1,971,435

Or close upon 1122 miles, which represents very nearly the distance from Paris to Lisbon. The greater portion of the main-laying work was done during the year in the outskirts, at the request of the Municipal Authorities, or in accordance with the outlying consumers. The remainder was, after consultation with the Municipal Authorities, to meet the demands for a diminution, undertaken with the view of securing to the advantageous to the supply of light which it appeared to us would be advantageous to the Company.

On the 22nd of June last, the *Administration Supérieure* gave their approval to the lighting contract which we had a few months previously entered into with the communes of Ville-d'Avray. The communes have since been lighted by the Company in the districts lying beyond the fortifications, in the departments of the Seine-and Seine-et-Oise, it thus brought up to 822—one.

The Universal Exhibition.—The Exhibition of 1878 furnished us with an opportunity of showing the successive improvements that had been effected in the arts and manufacturing processes, and of calling the attention of the enlisted men of all countries to the results of our labours in the scientific sphere.

The special pavilion which we had erected in the Champ de Mars contained, in a comparatively limited space, a very complete collection of all the various articles and appliances connected with our industry. The various articles and appliances connected with our industry. The drawings there exhibited, rendered the visitor able to take in at a glance the whole process of gas manufacture, as well as that of the treatment of the various by-products, the collection of the numerous products which we obtain, for instance, by extracting from tar, not from which we obtain, for instance, by extracting from tar, not from which we obtain as they are, dyeing of fabrics, a series of colouring matters, and arrangements for isolating gas varied; our improved gas-cocks; our regulating by valve, the gas-engines mains; and, lastly, the appliances for using gas indirectly—all these things attracted and the refractory products of gas manufacture—all these things attracted

the banks of the Seine, and alongside the Western Railway, are undoubtedly exceptionally well placed for carrying on their operations to the greatest advantage.

The other works carried out at our other stations have been undertaken with the object of completing the distributing plant, perfecting the methods of condensing and purifying, and bringing the capacity of the coal and coke stores, as well as of the apparatus for the treatment of the coke, tar, and ammoniacal liquor, more into keeping with the manufacturing power of the ovens.

The total amount expended on works of first establishment during the year 1878 was 2,110,716 fr. (£84,288), apportioned as follows:—

ACCOUNT OF EXPENSES OF FIRST ESTABLISHMENT FOR THE YEAR 1878.

Expended in the Purchase of Land, &c.

	Francs.	Sterling.
Land acquired for the erection of a coke shed	70,421	2,257
Land acquired for extension of coal and coke stores at Billette	24,000	1,120
Ditto for enlarging the coke yards at Ivry	66,961	2,709
Legal and other expenses in connection with above	51,164	2,027
	236,576	43,953
Less value of land acquired by the Municipality for street improvements	11,260	453
Total	225,316	43,500

Expended on Works and Plant.

La Villette.—Completion of two gasholders; erection of two exhauster-engines and tanks; erection of two steam-generators; enlargement of pipe conduccers; sundry works	189,833	25,231
Ivry Terrace.—Repair of gasholder and tank; completion of additional gasholder of 20,000 cubic metres (706,000 cubic feet) capacity	529,762	14,791
Passy.—Enlargement of pipe conduccers; construction of water reservoir	21,612	865
Vaugirard.—Construction of boundary walls; enlargement of coal store; erection of a coke-crusher	88,476	3,539
Ivry.—Completion of two settings of retorts with Siemens's regenerator; completion of steam-engine, condenser, station-meters; construction of site for new coke shed	605,289	21,212
Billette.—Conversion of two ordinary settings of retorts into Siemens's ovens; new station-meter of 20,000 cubic metres (1,000,000 cubic feet) capacity; new steam-engine	25,027	1,024
St. Mandé.—Erection of four water-condensers on Siegen's system; completion of exhauster-house, buildings, and apparatus	53,993	2,116
St. Denis.—Erection of an additional setting of three through retorts; paving coke shed	19,221	722
Boulogne.—Erection of two of Pelouze and Audouin's battery condensers; sundry apparatus; completion of coke-crusher	13,227	529
Maisons-Alfort.—Enlargement of coal yards; improved tar-well; construction of a boundary for crane of coal shoot	12,191	495
Clichy.—Boundary and other walls; earthwork and masonry of three gasholders; foundations of new retort and purifying houses, and other works	1,095,717	13,810
Tar-Works at La Villette.—Construction of a fourth tar-well and a water reservoir; new steam-power steam-generator	71,398	2,864
Sundry works at the other stations, offices, &c., of the Company	189,253	7,238
Total	2,710,201	£160,636

Expended on Mains, Services, Fittings, &c.

	Francs.	Sterling.
Main-laying.—New mains laid during the year (26,250 metres or 50,997 yards), and replacing (20,596 metres or 22,438 yards)	676,313	27,052
Services.—Expenses of laying on	729,822	30,266
House Services.—Expenses of laying on	826,693	13,467
Branch-pipes and Fittings.—Of 1878	1,261,826	52,993
&c., let out on hire during the year		
Meters.—Purchase of meters let out on hire		
Tubulures.—Increase in the number of keeps and valves for the conveyance of coal, coke, and ammoniacal liquor, &c.	41,230	1,768
Ditto for increase of material	113,215	4,530
Tools and Material.—General increase in stock		
Establishment Expenses.—Miscellaneous expenditure	933,870	6,215
Total	5,457,000	136,351
Total expenses of first establishment	5,467,753	£219,700

The general position of the account of expenses of first establishment may be thus stated:—

	Francs.	Sterling.
Amount expended to Dec. 31, 1877	165,660,448	25,791,145

[illegible] the [illegible] of the Seine, and [illegible] in the [illegible] In the explanations which you have hitherto given us, the state- [illegible] of very great interest. Cer-

HOUSE OF LORDS.

MONDAY, APRIL 28.

The Examiners reported that no further Standing Orders are applicable in respect of the following Bills:—Glasgow Corporation Water, Ravenarde Local Board, Portsmouth Water.

The Birmingham Gas Bill was brought from the Commons, read the first time, and referred to the Examiners.

The Westgate and Birchington Water Bill was read a second time, and committed.

Bills read the third time, and passed:—Bury St. Edmund's Gas, Nottingham Inclosure, New River Company.

The Dudley Sewage Bill was referred to a Select Committee, consisting of Earl Sidney (Chairman), Viscount Powerscourt, Viscount Canterbury, Lord Sudeley, and Lord Foxford; to meet on Thursday, May 1.

TUESDAY, APRIL 29.

The Birmingham Corporation Water Bill was brought from the Commons, read the first time, and referred to the Examiners.

Tenterden Local Board Bill, Sleaford Water Bill—read a second time, and committed.

Petitions against the following Bills were presented:—Glasgow Corporation Water, from (1) Wilson, Patten, Bolton and others, (2) Charles Tod and Highcliffe, and Alexander Harvey and Son, (3) Trustees of the Clyde Navigation; Ravenarde Local Board, from the Corporation of Rotherham.

THURSDAY, MAY 1.

Dudley Sewage Bill.—The Select Committee reported that they had not proceeded to the consideration of the Bill, no parties having appeared in opposition thereto.

The Bromley Gas and Southend Water Bills were brought from the Commons, read the first time, and referred to the Examiners.

Glasgow Corporation Water Bill, Ravenarde Local Board Bill,—read a second time, and committed.

The Brighton and Hove Gas, Manchester Corporation Water, and Glossop Gas Bills were referred to a Select Committee, consisting of Earl Shelley (Chairman), Earl Manvers, Lord Clifton, Lord Lovel and Holland, and Lord Hemphill; to meet on Tuesday, May 6.

FRIDAY, MAY 2.

The Examiners reported that no further Standing Orders are applicable to the Birmingham Gas Bill.

Portsmouth Water Bill.—read a second time, and committed.

The Glasgow Corporation Water and the Ravenarde Local Board Bills were referred to a Select Committee, consisting of Lord Cheylesmore (Chairman), Lord Wharncliffe, Lord Clements, Lord Kenry, and Lord Norton; to meet on Tuesday, May 6.

HOUSE OF COMMONS.

Gas and Water Orders Confirmation Bills.—For confirming certain Provisional Orders made by the Board of Trade under the Gas and Water Works Facilities Act, 1870, relating to Cleethorpes Gas, Dewsbury Gas, Dronfield Gas, Ecclesfield Gas, Enfield Gas, Havant Gas, Longridge Gas, Northampton Gas, Rhyl Gas, Southend Water, Tunbridge Water, Ilkley and Esset Water, Maldeton Water, Mansfield Gas, Peckenham and District Water, Upnortemouth Water, Rhyl District Water, Shoreham and District Water, Stonebridge Water, Thirsk District Water, Aldershot Gas and Water, Vendover Gas and Water, and Yatton Gas and Water,"—was brought in on Friday, the 25th ult., by Mr. J. G. Talbot and Viscount Sandon, read the first time, and referred to the Examiners.

MONDAY, APRIL 28.

Republications to withdraw their petitions against the Mirfield Gas Bill were presented from (1) Joe and Gulliver and Calder and Hebble Navigation Commissioners, (2) Thornhill Local Board.

TUESDAY, APRIL 29.

Bromley Gas Bill, Southend Water Bill,—read the third time, and passed.

The Examiners reported that the Standing Orders not previously reported upon had been complied with in the case of the Colwyn Bay Water Bill.

The Houghton-le-Spring District Gas Bill was reported.

The Crystal Palace District Gas and the London Gaslight Company Bills were referred to a Select Committee, consisting of Lord Henry Lennox (Chairman), Mr. Dundas, Mr. Cates, and Mr. Fremantle; to meet on Tuesday, May 6.

The Mirfield Gas, Woodhouse Local Board, Ilkley Gas, Nottingham Corporation Improvement, Otley Improvement, Otley Burners Corporation, Queensbury, and Stanford-upon-Avon Corporation and Local Board of Health Bills were referred to a Select Committee, consisting of Mr. S. S. Allsopp (Chairman), Mr. Hardy, Mr. Kavanagh, Sir Arthur Hodgson, Mr. J. Maitland, and Sir John Duckworth (Reserve); to meet on Wednesday, May 7.

WEDNESDAY, APRIL 30.

The Llandudno Improvement Bill (Lords), as amended, considered; to be read the third time.

A resolution to withdraw his petition against the Alliance and Dublin Consumers Gas Bill was presented from the Postmaster-General.

THURSDAY, MAY 1.

Colchester Water Bill.—Petition for additional provision referred to the Examiners.

A resolution to withdraw their petition against the Mirfield Gas Bill was presented from the Heckmondwike Gas Company.

FRIDAY, MAY 2.

The Standing Orders Committee reported:—"That in the case of the Knutsford Light and Water Bill, petition for additional provision, the Standing Orders ought to be dispensed with; that the parties be permitted to proceed with their additional provision if the Committee on the Bill

A petition the petitioners not praying to be heard against the London Gaslight Company Bill was presented from Manchesterians, gas fitters, and traders in the Metropolis.

Republications to withdraw their petitions against the following Bills were presented:—Lancaster Gas, Mirfield Gas, and Morecambe Gas, from the Postmaster-General; West Kent Main Sewerage, from Dartford Local Board.

THE SELECT COMMITTEE ON LIGHTING BY ELECTRICITY.

FIRST DAY—FRIDAY, APRIL 25.

The first meeting of the Select Committee appointed "to consider whether it is desirable to authorise Municipal Corporations or other Local Authorities to adopt any schemes for lighting by electricity; and to consider what conditions and regulations such authorities, if at all, Gas or other Companies should be authorised to impose on any supply of electricity," was held on Friday, April 25, the Right Hon. Sir Stafford Northcote, Bart., M.P., and other members of the Committee present were Mr. Alfred Cave, Mr. Hardy, Mr. Hardcastle, Mr. Mitchell-Henry, Sir Upfurd Kay-Shuttleworth, Lord Lindsay, Mr. Arthur Moore, Earl Percy, Mr. Polexfen, Mr. Spencer-Stanhope, and Mr. Christopher Talbot.

The Chairman said we had

Professor James Thomson, LL.D., LL.D., F.R.S., &c., Professor of Natural Philosophy in the University of Glasgow, in reply to the Chairman, gave at some considerable length a history of electric light, from the time of the discovery of electricity by Galvani to the present day, illustrating his remarks by numerous experiments with electrical machinery. He pointed out that the voltaic battery had been proved to be too expensive a mode of producing electricity, as the waste of zinc plates and consumption was so great. Oersted, Ampère, and Arago followed with important discoveries, by which electricity and magnetism was demonstrated. Professor Faraday had, with great care, up the subject, and his efforts, in the main, had led to the great discoveries of the present century, but he had not applied his discoveries to the practical purposes of producing electric heat and light on an economic scale. Like a true man of science, he predicted that those results, which were exceedingly feeble in the first instance, would receive their full development hereafter. Witness then described and explained the different machines by which electric currents are, in the present day, generated.

The Chairman asked the witness if he could say as to the practical point as to how electric currents are applied in the process of electric lighting?

Witness. They require to be regulated, and I think I cannot do better than exhibit an example of a regulator—I think it is Foucault's. This is what we call an electric lamp, and the light is formed by causing the electric current to pass between carbon points made of carbon artificially compressed. The points are made from powdered gas coke, re-compressed enormously. The current is brought to them by means of the regulating apparatus, and is led to keep the two carbon points at the proper distance apart, for, as you are aware, they waste, and of course, as they waste away too much, the interval between the carbon points would finally become so great that the electric current could not leap over it; but, in order to keep them together, such an apparatus as this is used. It has a small electro-magnet, and when the current is strong this electro-magnet draws the carbons together, and, as long as the current continues strong, it keeps the carbon points at a certain distance. The consumption of the carbon goes on; the interval increases, and the current becomes weak; the resistance to the passage of the current augments in like manner. The current thereby becomes enfeebled, and finally a spring, which acts against the magnet, overcomes the magnetism of the electro-magnet. When that is done the two points come together again, until they are arrested by the path of thorough-put. So that you have a series of alternations between the carbon points. You have not continuous action; you have the carbons wasting away, and then the mechanical contrivance sets them apart again, but still, of late years, great improvements have been made in the electric lamp. We have for many years had these electric lamps in lighthouses at Souter Point, at the South Foreland, and elsewhere, and they act admirably; still, they are somewhat complicated, and in order to do away altogether with the necessity for these regulators, we have the device of Mons. Jablochkoff—what he calls the "electric candle." It is in use at the Grand Théatre Lumineux and in other places. It consists of two rods of carbon separated from each other by a more or less insulating substance, and the current passes from the carbon between these two rods by a little bit of carbon placed horizontally over the top of one rod to the top of the other; and the current passing up one of the rods goes through the bit of carbon and down the other rod. The bit of carbon at the top is very soon dissipated, and you have then the electric light established between the two carbon points. I would here remark, that in the Jablochkoff candle it is essential that the current should be alternated, and that is accomplished by a small piece of simple machine, for instance, and other machines of the kind, the current flow in a certain direction. When that is the case, one pole, as it is called, a one piece of carbon, wastes away more rapidly than the other. In order to make the waste equal, which is absolutely essential in the case of the Jablochkoff candle, you must have alternating currents. That makes all waste of both equal. The candle melts away without adding at all to the light. The candle is made of kaolin, which is pipe clay, and plaster of Paris, basically, inasmuch as it does not at all add to the light. But, by reason of the alternation of these currents, the carbons burn down equally, and you have always the two points at the same level. Where the current is direct one pole burns away nearly as fast as the other, and, therefore, the two poles must be kept at equal heights and equal distances, the rate is very large or candle no doubt the great source of the light, is the incandescence of the solid carbons; they are raised to a degree of almost solar intensity. But you sometimes see remarks made in the newspapers that the solid carbons are volatilised, and that is the source of the light; that is not so this. The bluish tinge is due to the arc—that is to say, to the state of the air between the two carbons, for they must always be separated by a given interval. There is a blue light there, and inasmuch as the earth magnetism usually acts upon it so as to bend the flame, it is called the "voltaic arc." The light is undoubtedly due to the incandescence particularly of the solid carbons and partly of the little particle of solid carbon passing from one point of the other; but I do not entertain a doubt that by far the greater part of the light is due to the incandescence of the solid carbon points themselves.

In the explanations which you have hitherto given us, the electric current is also a single field of very great intensity. Can

THE JOURNAL OF GAS LIGHTING,
WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, MAY 6, 1879.

Circular to Gas Companies.

As our readers will see in another column, the Select Committee of the House of Commons on Lighting by Electricity have begun their sittings, and commenced with the examination of Professor Tyndall. We have mentioned this as likely to be the preliminary statements of the Professor, in which he described the discoveries of Volta and the earliest practical application of electric light, and then brought it down to the days of Faraday and Wheatstone, would, as it did, embrace. Something more might have been said about the production of the light by a metal battery, the cost of which was gone into so fully by Liebig. Our continent friends, however, carried us back to the days when we obtained the light by means of Wollaston's batteries, and generally succeeded in getting inflamed ayes. This state of things has, however, greatly altered, and the dynamo-magnetic machines now produce the light at much less cost, while improved lanterns obviate the ill effects on the eyes which resulted from the employment of open carbon points. So far as Professor Tyndall's evidence went, the actual object which the Committee are sitting to investigate can hardly be said to have been advanced. We have not been told anything of importance which was not known before, by those who have studied the question of electric light anywhere but in lighthouses, and not much about that. We should have been very glad to have been told more, because, if we remember rightly, it has never been settled to what extent the electric light will penetrate a fog. It must be remembered that the intensity of the light cannot be increased, whatever may be the condition of the atmosphere; on the contrary, when Mr. Wigham's burners are employed, as on the coast of Ireland, two, three, or four rings may be used, according as it is necessary to increase the intensity and penetrativeness of the light. Professor Tyndall was not closely examined as to my opinions he may or may not entertain regarding the applicability of the electric light for public and domestic illumination. With the discretion of a scientific man who has a knowledge of the blunders of his predecessors, he avoids the dogmatism of Sir Humphry Davy and Sir Joseph Banks, who laughed to scorn the idea of illuminating streets and houses with coal gas, and wisely admits the possibility that some day electric lighting may come into more general use; but he acknowledges that the electric current cannot be established without interruption, and that even if it were, within a comparatively short distance, renders it worthless for illuminating purposes. This is a highly important fact; for all the grand schemes which have been devised have been derived from the brains of geniuses who have dreamt that the electric current could be carried any distance, and subdivided at any number of intervals. There was once an idea that gas might be made in the Dunbar coal-fields, and sent up to London to be distributed. There was some sense in the proposal; but, of course, it was never carried out. The idea, however, of a large centre for the production of electricity, such, for example, as has been projected for the supply of a city of the magnitude of Liverpool—that is to put it fairly according to our present knowledge—is now shown to be absurd, while it is likely to be done in the first place is to effect an improvement in the steadiness and colour of the light. It seems not even to be well understood, what occasions the fitful flickering of the electric light, which now causes so much discomfort. It may be impurities in the carbon points; it may be the want of efficient regulating. In any case, the result of the imperfections in the carbons and regulators is the production of undesirable annoyance, which if will, no doubt, be soon overcome.

The most valuable evidence was the well-known Electrician and Engineer, Dr. C. W. Siemens, whose practical knowledge of the matter is perhaps unsurpassed. It cannot be said that the learned gentleman's evidence was calculated to encourage Corporations and Gas Companies to go into the electric light business. We are candidly and faithfully assured that the light is capable of many special applications, and Dr. Siemens appears to believe in the possibility of setting up great centres of electric force, from which large subdivisions—copper mains, or three inches in diameter—shall convey the electric energy necessary for the generation of the light as a large source of points. It is acknowledged, however, that every subdivision of the stream of force greatly reduces the energy beyond the point of division. It is like diverting the water of a river into numerous channels, by which the main current is specially reduced to an infinitesimal proportion.

Up to the present time very little has been said by the witnesses which has suggested any ideas relative to the necessity for legislation. When the Committee met the projects of Corporations and Gas Companies with regard to the distribution of electric force were mentioned, but in all probability, the Postmaster-General would be found to be the strongest objector to their schemes. This has turned out true. In the evidence of Mr. Preece, the Electrician to the General Post Office, which we shall publish in our next issue, it will be seen that objections are raised to the use of the wires for the conveyance of electricity for illuminating purposes, in contiguity to telegraph wires. We can see many reasons for this; for induction from large cables might seriously disturb the currents passing along the telegraph wires. Mr. Preece thinks that the two systems should be placed at least six feet apart, and here is a case for legislation—the first we have met with; and whenever a Bill comes before the House of Commons for the purpose of sanction for the application of electricity for illuminating purposes, this point is certain to be borne in mind. For the rest, nothing that can be considered to call for legislative interference has been brought up; but more will have to be said when we have the complete evidence before us.

The Gas and Water Companies Association, have, in conjunction with the Chartered Gas Company, resolved to watch over the proceedings of the Committee, and to tender evidence. For this purpose they have selected a number of eminent scientific men and engineers, the London Gas Engineers, together with Mr. Michael, Q.C., the latter to give evidence on the legal bearings of the case as it is presented to the Committee. As stated above, the proceedings have, up to the present, been possessed but little interest to Gas Companies. Next Friday, the Agents of the Société Générale d'Electricité will be examined, and, after them, some witnesses from Local Authorities will be heard.

The scheme for the amalgamation of the South Metropolitan and the Surrey Consumers Gas Companies has been submitted to the Board of Trade, and in the course of a few days will be in the hands of all interested. Taking a cursory glance over its provisions, we see nothing to call for any serious opposition. It will, of course, be challenged; but we cannot think that many valid objections against it can be adduced. In the first place, it

Gas in Paris.

Hoag 79

In consequence of the influence associated with the Universal Exhibition at Paris, that highly progressive undertaking, the Parisian Company for Lighting and Heating by Gas, made a still further advance last year, and a very large advance into the bargain. The political history of Paris is reflected rather curiously in its gas consumption. The Second Empire was, at any rate, a period of material prosperity until the fatal moment in 1870, when Napoleon III. and M. Emile Ollivier went to war with a light heart; and accordingly we find that the consumption of gas in Paris experienced a rapid progress year by year—a progress which was not only rapid, but also unchecked. In 1855 the consumption of gas made by the company under notice stood at 60,771,400 cub'c metres, in 1860 at 75,618,-022 cubic metres, and in 1865 at 116,171,727 cub'c metres. In 1869 there was a further advance to 145,199,624 cubic metres. In 1870, however, came the terrible Franco-German w.r, and the encircling of the French capital by the armed hosts of Germany. The result was that in 1870, the Parisian Company for Lighting and Heating by Gas, sold only 114,470,969 cubic metres of gas in that year. In 1871, the siege of Paris, and the communist revolt which followed it, still further affected the business of the company, and its sales declined in that year to 87,481,916 cubic metres. But in 1872 there was a rapid recovery, and ever since that year the business of the company has been developing itself with remarkable rapidity. In 1875 its sales had grown to 175,858,241 cubic metres. In 1876 they had further expanded to 182,209,726 cubic metres, and in 1877 to 191,197,-228 cubic metres. Last year there was a still further advance to 211,919,-617 cubic metres.

It is rather curious to observe that the day consumption figured in last year's total for 46,877,003 cubic metres. These figures were 6,203,167 cubic metres in excess of the corresponding total for 1877. This consumption which arises exclusively out of the use of gas for industrial and domestic purposes, has made great progress of late years. Thus since 1875, it has increased to the extent of nearly 50 per cent. The company's receipts for gas, which amounted in 1877 to 1,998,223l., rose in 1878 to 2,161,026l. The number of public lamps served by the company last year was 46,001 showing an increase of 2,300, as compared with 1877. The productive power of the company's works, which stood in 1877 at 228,500,-000 cubic metres, was carried last year to 230,000,000 cubicmetres. The company's system of pipes was increased last year to 736½ miles, a length very nearly representing the distance from Paris to Lisbon.

The Universal Exhibition of 1878 afforded the company an opportunity of illustrating the successive improvements introduced into its plant and into its processes of manufacture. A special pavilion was constructed for this purpose in the Champ de Mars, near the Porte de Seine. This pavilion comprises in a relatively limited space a very complete collection of the models, specimens, and products associated with the company's industry. These drawings and plans were exhibited, showing at a glance the manufacture of gas for lighting purposes, as well as the treatment of various sub-products, and the distillation of coal, coke, gas tar, and ammoniacal liquor. There was further shown a collection of the numerous products which science has succeeded in extracting from gas tar, and from which industry has derived for the coloring of fabrics a series of material of tones as rich as varied. The collection further comprised the company's improved gas furnaces, its special exhibition junctions, its coke warming apparatus, its gas engines, and its refractory products. The pavilion attracted a good deal of attention on the part of the public, and the International jury recognized the value of the company's efforts by awarding it a grand prize—that is to say, the highest reward accorded to exhibitors. The company does a great deal of work, and realizes its r. ward in a handsome r ofit. In 1874 its 50l. shares received 2l. 6s. per share; in 1875, 2l. 8s. per share; in 1876, 2l. 10s. 6d. per share; in 1877, 2l. 8s. 6d. per share; and in 1878, 2l. 12s. per share. It is not surprising with such dividends as these to find the company's shares standing at about 66l. each.

Circular to Gas Companies.

The Committee on the electric light, of course, continues their sittings. To say the truth, very little turns up which is of special interest to Gas Companies, or really bears on the question referred to the Committee. The reference was for them to consider under what circumstances it is desirable to "authorize Municipal Corporations, or other Local Authorities, "to adopt any schemes for lighting by electricity, and to consider "how far and under what conditions, if at all, Gas or other "Public Companies should be authorized to supply light by electricity." No evidence affecting this reference has been offered; no suggestions of any necessity for legislative interference with the supply of the electric light, other than those we mentioned last week, have yet been put forward. It is given in evidence that cables conveying electricity for light must be kept far apart from telegraphic wires, and it is also in evidence that Electric Light Companies can make large profits. Here we have ground for that interference of legislation; but these are the only two reasons shown for such interference. To-day, we shall have that evidence of Sir J. McGael Hogg and Mr. Norner, the latter of whom will, of course, give us the views of the Board of Trade on the subject. Here the question will begin to get interesting. Hitherto the mere description of the various systems of electric lighting, the photometrical results, and all that, have possessed but little interest to those who have followed the question through all its phases. The photometrical value of the electric light, as compared with gas, is not easily ascertainable, and we place very little reliance on what has been said on the matter. What we know is, and what is placed beyond a doubt is that gas burnt in sufficient quantity can fairly compete with electricity, and, indeed, beat it out of the field. The report of the Engineer and Chemist to the Metropolitan Board of Works, relative to the experiments on the Thames Embankment, shows conclusively that electricity employed for lighting purposes is dearer than gas. It is stated, in the report of the two gentlemen we have mentioned, that the cost of the electric light is 9·73d. per hour, and that for gas equivalent to the electric light in an opal globe is 2·00d. per hour, and in a frosted globe 3·50d. per hour. Hence, on the score of economy, nothing can be expected to result from its adoption for public lamps.

As to return, however, to the necessity for legislative measures, we may remark that, whatever may be said by the eminent witnesses who will be examined to-day, nothing has been shown up to the present time which could possibly militate against the supplying of the electric light by Municipal Corporations and Gas Companies, supposing that the light was ever to be made a useful institution. We have always regarded the withdrawal of the Bills promoted by Corporations and Companies as rather illusions to their interests. It was, however, rendered advisable by the action of external influences. It is quite clear now that no legislative interference will be necessary with regard to the electric light, further than what we have referred to above. Mr. Farrer may possibly have his particular views, but we are certain that they cannot differ from our own. Limit the profits of the Electric Light Companies, and protect the Postmaster-General, and everything is accomplished.

The improved gas lights in Waterloo Place have been removed earlier than we expected, by request of the Vestry. Comparisons, as Mrs. Malaprop observes, are "odorous," and probably the Vestry of St. James's did not like to see the brilliant light in proximity to the dull glimmer they ordinarily furnish. We have repeatedly said that Vestries will not pay for good illumination. They are not bound to gas, which affords them the best light they can get; but whatever system of lighting may be recommended, it is certain that it will not be adopted if it involve any additional expense. We cannot say that the parish of St. James is the worst lighted in the Metropolis, but the illumination certainly might be improved, and we are sure that the respectable inhabitants of the district would willingly pay their quota towards the cost of the additional light. The Gas Company, of course, do not deplore the decision of the Vestry, for they supplied the gas gratis, and Mr. Sugg is not inconsolable, seeing that he quickly disposed of all his lamps. The action of the Vestry is, at all events, reprehensible, and it leaves us with little hope that any great improvement can be effected in the public lighting in the Metropolis.

THE STRONG FUEL-GAS IN SWEDEN.

GEORGE S. DWIGHT, Esq.:

DEAR SIR: A furnace for producing gas through the decomposition of water, according to the Siemens method, having been erected by me during winter, according to this Works, Stockholm, we, the undersigned, do the last winter in the Atlas Works obtained in the manner; that the above herewith that the results hitherto obtained in the said furnace with the assistance made with the employment of the gas, fully agree researches hitherto made with the employment of the gas, fully agree with the statements previously given by you, as well verbally as in a printed pamphlet; and that we are heartily convinced, through the progress and usefulness of the gas already employed, of the large future success of this gas as well for metallurgical and technical as for domestic purposes. Thus we confirm the statement that fuel-gas has been produced in this furnace by employing as well English coke, coals from Hogarna in Sweden, and anthracitic coals from Wales, in the generator, and coal-dust or peat-powder in the hopper; that the composition of the gas, by employing these different fuels, has been exactly the same as shown by the analysis; that the gas has by us been employed for welding wrought-iron, for smelting in crucibles as well pig-iron as steel; and that the results of these three different experiments have been very satisfactory as to the heating power of the gas; and that the economical results obtained by these operations, though made on a small scale, are such as to fully satisfy us of the superior economical results that must be obtained when the operations come to be executed on a larger scale in furnaces better adapted to the purpose. Thus we are convinced that fuel-gas has been the problem solved.

And in this furnace by employing as well English coke, coals from Hogarna in Sweden, and anthracitic coals from Wales, in the generator, and coal-dust or peat-powder in the hopper; that the composition of the gas, by employing these different fuels, has been exactly the same as shown by the analysis; that the gas has by us been employed for welding wrought-iron, for smelting in crucibles as well pig-iron as steel; that the results of these three different experiments have been very satisfactory as to the heating power of the gas; and that the economical results obtained by these operations, though made on a small scale, are such as to fully satisfy us of the superior economical results that must be obtained when the operations come to be executed on a larger scale in furnaces better adapted to the purpose. Thus we are convinced that fuel-gas has been the problem solved. This furnace will be the best, both effectually and economically, for most metallurgical purposes.

On the other hand, we can confirm the statement that the employment of the gas for cooking purposes causes extraordinary economy in the household department, and that the cleanliness and convenience of its use must make it a favorite with all housekeepers. Of which we are induced to you for the construction of a similar small baking and cooking stove, of the dimensions inside of 2' 2" × 18" × 18", giving, at a gas consumption of only 110 to 115 feet an hour, a constant heat of 250° C. And in the above dwellings, we have not yet made any experiments; but we have fully convinced of the usefulness, cleanliness, and cheapness of this gas for this as well as for the above-mentioned purposes.

In reference to the adaptation of the gas for illuminating purposes, we have as yet made only one experiment, by conducting it through a vessel filled with cotton moistened with benzine, and by this simple process we have found the gas acquiring a satisfactory illuminating power.

In inviting our gratitude that you have introduced a method that we are convinced will be most important to our country, at the same time we sincerely acknowledge the expert, straightforward, and gentlemanlike manner in which you have conducted the work.

We are, sir, with the highest esteem, yours sincerely,

LUDOVIG NORDL, of St. Petersburg, Russia.
OTTO TORELL, Director of Geological Survey of Sweden.
C. A. DEBAVE, Director of Metallurgic Dep't of Iron and Steel Masters' Association of Sweden.
E. FRAENCKEL, Manager of Atlas Works, of Stockholm, Sweden.
ANDELL, Engineer Stockholm Gas-Works.
OLOF. WITTENSTROM, Metallurgical Engineer.

STOCKHOLM, SWEDEN, May 8, 1875.

Gas Engines.—During the year 1873 we sold two horizontal engines on Lenoir's system, 10 vertical engines on Otto and Langen's system, and 30 of Otto's horizontal engines; making the total number of 320 engines—horizontal and vertical—that have left our works during the past 16 years. The two latter kinds of engines, which, unlike the former, do not require the employment of electricity, are susceptible of a tolerably large number of applications, and, for small manufacturing operations, might be used with considerable advantage.

We may estimate at 1,000,000 cubic metres (35,300,000 cubic feet) the amount of gas consumed in 1873 by the gas-engines usually working in Paris.

THE NEW GAS-LAMPS IN QUEEN VICTORIA-STREET.

ALMOST all the necessary information for making accurate estimates of the illuminating power and cost of the electric light, as compared with the ordinary street gas illumination and its cost, have been set forth in our columns in our notices of the reports of Mr. William Haywood, the City engineer and surveyor, and the assessment report of Sir Joseph Bazalgette and Mr. Keates. We have now before us the report of Mr. Haywood on the new gas lamps in Queen Victoria-street. In January last the Gaslight and Coke Company applied to the City authorities for permission to show experimentally what could be done in street illumination, by means of improved gas burners in Queen Victoria-street, between the Mansion House Station of the District Railway and the Poultry. The company received permission to make this experiment at its own cost. The company therefore commenced the removal of the common burners and lamps on the 21st February last, and the substitution therefor of Sugg's argand governor burners and lamps. Since the 4th of March the whole of the lamps in the length of the street have been so fitted and in use. The burners are of two sizes, the smaller consuming 22 cubic feet of gas per hour, and the larger 30 cubic feet. The smaller burners have two rings, as illustrated in THE ENGINEER of the 7th February last, at page 106, and the larger have three rings. They are provided with a main light, a very small burner, burning about a quarter of a cubic foot of gas per hour. These are constantly burning, and by their aid the large burners become self-lighting by merely turning the gas on. These burners and lamps are fixed on the common lamp standards, there being thirty of the smaller and five of the large burners, the latter being on the standards at the large entrances, or resting places. Fifty-five of the different reliugos or resting places. Fifty-five of the ordinary burners are suspended by the thirty-five referred to. The total illuminating power of the thirty-five lamps is estimated, by photometrical comparison with the Gas Referees' standard burner, to be equal to 580 candles, the double-burner lamps to 24 sperm candles, and the treble-ring 200 candles, with the consumption above stated. The thirty-five smaller self-lighting burners of the temporarily displaced lamps should give a light equal to 210 standard candles, each being equal to fourteen candles, with a consumption of 5 cubic feet per hour. The ratio which the estimated quantity of light given by the thirty-five experimental lamps was likely to bear to 1, as compared with the estimated light given by the ordinary lamps, the ratio of the consumption of gas being respectively as 2·25 to 1. The relative cost of the two systems is given as £177 2s. 6d. per annum, and £208 2s. 6d. per annum, the former cost being furnished by the gas company to Mr. Haywood, while the latter is by the gas company to Mr. Haywood, while the latter is by the London contract price paid by the City Commissioners. The relative cost of the new and old system is thus as 850 to 1. Thus the report result roughly stated is that the new system gives four and a-half times the light given by the old system, and costs approximately three times as much.

On the Thames Embankment the electric light cost 1·73d. per hour, while gas to produce light equivalent to that of the electric light cost 1·92d. per hour. On the Holborn Viaduct the relative cost of electric and gas light was as 7·5 to 1, the gas-light being 7·5 to 1; Under present conditions, therefore, the cost of improved gas illuminating power is quantities of light, materially cheaper than the electric light. It may of course be urged that the electric light is steadier, and can be made in the use of electricity are now obvious; but much may also be said in the same way as the result of the experiments with Sugg's large burners. The experiment in Queen Victoria-street does not, however, show, as Mr. Haywood says in his report, that the public ways may be lighted in a very ample and satisfactory manner by means of gas. Mr. Haywood, however, evidently looks upon it as doubtful whether the increased quantity of light is, in the opinion of the general public, worth the increased cost involved, for he says that "the question to be considered, before the increased cost is incurred in street lighting, is whether the public necessities are such as to render specially necessary a more expensive mode, than that now ordinarily in use."

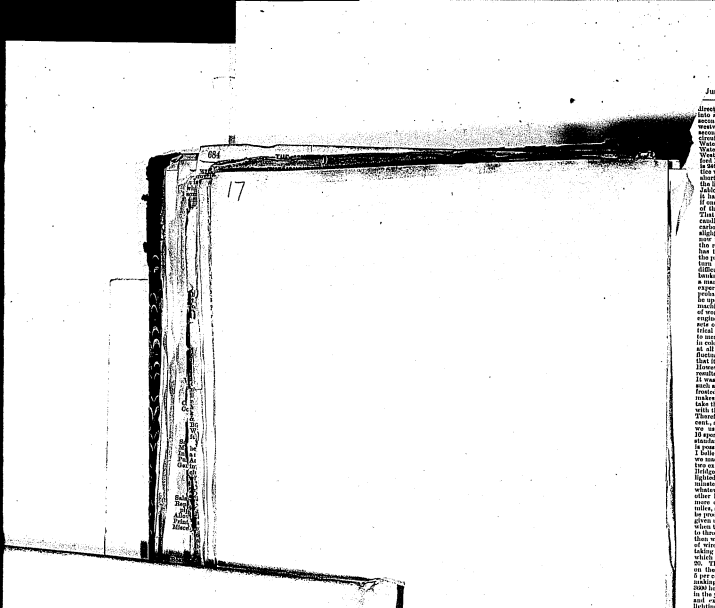
It seems to us that though the public would be pleased to have the good bright light, that it will not care to pay extra for it, when a very fair amount of light can be obtained for £208. Those prices are, on one side, those charged by the company, while the others are from the estimated consumption. It would be advisable to wait a while ere for the adoption of any of these new lights. It might be worth, while to pay a little more for better lamps on some such plan as Mr. Sugg's, but improvements as yet to be made both in the burners and glasses for the large burners, and in the methods of lighting by electricity. One experiment with the electric light must be necessary. The electric light, at present, is only to have been first placed at the ordinary height of gas lamps, at the side of the street, within a waterfall opal globe. To be efficient, and to give the greatest duty, the electric lamp should hang over the centre of the street at a considerable elevation, under a large reflector, and with a small opaque shade immediately beneath it. The lamp thinks for burning for a long time, and in such a position, has not yet been devised. When it has been it would seem then time to make a definite test of comparison between the old and the new systems.

THE SELECT COMMITTEE ON LIGHTING BY ELECTRICITY.

(Members present: Dr. Lyon Playfair, in the chair; Mr. Alfred Guillemard, Mr. Macdonald, Mr. Monsell-Bruce, and Mr. Russell. Mr. Arthur Moore, Earl Percy, Mr. Puleston, Mr. Spencer-Stanhope, Mr. Chichester Fortescue, and Sir Henry Woodward.)

Mr. Thomas William Keates, examined by the CHAIRMAN.

I am Fellow of the Chemical Society and of the Institute of Chemistry, and am the Consulting Chemist to the Metropolitan Board of Works, and to the Commissioners of Sewers, and to the Corporation of the City. In conjunction with Sir Joseph Bazalgette, the Engineer of the Board, I have been employed in carrying on the experiments with the electric light on the Thames Embankment since the 15th of December last. We recommended a trial of the Jablochkoff candles in preference to any other mode of electric lighting. I may say that in about October of last year many applications were made to the Metropolitan Board of Works for permission to make experiments for the introduction of electric lighting; and Sir Joseph Bazalgette and I were instructed to report upon those various applications. We considered the question, and came to the conclusion that the best system to be applied in an experimental in street lighting was the Jablochkoff; and I may state very broadly what led us to that conclusion. In the first place, that system had been in operation in Paris for more than a year previously, and it had taken something like a settled form there. There is at the present the only system by which the light was produced without the intervention of a mechanical regulator. All the other systems that have been employed a mechanical regulator or lamp of some kind, but in the Jablochkoff system that is entirely done away with. Besides that, it was the only system which offered us a division of light. The Siemens machine of Siemerick offered to give us 20 lights on the Embankment, and that appeared to us to be a matter of much importance, that it should subdivide the question. However, taking those three matters into consideration, we thought that the Jablochkoff system was the best to serve for the practical experiment. We also thought that was put on the Embankment to work the Gramme machines was nominally a 24 horse power engine. The maximum power that has been applied from the engine has been 23-horse power for the 22 lights. The exact cost of the motive power was 21·9d. for the 22 lights per night of 6½ hours. The cost would be 17·8d. per electric light per night; or, bringing it down to the cost per standard candle, it would be 0·95d. per night. The cost of the machinery was as follows:—The engine complete, with the governor, £162; the two Gramme machines, the exciter and the distributor, £262; the driving-bands for the engine and electrical machines, £35; and 2000 metres of conducting cable, £200; making a total of £1260. That is the cost of the machinery as it stands; that is to say, with the 24 horse power engine; but it is understood clearly enough now that a smaller engine is powerful for the purpose. If we had had a 10-horse power engine instead of a 24 horse, we should then have the cost of the engine, £250; the Gramme machines, as before, £262; the driving-bands would be lowered to £35; and the conducting cable would be £200, as before; making a total of £996 altogether; and it has since been that we have calculated the interest and wear and tear in finally working out the cost of the electric light. On the Embankment there are two electrical machines —the smaller in which the current is generated as a continuous or



direct-coupled to an engine driving current and distributed. Passing away from the second machine, the current is led to four distinct circuits; and those proceed, one Westminster Bridge and taking in five lamps eastward; the second takes in the Victoria Embankment and Waterloo Bridge; the third circuit goes eastward from Hungerford Bridge, taking in five lamps towards Waterloo Bridge; and the fourth circuit leads off from the same bridge to Westminster Bridge, making altogether 20 lamps.

The distance from the engine-room to Westminster Bridge is 3,000 feet; the circuit between that and the nearest lamp is 3,015 feet; and the circuit from there onwards to Waterloo Bridge is 3,030 feet. The distance from the engine-room to Waterloo Bridge is 3,030 feet. In practice, the current of 3,015 feet. There is no perceptible difference between the lights on the two circuits. I think one of the great advantages of the Jablochkoff system of electric lighting was (I say "was," because, I believe, it has been corrected) that, as every lamp was part of the circuit, if the resistance of those lamps could always be lightened, the five lamps would cost, and the light would be increased. That defect, I believe, has been remedied beginning entirely afresh. candle, which, by altering the character of the materials used for making a carbon, they are able to change the resistance of the medium between the two slightly conducting material, I believe, is introducing, and extinguished. Some now the candle, if it becomes extinguished, can be lighted again by the passage has to be passed from one candle to another by switching; and, up to the present time, I believe, it is impossible for a man to go to every lamp and turn on the current from the exhausted candle to a new candle; but that difficulty has now been overcome. I saw a very simple arrangement on the Embankment, the switching is done from one central point near Waterloo Bridge; a man switches all the new candles as they are required, and the whole light as experimental lighting up of two of the circuits was accomplished, and perfectly to-night the four circuits will be lighted up, and then the dynamo machine. The individual lights worked by two additional Gramme machines. I think there is no doubt whatever that the engine is capable of working 80 lights each, and I am very much surprised from the maker of the sets of Gramme machines. We have used the power of working 60 lights from three trial experiments as to the value of the light. It is a very difficult thing to measure the electric light, for two reasons; first, the light is difficult to compare with the standard light, and there is no standard I know of that at all approximates in colour; then, besides, the electric light is very fluctuating, and some experiments in effect give the idea is changing, or that it requires more experience before you are able to measure it at all. However, we finally did measure the light, and were prepared to give you the results. There were three conditions under which we prepared to give you the It was measured as a naked light; then it was measured as the light was measured. Then as are on the Embankment generally, and it was measured in the frosted globes. All the measurements were taken horizontally, which is not the usual practice, but it appeared to me it was the fairest way to take them. The principle of the naked light is equal to 1791 sperm candles; with the opal globe 1570 candles. Therefore, the loss of light with the frosted globe 240 candles cent., and with the frosted globe to 22 per cent. We used for the standard one of our lamps, giving a light equal to 16 sperm candles. I am quite of opinion that the loss by the frosted globes is possible, because the disproportion is so great that I do not think it I believe it is the best method hitherto. On the 14th and 15th of March we made, I think, a very interesting experiment. We joined together the two extreme circuits, the Westminster Bridge circuit and the Waterloo Bridge circuit, making the length of wire up to 7,345 feet, and when we lighted up the lamps on the extreme parts of this circuit, that is, at Westminster and here at Waterloo Bridge, there was no apparent difference whatever; every one agreed that the lights burnt just the same as the other lights were burning. The next night we put in 1752 feet more of wire, making altogether a length of wire of 9015 feet, or 750 miles, and no effect whatever in the intensity of the lights appeared to be produced. We are intending to carry on that experiment further; it was given up at the time, because there was not sufficient time to do it, and when the new arrangement is complete to Blackfriars Bridge, we intend to throw the Westminster circuit and the Blackfriars circuit into one and shall have an opportunity of testing the effect to about 21 miles of wire. The cost of producing the electric light on the Embankment, taking all the charges for management, repairs, &c., is about 4½d. per light, which would be reduced to a certain extent if we had 80 lights instead of 20. Those figures are obtained from the accounts of the Board.—The interest on the amount of capital expended to establish the machinery, £2,000, at 5 per cent., is £10 10s.; and the wear and tear, at 10 per cent., is £21, making a total of £31 10s. I assume that the light may be burned about 3000 hours in the year. I find the gas-lamps are burned about 4300 hours in the year; but, of course, considerable time is taken up in lighting and extinguishing the gas lamps, which would be saved in electric lighting, which I have already explained is equal to 2½d. per light per hour; 80 lights would represent the time fairly enough. That brings the cost of the interest and wear and tear down to £12 10s., and the cost of the light at 2½d. per hour. Then we have to add the cost of working the steam-engine, which I have already explained is equal to 2½d. per light per hour; and when the new arrangement is complete to Blackfriars Bridge, we intend to put the whole of the candles at 2½., and that I am bound to say is completely, but I will explain to you my reasons for putting it at that. When first the experiment commenced, the Board proposed the Metropolitan Board of Works should pay for the light per hour. From the end of March they have undertaken to pay 2½d. per light per hour; but since the 15th of March they have undertaken to produce the lights upon a different principle altogether. They are now under contract with the Board to supply the lights at 2½d. per hour net, covering everything; they take charge of the machinery, and pay all the expenses connected with it, and are to receive 2½. per light per hour.

Mr. Pullman.—Do they own the machinery?

Witness: They have the use of the machinery; they lent that to the Board from the beginning; but the whole responsibility is put upon them; it is hired by the Board. Therefore there is the interest of the machinery to be added.

What I want to get at is the total cost to the Metropolitan Board?—That would come out something very small indeed. The £12 10 for interest and wear and tear only comes to ½d. per light per hour; and, of course, if the Board purchased the engine, it would come out under ½d. With regard to the cost of the Jablochkoff candles, of course it would have been absurd, in the face of the reduction the Société have made, to reckon 5d. for the candles. I am not at liberty to say much about it; in the French reports, and what I have heard from our own engineers, I consider, 5d. is a fair sum to put down at present. I think 3½d. would be nearer the but still I have put it down at that, and it brings the whole charge up to 6½d. The items are interest on capital and wear and tear, 2½d.; current candle, 3d., making altogether 9·75d. That is upon the present 20 lights. Examined further continued: I do not know what will be the reduction upon the cost now that it is extended to 40 lights; but it is quite obvious there must be a very considerable reduction. The figures in relation to the working of the engine are these: *For 12 nights of 81 hours each, 972 hours*, 27 tons of coal, costing 2s. 2½d.; 20 lbs. of coal to get up steam, 3½d.; wood to light fires, 1d.; oil for day, 1s. 7d.; two men to defend engine, and 1 to attend to electrical machines and candles, 12s. 6d.; and two men assisting, 10s.; altogether that comes to £2 11s. 7½d. I suppose the wages would remain much the same, whether we had the engines for 20 or for 40 lights; the cost of the oil per day would be increased, and the consumption of coal by the additional electrical machines; and the quantity increased by the furnace, would, of course, be largely increased; but I do not suppose the wages would rise more than half, at all events, to the end. Then, comparing the cost of the electric lights with the cost of lighting by gas, and also the effect, I have taken the number of gas-burners between Westminster and Waterloo Bridges in the Government offices and the parapet lawn each two burners, as that there are really in the houses on the Victoria Embankment which is lighted by the electric lamps. I have calculated a certain quantity of light which would be given by those burners. They consume 5 cubic feet per hour (Gramme cannel gas); and those farther down on the Embankment, where all the gas-burners are the same, consume 3 cubic feet per hour; whereas the gross amount of light from the gas, is equal to about 1200 candles; whereas the gross amount of light from the electric lights is equal to about 2400 candles; 24 is 20 times 120 candles. That is the gross amount of light. With the opal globes the gross light comes to 3696 candles, or 2·2 times as much as is given by the gas; whilst with the frosted globes the light amounts to 2280 candles, or about 1 times the light given by gas. Then, of course, a great deal depends upon the arrangement as to the unfavourable position in which the electric lights are placed—all along on one side. I think if you want to get the best effect from the lights they ought to be in the middle of the road. The light from them is thrown partly on the river, and, as the Embankment is about 100 feet wide, I think there is considerable loss of light by the distance which it has to pass over to the opposite side. We should get a more economical result if lights be able to throw a light of 700 candles, for supposing one of the candles that would be reduced to 350 candles on the footpath on each side. As to the comparative cost of the electric light and gas, it is not easy to deal with the question of naked lights, because no naked electric light could never be used; but the light in an opal globe is very much softened and equal, and a frosted globe to 350 candles. To produce a light of 122 candles with gas with one of the large Sugg 256 candles, about 80 feet of gas would be consumed. The cost of 80 feet of gas would be about 5d. per hour; and the cost of 35 feet would be about 2d. per hour. I have already stated that the cost of the electric light is 2½d. per hour, and this is now a comparison between those lights, light for light; that is, the gas equivalent to the electric light in the opal globe is 5d.; and the cost of gas equivalent to the electric light in the frosted globe is 2½d.

The Chairman: If you placed the electric lights in more favourable positions in the middle of the road, would you require the same number of lights?—I rather difficult to say, because you have to light the whole width of the road, and if you diminish the number of lights, of course the loss of light is increased. I should say that you would require more lights, but you have a great deal of light in one place, and but little in another. Therefore, whatever may be the number of lights, I think one that is placed the light in the best way. The one great difficulty with regard to electric lighting is that whether you require a large light or a small light, you are obliged to accept the large light; and at present, so far as I am aware, there are no means by which this difficulty can be overcome.

If you raised the lamps higher, although you increase the light, you enlarge the area over which it spreads?—That is so; but it seems to me there is a great waste of light in the direction of the river, and not much in an enormous extent. It would be to the lights on the Embankment are at about the best height. Perhaps they are rather too high; they were, say, 6 feet higher, it might be better; but when you talk of putting up a light 50 or 60 feet high, it would entail very considerable loss of light.

In the present price of production, as far as your experience goes, even if you had the cost reduced to one-half of 2½d. would be more economical than electricity for the production of light?—I was unaware of light?—That is obviously so; but, at the same time, I think the electric light would be very much allowed in a little while; the putting on the additional lights will produce a great effect. If it were possible to put on 40 lights instead of 80, for instance, the 2½d. would, no doubt, be largely reduced. Then the cost of 2d. for the Jablochkoff candles is rather excessive, and I think that it will be found that there is another candle which I only heard this morning, I understand a modification of the candle has been made, so that it will last for two hours, and that candle is to be put at 3d. per candle. The candles are supposed now to burn for an hour and a half—in practice, in fact, they do not burn quite so long; but I am told they have been made to burn for about three hours, and that would be a very great economical candle.

I think giving evidence as a scientific man as to the actual results obtained up to the present time by your experiments, you are, of course, not able to give an opinion as to the probable cost of the electric light; you could not do that. I think I should be wrong if I were to say that I looked to those figures. I think that, as time goes on, the figures will be modified. My own feeling with regard to the electric light is, that it is undoubtedly established itself. I am not one of those who anticipate any sort of competition between gas and the electric light; I do not think there is any danger at all of that; but, at the same time, I think that the electric light will be found very valuable for many purposes. I have seen, in the lights on the Thames, that there are certain defects that have been talked about. The light, I believe, is very unsteady. We have never had a serious mishap. We have never had a check that could be looked upon as a practical difficulty; and, with regard to the quality of the light, I cannot see that there is anything to complain of, so far as the Jablochkoff candle is concerned. It is a soft, agreeable light to the eye, and I should say that, generally speaking, I used its eyes, I suppose, if one of the lights went out, I should be very much annoyed at the apparent as to be distressing; but for street purposes, and for the lighting of large factories, where that flickering would be removed by the use of perhaps more than one light, I do not think it amounts to anything that could be called a practical defect. When you come to attempt to measure the light, and get it upon a screen, where you observe every slight flicker, of course it is very apparent indeed; but if you look at the lamps in the street, I am of opinion that those lamps are steady enough for all purposes of practical illumination. I have seen, myself, in the lights on the Thames, slightest chance of its competing, in a general way, with gas. There are defects about the electric light which, unless some essential change takes place, must entirely prevent its application to ordinary lighting purposes. The single fact that at the present time you cannot divide the light, and that you must take the large light or nothing, is, of course, an insuperable impediment to its use.

Sir,—In reply to your letter of the 2nd ult., calling attention to the Electric Lighting Company, Limited, Bill, and asking for the Board's observations on clause 2 of the Bill, I have been directed to submit, for the information of the Secretary of State, the following remarks:—

The question whether the electric light should be introduced here has been, both in no small one of great importance, but the Board is of opinion that, if such powers as are applied for in this Bill are given, the whole sense of the undertaking should be contained in a Bill in order that the subject matter may be fully before Parliament, whereas the Bill proposed hardly seeks power to deal in a very important manner with public highways and property.

It seems doubtful whether, as the Bill stands, the Board would have any control over the breaking up of the streets, which would be necessary for the purposes of the Bill. By the Thames Conservancy Act, the Metropolitan Board has a veto in the Tideway and the Docks, and not in the Metropolitan Board. Supposing, however, that the Bill did give the Board such control over breaking up the streets, the public thoroughfares, it would be necessary that the Bill should also provide for the Board fixing the amount of capital and in the case of dividend, and providing by section clauses that no dividend should be paid exceeding 10 per cent. and that by means of a sliding scale of dividend, as recently applied to Metropolitan Gas Companies, some security may be given to the public that the land-lighting should be carried out with economy and efficiency, and that the public had not to pay, either at a remote period or otherwise, for undue profits. Further, if any benefit it would have were to the public it, when gas and water companies originally acquired compulsory powers, proper provisions were inserted for purchase by the public.

Apart altogether from these considerations, if powers are to be given to a new body to break up the streets, it might be desirable to consider that question in connection with the Bill now before Parliament for the Consolidation of the Metropolitan Police Acts, and whether some more effectual control should not be given to the Board. In the present case, however, with a Company whose capital is to be only £200,000, and which is to be limited to 10 per cent. dividend, and in some respects peculiar, it would be unfortunate if the Board were involved in an expensive inquiry before Parliamentary Committee upon the question of the introduction of the electric light. The Board therefore, unless the Bill be amended in the sense suggested in the Bill, and the Secretary of State will, no doubt, be requested to present its objection on several grounds. It is hardly necessary, but the Board appreciates that the Vestries and District Boards of the Metropolis would almost unanimously oppose the measure.

(Signed) J. S. WARDROP.

Lord LINDSAY: As to the question of appeal from the Vestries decision to the Metropolitan Board of Works, would the Board be a court of final appeal?

Mr. HAWKSLEY: Yes; we are the court of final appeal now in many cases.

Do you consider that the Metropolitan Board of Works are sufficient judges of electricity to be a court of appeal? I do not appeal as regards the breaking up of roads. I do not say that they would be sufficient judges as to whether one sort of electric lighting would be better than another.

But practically it would come to that, because the appeal might, at all events, arise on the same questions as you have with regard to gas. You are a court of appeal in the matter of gas. Supposing, for instance, any question arose as to whether the gas was strong in sulphur, or that there are too many impurities in it, and that the effect of a bad illuminating power, your officers inquire into the matter, and you have to decide whether the gas is or is not corrupt in the case of electric lighting, as you have in the case of gas?—We have many gentlemen of great eminence who have investigated gas matters, and they are doing it, in fact, every day. We have a Superintending Chemist, who understands all those matters, and I apprehend that his opinion would be taken and followed.

Then you would appoint an officer specially for the purpose, I suppose, to inquire into questions which may arise in connection with the electric light?—Exactly; we should consider it our duty to do so.

By Mr. HAYWOOD-HANDS: I think that at the present moment the question of electric lighting is in so experimental a condition that it is not desirable to give very large powers with respect to it. That view is founded on what I have read and seen of the experiments. I think it would be a wise course to allow private individuals and private companies, to a limited extent, to do so without compulsory power, to test the further development of the light before giving any larger powers to companies or corporate bodies.

The CHAIRMAN: Would you not give corporate bodies pretty extensive powers to make experiments, and to try the utility of electric lighting in their own districts?

Witness: I think it is most desirable to give public bodies the power of doing so. We are doing it now in the public interest. I may say that the Board, as a board of the electric light being perfected, so far as it has been, we think, perfected, have not committed themselves to any expenditure which went into the matter. We then decided to try it, at some small certain expense, but, being the local authority, we considered that it was an expense that was perfectly justifiable; and I think the result has shown that we were not wrong in what we have done.

You have said that very limited powers should be given to private companies in regard to any monopoly they might have of breaking up streets; but would you give facilities to them?—I think we should give large powers to suitable companies to distribute the electricity. I say, safely, if they considered it to be to the interest of the ratepayers. I do not think so. For instance, in such places as the St. George's Hall, at Liverpool, in large places and squares, or in large buildings, they might try the electric light with great advantage, and test how far it answered against gas.

If a public company, for instance, having charge of docks, might try the light that would be an instance in point; they might have power to light their own docks. In fact, you would like to be the public stage to test the experiments as far as possible?

Having a new invention, the future of which you do not see, you would not be inclined to do anything that might retard its development, whilst you would not give any monopoly in advance of our knowledge upon the subject?—Precisely.

Lord LINDSAY: Is it necessary for docks, or for large buildings belonging to companies, to have powers to break up the streets?

Witness: I should think not. For instance, Messrs. Woodhead have done it at their own cost. I was going on the assumption that powers were required. I could light their premises with it if I liked.

The CHAIRMAN: Supposing, for instance, that the Lloyds Trustees desired to light up the docks near Glasgow, they might have to pass through public roads in doing so, for the purpose of laying their wires. In such a case would you give facilities so that they should not be stopped on the ground of any temporary obstruction of the right of way?

Witness: I think the powers should be very much arranged. I think municipal authorities should be only too happy to grant any reasonable facilities, if they had the power.

Mr. *Thomas Henry Farrer*, C.B., examined by the CHAIRMAN.

I am Secretary to the Board of Trade, and in that capacity have paid considerable attention to the electric light. We have had occasion to do so, both with respect to lighthouses and to lights on ships. I Witness then read the following objections to the Electric Lighting Bill, as to the use of the electric light on ships, which, coming in the course of the evidence various reasons why the Board of Trade, and letters written, to the Board on the subject. He then proceed to consider the application of the electric light to lighthouse illumination; as to reply to the Chairman's question: "In your opinion, you having seen, in contact with all the information about the electric light and lighthouses, you consider it established its position as a means of illumination in lighthouses?" "Certainly; and if I were to venture to prophesy, I should say that we should see it sooner or later, not in all the lighthouses by any means, but on the most important stations, such as the Lizard, the Start, Portland, the Isle of Wight, Dunnby Head, the Forelands, Lowestoft, Flamborough Head, and so forth; on account of the great distance at which a powerful light, and the distance to which it travels. The real test, if necessary to be considered, but the cost of a lighthouse is as nothing compared with the cost of a ship, and therefore I should mention that there are other experiments going on. Upon my experiments, of which Professor Tyndall thinks very highly, with gas, in Ireland; as that is does not do to go too far in anything, even where there are other things that may be equally good." There are other experiments now being made at the Admiralty. I have taken into consideration the present position of the gas companies in regard to the legislative powers that they possess, and the Board of Trade have had to consider the question recently in connection with the Bill introduced into the Metropolis Gas Bills." The history of the gas companies is very interesting as bearing upon the way in which Parliament has dealt with things which become inevitably monopolies. The first attempt of Parliament to regulate the price of gas companies generally, I think, was by the Gas-Works Clauses Act of 1847. By that Act the dividends of gas companies generally were limited to 10 per cent., and the principle of sliding scale of dividend was mentioned in the Company's own Act. The Gas-Works Clauses Act was also incorporated with every Gas Act, and under that Act the capital had to be offered to the shareholders at par. At first it was supposed that competition between the gas companies might be undesirable, and in London there was a period during which that went on to some extent, a great deal of capital was wasted; shares were torn up by competition, and dividends fell very much below the sum that the Companies reasonably declared London would be benefited, making a practical monopoly; and that was confirmed by the Metropolis Gas Act of 1860. By that same Act a certain limit of price was put upon the gas. That limit was, of course, adapted to the then circumstances, and there was a liberal limit; but it proved to be more than sufficient to enable the Companies to pay 10 per cent. It was 14. 6d. per 1000 feet for 25-candle gas, and 2s. 6d. for 20-candle gas. Then there was great discussion and grumbling, and a Committee sat in the House of Commons in 1866. In 1867 there was another Committee, of which Lord Cardwell was the Chairman, who reported that the price was far too high, and that there was difficulty in altering the arrangements which had been made with the Companies, except on the threat of competition. In 1868 there was a competing Bill by the Corporation of London. Lord Cardwell was again the Chairman, and he reported against the Bill, which they feared the Bill would give power of permanent division, and made certain provisions for testing the purity and power of the gas, and for reducing the price to 3s. per 1000 feet. Then with regard to power the price of 14 candle gas was fixed at 3s. 6d., and there was a provision that either the Corporation or the Metropolitan Board of Works on the one hand, on behalf of the consumers, or the Companies on the other, might apply to the Board of Trade to appoint Commissioners to review the price in case it became too high, or too low in regard to the profit. When the price of coals went up, the Companies applied to the Board of Trade, and the Board of Trade granted an increase in the price. They did appoint Commissioners, and those Commissioners raised the price, and gave a higher price than 3s. per 1000 feet. There was great discontent expressed at that. The objection was not so much simply to the raising of the price, but to the principle of the sentence. It was thought, and the Board of Trade were of opinion, that it was really impossible for any official persons sitting as Commissioners to go into the question of the expenditure of the Companies, and to say what and such profits; and the Board of Trade again met forward the plan which they had suggested in 1868, by which it might be possible to harmonize the interests of the consumers and of the Companies, by fixing a certain dividend and a certain price, and then in allowing the dividend to rise as the price diminished. That proposal was adopted by the Committee of which Mr. Forster was Chairman, and they decided in favour of a dividend of 10 per cent. with a price of 3s. per 1000 feet for 14-candle gas, and in which the dividend dividend should be the maximum dividend 10 or 7 per cent. already fixed by Parliament. That system is now in force with regard to the greater number of the Gas Companies in London, and, I believe, has acted very well. The great Companies on the north of the Thames are now making 11 per cent.; I think, by reducing their price, while the South Metropolitan Company on the south of the Thames, who have a lower price—namely, 3s. 6d. instead of 3s.—are making the same dividend. That system has, by virtue of a Bill brought into the House of Commons last session, been applied to the case of Companies out of London. The evil of the old system was that with an easy 10 per cent. dividend, the companies had no interest whatever in economy or improvement. That system operated about the old legislation of the gas companies was the mode of raising capital. Of course gas companies, with the growth of trade and the increase of consumption, are constantly requiring new capital. They have to raise it, and they have to raise it at a dividend of 10 per cent., sometimes 7 per cent., offering it as par to the shareholders. That was, in fact, giving one-half of the capital to the existing shareholders, and charging just twice as much upon the ratepayers as was necessary. There was a great struggle about it, but the Gas Companies of London were compelled, in 1875, to introduce what had been already introduced in the case of a few provincial companies—namely, auction sales of capital. That is to say, instead of giving the capital to shareholders, the companies received those enormous premiums upon every issue of new capital, but the companies were encouraged to create as much new capital as possible. It was both an extravagant mode of raising capital, and a stimulus to unnecessary capital. It was hoped to have had a financial arrangement arrived at made. In 1877, I see that 21 Bills were passed with auction clauses; I do not know how many in 1878, but, in fact, the auction clauses are now applicable to all gas companies in London. Of course, the question as to sale of gas and water undertakings have been much considered. There has been one case in which Parliament passed a Bill for compulsory sale of water-works in the session before last; but whether that has been followed up or not I do not know. If the electric light companies get any power of breaking up streets, the result will be practically to give a monopoly to one company, because you would scarcely allow any number of companies to break up the streets. The Board of Trade would not like to see the streets in the light to be disturbed. Of course, as far as the electric light is introduced for the purpose of one establishment, such as Woodhead's, there need be no monopoly, and there persons may be free to adopt their own system; but where the public ways and streets or private houses may have to be lighted from one centre, it will necessarily lead to monopoly. If you create a vested right of that kind in the electric light, great caution must be used not to injure the existing gas companies; and if the monopoly is to be given to them, very great caution must be used that the introduction of light is not made the means of supporting the present large dividends. They have the right of supplying gas, and they have the monopoly of doing so, and upon that, by what has happened, they have the right to their 10 or 11 per cent. dividends; but I

* See JOURNAL, Vol. xxxiii., p. 501.

You are aware that it has been necessary to apply for such powers in the case of tramways?—Yes; and, on the whole, the spirit of legislation in the hands of the local authorities is

The CHAIRMAN: Tramways have been rather referred to as a case, from having the intelligence of corporate bodies. Do you think that a corporation is competent to fairly hold the functions of tramways, and the consideration of the opening, and that, under those circumstances, they would be justified in granting powers to them?

Mr. Rowe: I think they would be justified; and I would be only in a very strong case that the Board of Trade would exercise any supervision over the powers they have.

Mr. Alderman Cubitt, Chairman of the Committee.

I am Town Clerk of Liverpool, and have occupied that position since 1854. The matters connected with the gas question have been referred to the Gas Committee of the Corporation, and during the summer of last year the question of lighting the streets by moonlight was brought before the Committee, and in connection with that special matter referred to them. The view which the Corporation took of it was that the light question was one thing, the supply was another so far as relates to that; and the Corporation would be justified in going for power to light the whole of the town with gas, or with electric light, as you may say by retail; because, as soon as they acquire corporations have to satisfy Parliament that it is a good bill, and they are aware, consequently, that in that respect they labour under considerable disadvantages; besides, under the Borough Funds Act, they are liable to be opposed by the owner by the ratepayers. The Corporation felt that the question of electric lighting was sufficiently advanced to justify them in giving the matter a fair trial, and, in some respects, had peculiar facilities for doing so. As regards St. George's Hall—the large music hall—and the public buildings on the opposite side, the Picton Reading Room, and the Free Library and the Museum, they thought that they could give them a supply under very favourable circumstances in connection with those buildings; and, with the same engine power and the same boilers, they might light the front of St. George's Hall, where there is an immense amount of foot traffic, and the whole of the railway station, and also possibly light up the interior of the Lowden and North-Western Railway Station. In St. George's Hall we have a large area that is used great at night. I think the Engineer said it was for some time, but not that is a matter of small moment. Then, in connection with the floating approach to the Victoria Dock, which is now partially lighted by the Dock Board and partially by the Corporation, it was thought that this was a place where the electric light would be tried with great advantage, and that the Corporation would be the party to supply the light and charge the Dock Board the proportion of the lighting of the floating approach to the two bodies. It was needful that, as a Corporation, we should come and ask for parliamentary powers, as we had in the first instance, and should have to borrow money; and, secondly, the Corporation felt that they would be the servants of the Londoners and the public generally in the matter of the streets without your permission, so as to injure the public?—I think that if their experiment with the electric light be successful, the Corporation should be entitled to some of the profit of the streets; and I think that, as between them and the ratepayers, they are asking for

You are aware that there might be difficulties unless provided for by legislation, inasmuch as if electric wires were used to carry the current of electricity, in order to attach the mixture wires necessary to complete the circuit, to the gas pipes or to the water-pipes of competing companies?—Yes. I can imagine that there might be a difficulty in using the gas-pipes and the water-pipes, which might be a difficulty to where both of course, that objection is got rid of by using two wires where one gas or from the bituminous, we would rather have the anthracite; and, as I understand wires are used.

Practically, it is certainly that a water company would refuse the use of their pipes, even if they were willing, as a matter of business, to allow the use of return wires?—They would probably refuse it, of course, for the sake of getting a consideration for the use of their pipes; but not on the ground that the gas and the water supplies are in the hands of companies; I should think, myself, that the water supplies are in the hands of companies; but, if you look to your Bill you do not claim on the part of the Corporation that they possess the exclusive right of supplying the electric light in Liverpool?—No; we do not give you the existence of any such powers by the Corporation to sell by agreement to any company or merely to sell to the Sailors' Home, or to sell, as I have explained, by retail, but public authorities where the Corporation are for their own sakes providing better means of lighting in open places, and in the Queen's Dock entrances, and places of that sort. In such cases they think that if they are at considerable expense in providing an increased means of lighting for the benefit of traffic, there is a great deal of cross traffic and that is a subject to them before selling the electric light, if they can, to a particular ratepayer, that they should be entitled to moderate the scale in reference of the additional lighting which is rendered necessary.

But any question went further than that, and you have asked Parliament even the powers you ask for, do you think there should be a provision in your Bill that any company might come into your district as a rival company, subject only to the modifications that they do not break up the streets without your permission, so as to injure the public?—I think that if your Bill is to be carried, it must be granted; but I should imagine, I think if their experiment with the electric light be successful, the Corporation should be entitled to some of the profit of the streets; and I think that, as between them and the ratepayers, they are asking for

What as you have a preference in the case of tramways?—Yes; and powers, as regards both the Tramways Act and the Gas and Water Facilities Act, the consent of the local and public authorities is abrogated necessary, except where the Board of Trade, for some reason stated in the Committee of the House of Commons, that the local authorities are acting unreasonably and improperly. In fact, my company ought to have the consent of the local authorities before they can lay down the streets; and I think the tendency of legislation is either to increase the powers of local authorities in that respect.

Your Bill is still before Parliament; it is only being up, I believe?—It is still before Parliament. It depends, of course, upon the time when the Committee of Commons considers it; whether it will go on this session.

Mr. T. Hare: Is not the gas companies obtained the power to monopolize the use of the electric light in their pipes, to some danger that they would refuse the power to persons in connection?

Witness: I have said that the interest of the gas companies, with their very large plant and appliances, might be to prevent the development and commercial use of the electric light. They might get the power and not use it.

Mr. HARDCASTLE: What would be your view with reference to allowing a company to break up the streets across a street, or for instance, across the corner of a shop was made in order to obtain any place for the machinery for the electric light in his shop, but only to lay down the electric wire in the street road, perhaps. Do you think the Corporation would allow the opening of the street for that purpose?

Witness: I think there are many cases in which a number of shopkeepers on the side of a street might combine, when the Corporation would be willing to allow the street, underground or overhead.

Mr. STEVENSON: Could you pass your Bill, it will practically give a monopoly of electric lighting to the Corporation of Liverpool, will it not?—I do not think so. We should simply, I apprehend, be empowered to say one who liked to take it. There is no doubt it would be a monopoly to this extent—that the Corporation would be the only body who could break up the streets for the purpose of lighting by electricity.

Supposing the Corporation obtain that power, and do not yet it into operation, and Liverpool will never be lighted by electricity, will it?—As I have already explained, the Corporation have peculiar facilities for doing it, which do not affect a company; but if the Corporation did not exercise powers in force, they would have no answer if the the Company applied to do so. I think the risk would be far greater in the hands of the Gas Company than in the hands of the Corporation.

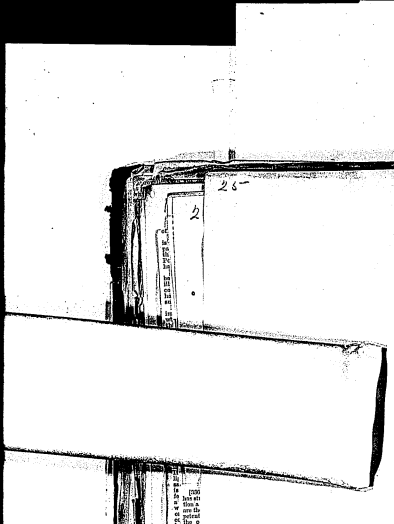
Practically, is not your Bill an attempt to repeal the Borough Funds Act of 1872?—I do not regard it as such.

Supposing the Corporation do not, for a limit of time within which, if the Corporation do not put their Act into practical operation, it should be a dead letter?—I do not think so. The Gas Company will be at liberty to come to Parliament if the Corporation do not do their duty in the matter; but my opinion is that the Corporation will advance to the practical development of science advance, so as to supply the light retail, if it be practicable.

Is it the case that the Corporation of Liverpool did not consumer lighting by gas for many years after the Corporation of Manchester?—I do not know that at all. All I know is, that the Liverpool Corporation had a Lighting Act in the reign of George II. I do not know the circumstances under which the lighting passed into the hands of the Gas Company; but the Corporation had a Lighting Act, I should think, quite as far back as the Corporation of Manchester.

(*To be continued.*)

less room than they gain by it from the increase in the quantity of gas to be taken from the gas. This is all very true and contains the reason why the consumption of gas is limited, and why it will be never more than it is. But it is not true that coal consumed in the retort is the only coal which is consumed in the production of gas. If the coal is placed in the retort, and the gas is made from it, a great portion of the combustion can take place in the retort, and then the sulphur is retained in coal which is used over the fire, and the gas will have to be taken out by the exhauster before it can be purified, and the expense of working the exhauster ignored. It is not to be denied that the gas will have to be taken out by the exhauster, whether it is made in the retort or elsewhere, but the expense ignored. Can it be denied that the expense ignored. Can it be denied that after the mixture of gas, coal, and air has been exhausted from the retort they are passed through a coke, or any kind of fire? I would ask the former will they not be exposed to a greater expense, coal-gas standing over 16 candles instead of seven? Will not the gas



whatever had been used that day. This gentleman is now paying about £60 a year for gas for cooking purposes.

Although a good deal has been done in the way of exhibitions—awarding prizes to good cookers, and supplying stoves at reduced prices—the efforts will prove to have been futile. We must assist the consumer in the economical application of gas, and thus indirectly reduce its price. It is a well-established fact that the cheapest gas at present is an expensive fuel, unless used with economical appliances.

I know there are stoves which will consume their own stoves in perform a certain amount of work with a certain quantity of gas; but I am afraid I must appear to be charged than cost. I have tested such stoves, and found that, on the whole, very nearly up to the representations. I found that, on the whole, very nearly up to the representations. I found that they would first ignited there in the consumers, with the assurance that they would first ignited there in the consumers, with the assurance that they would first ignited there in the consumers, with the assurance

meter. One of these candles burns a little over an hour. At the end of that time the current must be switched off, from the one which has been burnt down, to the fresh candle next to it. So it is necessary that an attendant shall go to every lamp once in an hour, and turn on the current to the new candle. The lamps are lighted one after another, an hour after sundown, and are extinguished at midnight. Of course, if they are used already lighted up, must then to be put into requisition. Thus the lighting till midnight is effected.

According to the official report, from the 20th of May to the 10th of October, 1878, a little over five months, the lamps were in use less than 50 entire times, lasting from 1, 2, 3, 4, or 10 minutes, up to 15, 30, or 45 minutes. The Company, it is said, hope to do better. There have been no days yet if light up whenever the electricity is indispensed.

The number of light given by each of these lights is stated by M. Lebloun to that given by 200 gas burners, when they tried it at the Avenue de l'Opéra candle is not entered by no absolute light globe. This light is too painful to the eyes, and from its vast of volume, is not serviceable for lighting streets or houses. Besides it needed it cannot therefore be surrounded with an electrolier globe, and then the amount of light is greatly diminished. In fact the electric light does not, like an Argand burner, give the horizontal light in all directions, but the volume are is never to the screen specially front of the candles, and others it is at the back of the candles. I am not tell you that on a short distance, because the eye is not capable of testing the power of the electric light as the gas lamps been used for important difference. Such a very near room as this little distance makes a very would be exposed to give so much credence to it, yet, I do not think he they were intended to be used.

that although the light is given at the time of the trial, simultaneously stated, yet that effect is not produced when the ground is seen under a one only equal, in round numbers, to 315 candles; so that in practice, although the beautiful white from the electric lamps is the average illumination ground there was only the light of 115 candles, about 100 candles, yet on the Avenue de l'Opéra.

Mr. Lebloun has also experimented as to the comparative cost of lighting by Messrs. Jablochkoff and Yalow, they found that the light given by Wenzel-sen-Sen candal like by a Jablochkoff lamp was there equal to 107 candles. The difference between their experiment and that I have mentioned is only to be accounted for by a slight difference in the quality of their engine and that used in Paris. I think that in all estimations of the electric light the speed of the dynamo machine should be taken, as well as the number of lights in the circuit at the time of the trial, simultaneously with the photometrical experiments. This has a most important bearing on the question of cost.

Now as to the question of cost. This is, as told me by an eminent Paris electrician, a very delicate question. I shall give it you in figures founded on my own experience and observation, checked by those of the most experienced engineers who have come under my notice.

At Th. Lévy refinance but his experience shows that to obtain a light it is a Jablochkoff lamp, producing the effect of 115 candles, there must be consumed, in the form of electrical power, the force of a 2-horse power engine. Three burning together, produced by the force of a 20-horse power engine, there are 16 corroborated by Messrs. Jablochkoff and Yalow, and by Messrs. Rapieff, obtained are lights of 315 candles power. Messrs. Jablochkoff and Yalow, and Lévy, with a force of nearly 20-horse power, obtained by Messrs. Lebloun and Tremeschini, with a force of 20-horse power, or all the other of one and Bazalgette. So we may take it that we can get one light of 115 candles power, by the directions for the Avenue de l'Opéra, with a force of 120 horse power.

Now we have the question of cost. This is the Electric Light Company going to charge for their lights from 1-horse power? Of course they are concerned to inform the world. Thus the 62 lights in the Avenue de l'Opéra require 92-horse power to keep them going.

I need only say, with respect to the scope of the Electric Light Company, that, considering the very considerable number of lights they have in existence before the Select Committee on Lighting by Electricity, allows the conversion of motive force into light by electricity, and the light is effected from the motive force employed, there hopes of the Company never to be realized. Assuming the motive force employed, there hopes of the Company are at the rate of 120 candles power of light all round, from the 62 lights.

Table No. 2, appended to the Report, gives the cost of the cost of the electric lighting in the Avenue de l'Opéra, by taking the figures, as to the working expenses, of M. Lévy, and adding thereto the charges and interest on the capital expended. This, as I have already mentioned, is 2,000 francs per horse power for the 92 horse, or 54, 385, per lamp per hour = 2,170 11s. 4d.

Now, as to the question of cost of gas lighting. I have already stated, by Electricity that the commercial value of the electric light is that which the Electric Light Company charge for it. Now, without disputing his estimate, it seems to me that, as a gas engineer, as at liberty to examine into the cost ourselves, and this I have done before you for your information and criticism.

I now address myself to the comparison of gas and electricity as a means of lighting the Avenue de l'Opéra. The Electric Light Company of Paris have undertaken to light the Avenue de l'Opéra for the period of one year, beginning on the 15th day of January, 1879, at the rate of 36, per light per hour from dusk till dawn.

The number of gas-burners in the Avenue de l'Opéra electric lights was 311, each by the 311 burners have been consumed in the 200 candle burners such as shown here, they would consume the light of 1 cubic foot of gas consumed that quantity of gas, or only 200 candles less than that given by the electric lights; so that if forty 200-candle burners had been placed on the columns on the boulevards and in front of the houses, instead of the electric lights, there might be a continuous, steady, and brilliant light. The actual position of these lights might be as follows:—Six globe lanterns on the pedestal columns in front of the façade of the Grand Opéra, fitted with burners consuming 25 cubic feet per hour, and giving the light of 30 candles each. Eight lanterns of a globular form, one on each of the safety posts in the Place de l'Opéra, each of three to have a burner consuming 66 feet of gas per hour, and giving a light of 200 candles each. Six lamps fixed to the Place de l'Opéra, each fitted with burners each consuming 66 feet of gas per hour, and giving the light of 200 candles each; and last of all to the Avenue, fixed on columns, the eight lanterns on the Paris columns, but 12 feet high, fixed on columns, the eight carriage lamps now existing, a total of 62 lights. Now, as to the centre of the 92 feet of gas per hour, and give the light of 200 candles each. These would each burn quantity of gas consumed by the whole of the lights of the Avenue de l'Opéra, and the total amount of light a candles result in 12,400 candles power, that can be produced by the electricity, as I have stated, in 12,000, or 400 candles power, and which I have explained already steady, reliable, and working, I do not think that the electric light, when at midnight the electricity was reduced to 7,440 candles. If, however, the 1,720 cubic feet of gas formerly consumed by the 311 old 4-foot per hour burners, be consumed, the result would be a saving of 1,720 cubic feet per hour, or 41,280 cubic feet per day of 24 hours. Thus, the increase in light produced by the electricity is only 37 per cent. more than might have been produced by the consumption of the 1,720 cubic feet, at the exceeding low figure of 3s. 2d. per 1,000 cubic feet, as shown an increase of 123 per cent. on the 3s. 2d. per hour for the 62 lights, amount of light. The cost of the new lighting by gas to produce the same proposed, and which I have demonstrated is not only feasible by gas well-known to gas engineers, would be but half the price now being paid by the Municipality for the inferior electric lighting by electricity. All this leather of machines, engines, dynamo machines, candles is the expenditure by the Municipality of a large sum of money for doing in an inefficient manner the work which can be efficiently carried out by the Paris Gas Company for less than half the money, which they are now paying.

It is not clear that if the Paris Gas Company were to have come forward, in the small sum of money just mentioned, the Avenue de l'Opéra would have all possibility of the electric light have been lighted by electricity? and there simply because the gas lamps, as I have shown, are more than sufficient for public would never have been disturbed, and the constituting the standard, the light in place of the steady and brilliant gas-lighting and numerous electric lights were only the old flickering yellow bat's-wings of former nights. Unfortunately, there is a great evil, the electric light feed it all its own way; but in the end the best and cheapest will, and that it in the future for gas.

It is a curious fact, in the history of Vulliamy that, being present at a trial of fluidine destructive effect, which I predicted would supersede gunpowder, and gunpowder would have been an end to all wars, I got up a splendid improvement gun-cotton. Now we might say with regard to street lighting by gas and electricity.

At the Rue du Quatre Septembre, a street about half the length of the Avenue de l'Opéra, the Paris Gas Company have put up 80 lanterns, with burners composed of a fresh form of the Siemens lamp burners, each burner consuming nearly 70 cubic feet of gas per hour. The total quantity burned by the 80 burners is 112 cubic feet per hour, or 2,688 cubic feet per hour. Now, if these lamps were given, it is said, the light of 22 candles, the light given by all the 80 burners is, therefore, 10,000 candles power. Now, if the electric light in the Avenue de l'Opéra, the quantity of gas consumed in only 200-candle burners, the amount of light obtained would be 40,000 candles, or 4,000 candles more than the Rue du Quatre Septembre lighting. Now, the length of the Avenue de l'Opéra is 1,312 feet, and that of the Rue du Quatre Septembre 1,000 feet. Municipality, is 16 fr. 80 c. per hour. The Paris Gas Company are only to be paid by the Municipality for the actual gas consumed, and the Municipality would be clear that if this gas, regarding the inferior light as being of nearly double that it would be much better if they would confine themselves to the gas lighting, and give light for light and keep for keep.

In the Place du Châtelet there are 77 lamps fitted with gas-burners; 12 of these burn 11 litres of gas per hour, and the other 68 burn from 7½ to 8½ litres per hour.

In the Halles Centrales there are two pavilions lighted—one by electricity, the other by gas. They are both lighted for 1000 hours per annum. In the pavilion lighted by gas there are 24 lamps. In the pavilion of the electric light, there are six candles. Since the six lights, and the cost of 30 bat's-wing burners, each consuming 5 cubic feet per hour each, were fixed in the pavilion of the electric lights, they would produce the 720 candles for the sum of 90 centimes, or 7½ centimes per hour for the entire lighting, instead of nearly 20f., for the same work done lastly by the electric light. (Note that there were 21 extinctions and 61 relights of the electric light in the month of April last, the lamps having burned steadily from the time it was commenced, without any extinctions or starvation.)

I shall not take up your time by any consideration of the lighting of the Halles Centrales by electricity as compared with gas, or the cost of the electric lighting with respect to the lighting in Leicester. It is probable that the quantity of coal, or even electricity, does not enter into the calculations of the people who have charge of these buildings. They have seen everything to sold, seen how observed that the gas lighting is primitive. The lustres and brackets are excellent examples of the competitive effect of lighting by gas and electricity, it is about the same as a comparison between the old Roman lamp and the electric light as used on all lamp, the Carel. Besides, the electric light has not been established, as well as for others in this country, an excellent advertisement, as a matter of little importance whether the light is produced by gas, or a change the gas lighted and ready to be turned up at a moment's notice when the electric lamps go out. In most cases the

So much are the lamps felt to be a hindrance rather than a benefit, that I believe if all the lanterns were asked to vote for the cessation, they would vote almost unanimously for the entire suppression of the lanterns, if they could not have a light without shadow; but it is by no means the only thing if the shadows were more distant, and there, I think, is the first step for improvement which can be made in the future.

Mr. Woodall, as a refractor over the lamps in street lighting, at a very slight angle, is very good; Mr. Woodall, the inventor of these, I believe, was the first to introduce the internal horizontal refractor. Up to the Prussian war, in England, it was universally used, although his example for the glass top usually adopted by Mr. Stevenson was followed in South America. All the lamps in Paris at that time were glazed with the Gaudin prismatic top.

The next improvement in the direction generally is the use of the Argands in preference to the fishtail, which is mainly responsible for the blackness and dinginess which is so often seen. Next, if Argands are the troublesome shadowers they still be in favour of at least 20 per cent. more additional for the same. The railway station at most many chimneys are in the amount of light in Paris, its parts. In England chimneys to Argands only, with chimneys, instead of chimneys; but I have been told by Mr. J. N. Douglass, the Institution engineer to the Trinity Lighthouses Board, that although we have in some perhaps the greatest amount of knowledge, our chimneys of the large and small sizes are not always correct, even with the rough weather to them in their wear and tear accounts. Then comes the use of large burners in the rooms, at refreshment and, lastly, comes the use of large burners candle burners in the main corridors, and if they do not get them with gas, a public desire larger lights are erected streets.

Then they will with electricity. In case and if they do not get them with gas, electricity will vanish from the Avenues fended more than once that lamps, and other places where it is used, as in the Opéra, the Thames Embankment, and other places where it is used, as in the Opéra, the Thames Embankment, and other places where it is used, as in the Opéra, the Thames Embankment

thought it was very doubtful whether it was economical to use large burners at considerable distances, instead of small burners close together. In the Waterloo Road he put up lamps at frequent intervals, adopting the objectionable basket system. Around the shadows, whilst reflecting light, and increased the consumption of gas to 6 instead of 5 feet per hour. The general effect of the light was good, but very costly, effective, and would long remembered the ordinary large stalls for gas lighting, it was seen that there was room for economy in that direction. By reductions in expenditure, in that way for existing lighting the district lighted could be under 200*l.* per mile of lamp-bearer road, the lighting was effective, and the cost was moderate. Contrasting that with electric light, which could under favourable circumstances be done for 20*l.* per mile per annum, if it was sufficiently large margin there was for increased efficiency, if it was called for, and clearly agreed with Mr. Hartley, however, that the ratepayers would not stand the increased cost involved by existing gas systems when sufficient at the present time. In great thoroughfares, where there was much traffic, it was necessary to have a powerful light, and in the centres of traffic; but so far as the general illumination of the streets was concerned, he thought it was a question of sufficient, and any large increase in the price of a town or parish, called for in order to increase the general lighting, would be met with strong opposition.

Mr. Hartley said the paper had been so kindly received that there was very little he could add, except the remark of Mr. Wesley, that there would be more light in the streets than they now did, it was perfectly clear that they would have anything to do with electricity; and it was equally clear that they would not spend any more money in lighting streets than they now did, even with the electric light. Mr. Wesley had said they would not spend any more money in lighting streets, but what he understood him to have asserted was that, even with the number of feet of gas at present consumed, it would be possible to give much better light by the use of improved burners, and more effective illumination by shades. He was quite sure, however, that there would eventually be an increase in the consumption of gas for the public streets. Of course, the readings would be improved, and the time other places would by degrees follow suit.

[The other papers read will follow in due course.]

ROCHDALE CORPORATION GAS-WORKS.

ANNUAL REPORT OF THE GAS COMMITTEE.

At the Monthly Meeting of the Rochdale Town Council, on Thursday, the 5th inst., the following report of the Gas Committee for the year ending March 25 last, was presented:—

The Committee are again sorry to state that there has been a decrease in the consumption of gas during the year, it now being 2 millions under the previous year, a decrease of nearly 3½ in the last of the two years, although there is a corresponding profit this year amounting to £9,323 16*s.* 3*d.*, but your Committee consider this a satisfactory result, under the circumstances of the case, and as it will be seen that the amount received for public lamps is about £500 less than last year, there has been a reduction having been made in the amount charged for such lamps.

During the year the new station governors have been working. Each governor consists of a gasometer divided, and it is satisfactory to state that the pressure is now much more regular on the whole area of consumption, there being now no pressure to send gas through the long-continued [illegible] to Castleton, as was the case with one governor during the long-continued frost; in fact, with our extensive mains, no trouble was recorded.

Your Committee have also to state that the large new stalactite erected last year, and capable of replacing 80,000 cubic feet of gas per hour, is now in full operation. Taking the combined capacity of our purifying house, we have now a capacity of nearly 3 millions per day.

The following account represents a comparative view of the working for the year ending March 25, 1879, and the year ending March 25, 1878:—The make this year, 311,784,000 cubic feet; last year, 313,784,000 cubic feet, showing a decrease this year of 2 millions. The quantity sold this year, 283,372,000 cubic feet; last year, 285,372,000 cubic feet, showing a decrease this year of 2 millions. The unaccounted-for gas this year, 28,412 per cent.; last year, 27,588 per cent. Value of gas sold, this year £20,419 19*s.* 11*d.*; decrease, £921 2*s.*; last year, £21,341 2*s.* The gas sold this year amount to £9,323 16*s.* 3*d.*; the profit, £11,096 3*s.* 8*d.*; decrease, £921 2*s.* 5*d.* The number of tons of coals carbonized this year, 19,207; last year, 19,511; decrease, 304 tons. The number of consumers this year, 18,887; last year, 18,787; new tenants, 1,151; new services laid this year, 207; number of consumers lost during the year, 1,051. The number of meters fixed this year, 1,258; number of meters removed during the year, 1,051; number of meters fixed and additional meters fixed, 207. The amount received for sales this year, £20,419 19*s.* 11*d.*; amount received at rent of £1,757 10*s.* 0*d.*; the amount for gas, £20,419 19*s.* 11*d.*; amount for rents, £1,757 10*s.* 0*d.*; total chargeable to capital, £1,677 10*s.* 0*d.*; total, £22,177 19*s.* 11*d.*

TO CORRESPONDENTS.

R. M.—*Too late for this week.*

We would again remind correspondents that, to ensure insertion in the next number of the Journal, letters should reach the Office by Saturday at latest.

No notice can be taken of anonymous communications. Whatever is intended for insertion, must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of good faith.

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, JUNE 10, 1873.

Circular to Gas Companies.

THE big sale of Chartered Company's stock will come off on the 19th inst. What prices the new issue will fetch can only be imagined from those at which the present "A" stock stands in the market to-day. The premiums realized, we believe, will be, we will not say enormous, but it is probable that little will be thought to pay much over five per cent. This is small enough interest for investors who put their money in the concern for the first time; but the provisions of the Act under which the sale takes place are specially hard upon old Shareholders, who are fairly entitled to a *pro rata* issue at par. The sale will, no doubt, leave a very large number of investors, but the range of prices is certain to be small. The lots are arranged so as to suit all classes, from the man who can put his two thousand pounds per lot in, to the poorer investor who can only put in his hundred pounds. We expect, however, that the lots will all go off in large quantities, for it is one condition that the purchaser of any lot will have the opportunity of securing a considerable number of other lots at the price he gives for the first lot, without any further advertisement. This sale will constitute an era in the history of the enterprise. The electric "scare" has passed away, and gas will be remarkable in another sense; it will be the first occasion on which gas stock on such a considerable scale has been put up to auction, to produce premiums which will not be entitled to dividend.

An extraordinary meeting of the Shareholders of the South Metropolitan Gas Company has confirmed the resolution of the Directors to unite with the Surrey Consumers Company. It was, of course, a foregone conclusion, for although but few Shareholders were present at the meeting, the whole body have, with good reason, as much confidence in the Directors, that their sanction to the scheme was certain to be given. Happily, no discussion arose at this meeting as to the retiring allowances of the Directors and Auditors of the United Company; by the good sense of the South Metropolitan Shareholders they were passed over. The only opposition which now remains is that raised by the Phœnix Company, who object to the scheme proposed, as standing in the way of a larger combination. This Company might have had the matter entirely in their own hands, but they neglected their opportunity, which has now for ever passed away from them. What the Board of Trade may say we have no idea, but it cannot be supposed that they will endeavour to force any union between the Phœnix and the South Metropolitan Companies. There is one combination, however, which is still open to the Phœnix Company. They may, with much propriety, take all the district of the London Company south of the river, leaving to the Chartered Company all that lies to the north. This would prove a most valuable amalgamation. There might be some little difficulty in splitting up the museums of capital to be allotted to the two Companies; but it could easily be settled by a calculation made by competent engineers. The London Company may be said to be an anomaly. How their districts were allotted, when the districting arrangements were made, we could never imagine. All the area north of the Thames now properly belongs to the Chartered Company, who have the means of furnishing a supply to the districts in that area, while that on the south would naturally fall to the Phœnix Company, who would profit by obtaining the large manufacturing power of the Nine Elms works. But the London Company show a great unwillingness to enter into any combination. It is, in our opinion, a short-sighted policy, and it is to be hoped the Directors will take into serious consideration the propriety of entering into some union with the Companies south and north of the Thames.

We are sorry to see that the Birmingham Corporation are about to appeal against the judgment of the Court of Queen's Bench in their attempt to set aside the award of Sir Henry Hunt. As the case is still *sub judice*, its legal bearings must not be referred to. We object to the process because all the expenses, whichever way the ultimate decision goes, will fall upon that unfortunate overburdened animal—the ratepayer. Birmingham, as we said last week, had an excellent bargain when the Corporation purchased the Staffordshire Company's works, and could afford to be generous. The principle of arbitration adopted by Sir Henry Hunt cannot here be commented upon, as, whether the fragments of the undertaking should be sold at a proportionate price to that paid by the Birmingham Corporation, or whether they should now be disposed of at their increased value, is a question which the Court of Appeal will have to consider. All that can be said now is that it will be a blessing when this litigation is settled, and the Local Authorities get their several undertakings into fair working order. As we intimated last week, some of them may not do well; but, reviewing the whole case, we consider that it would have been better for everybody if the whole undertaking had remained in the hands of the Company.

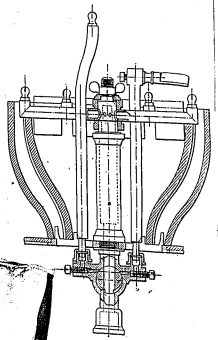
The electric light again attracts attention, and attempts are once more being made to write down the value of gas property. Much of the nonsense outlet is founded on the evidence of Sir William Thomson before the Select Committee on Lighting by Electricity, which we publish in another column. We have rarely seen a man of undoubted eminence and science fall so conspicuously to impress on his hearers the actual facts regarding the electric light. The first part of his evidence will be only intelligible to electricians, and we may pass on to such practical matters as stand out in the examination of the learned Professor. Sir William Thomson believes that the electric light has a great future before it, and no one can gainsay that; but there is still a doubt as to the source from which the electricity is to be obtained. Batteries, wet or dry, will not suffice. The employment of mechanical force, therefore, has to be resorted to, and the question is how the energy is to be obtained in the most economical manner. There is a choice between a steam-engine and a gas-engine, and Sir William Thomson appears to think that the former is the more economical. Among the immediate possible applications of the electric light, the Professor appears to think that it may be used to illuminate the drawing-rooms of noblemen's mansions. An engine of some kind may be placed in the basement, and, proper arrangements having been made, the drawing-rooms may be lighted with splendour. No scientific superintendence is considered to be necessary, but what James Plush or John Thomas would say to having the management of a steam-engine, electric apparatus, and the supply of Jablochkoff candles added

THE NEW GAS-LIGHTS IN PARIS.

As recorded in the *Journal* for May 6, p. 670, the Paris Gas Company, on the 30th of April last, introduced a new system of illumination by lighting the Place de l'Opéra by means of improved gas-lamps and burners. As the latter are altogether unlike those which have been employed in the recent street-lighting experiments in the Metropolis, the accompanying sketches and description of the apparatus, which appeared in a recent number of the *Journal des Usines à Gaz*, may possibly possess some interest for the English gas world.

It is not claimed for the new burners that they produce results superior, or even equal to, those obtained with the Siemens regenerative lamps, but they are certainly far more economical than the ordinary flat-flame burners, and consume a minimum of gas. The light is protected from the outer atmosphere solely by the glass of which the lantern is composed, and the supply of air necessary for combustion, as well as for carrying off the products of that combustion, is so arranged as to allow of the present form of street-lamp being preserved, the only difference being, of course, in the dimensions.

The upper part consists of six inbowing burners, mounted upon copper tubes, and so arranged as to form a ring about 4 inches in diameter, the bottom being cut at a tangent to the circle. Two crystal air-channels, placed below the ring of burners, serve to convey currents of air—one to the inner, the other to the outer side of the circle of flames. These air currents regulate combustion, and give steadiness to the lights. The section of the burners have been so arranged as to afford the maximum of light for the amount of gas consumed, the flow of the gas being governed by a pressure regulator.

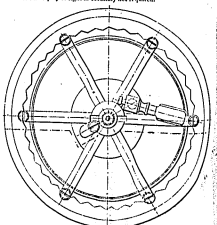


A small jet, which is kept constantly burning, enables the gas to be lighted without necessitating the opening of the lantern. There is in addition a central burner, which can be lighted from the ring of jets by the simple turning of a tap. This burner is similar to those ordinarily used in the street-lamps in Paris, and is intended to furnish the regulation supply of gas after midnight, or whenever the higher degree of illumination is not desired.

Each of the six jets of which the entire burner is composed, if taken singly, would consume about 5 litres per hour, and would yield a light equal to about 16·15 sperm candles. The amount of gas consumed by the entire apparatus is rather under 30 cubic feet per hour, and the light produced is equal to about 135 candles, or at the rate of 225 candles for each jet. This increase in illuminating power is partly attributable to the judicious manner in which the supply of air to the burner has been arranged, and partly to the absence of the blue, non-luminous portion of the flame, enabling its light-giving power to be utilized to the fullest extent. As each new gas-light has the illuminating power of 135 candles, it is estimated that the 250 lamps will be equal to 33,750 candles, or to 337 lights each of 100 candles. The Place de l'Opéra, which has been estimated by one of Montfaud Engineers at about 116 candles.

The line de Quatre Septembre is a thoroughfare about 900 yards long, by about 12 yards wide, giving a superficial area of 7800 yards. To light this area the Paris Gas Company have erected 62 lanterns, each furnished with one of the new burners, yielding an aggregate quantity of light equal to 8000 candles, at the cost of about 2s. 2d. per hour, or 17·24 per lamp, reckoned, of course, per hour, the cost of each electric light in the Avenue de l'Opéra. The lamps are placed at the height of about 10 ft. 6 in. from the pavement.

With regard to the relative merits of gas and the electric light for the illumination of public thoroughfares, the *Journal des Usines à Gaz* says that, standing at one of the refuges in the Place de l'Opéra, the spectator may form a very fair estimate of the effect produced by the two systems of lighting. Looking along the Avenue de l'Opéra, one would suppose it to be illuminated by the electric light, as the gas-lamps and their accompanying half-candles were not visible, and if the eyes they contrast still a moment vary in intensity of colour. The light, too, is unequally distributed; it is intense at the foot of the lamp-pillar, and diminishes in power in proportion to its distance from the lamp, the middle of the carriage-way being worse lighted than the rest of the thoroughfare. The line de Quatre Septembre, on the other hand, presents to the view a magnificent illumination. The lamps succeeding in perfect line seem to contain bowls of gas-light, the crystal rings encircling the burners appear to be filled with flame, which burns tranquilly, and not like the flame of a torch. The power of effect is magnificent; but, adds the *Journal*, for ordinary street illumination such a display of light is certainly not required.



So to obtain results similar to the analysis. No. 1, I have discussed of; No. 2, of course, need not be discussed; I have then only to deal with No. 3.

Mr. Paterson's meaning evidently is that all works where the standard into value of the candle is not attained, are defective in that respect. What have commercial results to do with the question? I know of works making 20 millions a year, that produce less than 9000 feet per ton from Newcastle coal (and that, too, with a liberal percentage of Lesmahagow), and yet pay a 10 per cent. dividend. So commercial results have nothing to do with efficiency of working. I strongly object to the idea that, because a manager is obtaining good value from coal, he ought to remain satisfied. There are many things that would dare good commercial results, under high makers per ton—e.g., small area of capital, proximity to coal-fields, &c.; and I am surprised at Mr. Young subscribing this as a proof of scientific working.

Of course, if the sample analyzed is not the same as that used in practice, as suggested by Mr. Carville in your last issue, no value can be attached to the analysis. This is outside the question at issue.

C.

THE CHEAPEST GAS IN SCOTLAND.

Sir,—Among the "Trade Notes from Scotland," in your issue of the 3rd of June, is the statement that "there is certainly no instance of cheaper gas in Scotland than that supplied to the consumers in the Dundee district." Statements to the same effect have repeatedly appeared in the Scottish daily newspapers, year after year, when your official representative repeats the expression in the statement must be challenged in the interest of other companies, though I, no doubt along with others, am well pleased to see that the Dundee Corporation Works, under the able superintendence of Mr. M'Crindle, are supplying gas at lower rates than the enterprising consumers of Kirkcaldy had to pay.

On reference to the year, it will be found that in the year ending April, 1870, the Dundee Corporation made 285 millions cubic feet of gas, which they sold at 3s. per 1000, and the net profit, according to your official correspondent's report, was £9600. The Illustrated London News, 1870, the Gobaldale Gas Company made about 31 millions cubic feet of gas, which they sold at 5s. 7d. per 1000 feet, and made a net profit to the shareholders of £2275. In the same year, 1870, the Dundee Gas Company made 285 millions cubic feet of gas, which they sold at 3s. per 1000, and the Dundee rate was 4s. 2d. per 1000, with 2 per cent. deduction for cash within seven days. In Kirkcaldy, in the year 1870, when the Gas Commissioners considered the advisability of reducing the quality of the gas, and, though I cannot find in the file of your Journal any exact statement as to the quality, I cannot find in the file of your Journal any exact statement as to the quality, I cannot find in the file of your Journal any exact statement as to whether or when they decided to do so, I infer it must have been here at 20 candles. Your Inspector, reported that the Illuminating power of the gas was 20·4 candles. During the year ending April, 1871, the Illuminating power of the gas was 20·4 candles. The Illustrated London News, 1871, the average Illuminating power of the Dundee gas was 20·59 candles (quite in accord with your Notes from Dundee), in December of the same year, Mr. Falconer Kinnear reported that Dundee gas was equal to 20·59 candles. I am, therefore, safe in assuming that during a portion of 1871 and ever since, the standard of Dundee gas has not been much under 20 candles. The price for the year 1871 was 3s. 7d. per 1000, with the 2 per cent. discount for cash as before. The Gas Commissioners made that year a profit of £3,292 million cubic feet of gas sold, and at the year's end 3s. 4d. per 1000, and a dividend of 5 per cent. was declared on the stock. It cannot give the comparative figures for the year ending April, 1872, as I inserted in your abstract but the Dundee profit was £9500, or they paid a dividend of 6 per cent. and carried forward new plant, of which £2614 was a balance from the previous year. Gobaldale, I inserted in your abstract but the Dundee profit was £9500, and the next year's sale began with a dividend rate of 3s. 7d. per 1000 feet, with the 2 per cent. discount for cash. Your correspondent, in spite of the further reduction of 2d. per 1000, still considers Dundee gas "certainly cheapest." Gobaldale, of which the gas is Scotland," with "no comparison," supplying "the cheapest gas in Scotland," with "no comparison," supplying "the cheapest gas in Scotland," with "no comparison," supplying "the cheapest gas in

THE USE OF GAS FOR OTHER THAN ILLUMINATING PURPOSES.

To any one who has given the matter any thoughtful consideration, it is self-evident almost, that if the distributing part of the plant of any gas company could be as fully employed throughout the entire twenty-four hours as it is from six P. M., to 12, midnight, there would be a very decided reduction in the "cost of distribution," per thousand feet of gas sold.

There are peculiarities incident to the distribution, as well as the manufacture of gas, that do not obtain in water supply, which is more nearly like gas supply than anything else. The capacity of the mains must be equal to the maximum demand, which occurs only during about two hours of the twenty-four on each day, and varies for almost every day in the year. During a large portion of the day the mains are practically unemployed; hence, the interest on the capital invested in those mains must be earned during the short time they are actively employed.

In the same way the manufacturing plant must be largely unemployed during the summer months, owing to the reduced consumption at that time, and yet interest never stops, and, whether used or not, the plant must be ready at all times to meet the requirements of the maximum consumption. All of this is perfectly evident to all managers; but the great fact remains that for years manager have been content to accept the fact without taking active measures to change the conditions at least partially. The problem is, in a few words, "how can an increased day consumption be secured"? This is purely a matter of business; and the answer to it is to be found exemplified, in hundreds of cases, in almost every other business enterprise in every city and town in the land.

It is simply in stocking, by every fair and honorable means, to extend the amount of business, and not only this but new channels of trade, and new applications to useful purposes, must be sought out and supplied.

The price of gas in Great Britain is very much lower than in this country. Gas is sold there at prices varying from seventy-five cents to two dollars per thousand feet, and yet the very clever men who manage their works are very wide awake to the necessity of still further deepening the price of gas to their consumers, in order that they may avail themselves of the increased profits to be derived from an increased business.

At Leeds, England, a very large exhibition has just been brought to a most successful termination, wherein the people were shown, in practical operation, the many economical uses to which gas might be applied. Thousands of people flocked to the great hall to see what washers—cooking in all kinds of ways; heating apparatus for various mechanical and domestic purposes; gas engines; laundry stoves; soldering iron heaters, these purposes; and, doubtless, the next annual report of the gas company will show a large percentage of increase in the annual sales of gas.

In many other cities and towns the same thing is being done. The object, in every case is to obtain increased day consumption, and we are glad to see that steps are being taken to extend the day consumption in our own country. Reduced prices are being announced in many places; but the following announcement will put the question to a practical test in one city, at least. It would seem almost certain that, at $1.50 per thousand, in a few citizens, gas would distance all competitors.

REDUCTION IN PRICE OF GAS IN NEW YORK.

At last the natural and inevitable result of opposition has made itself manifest, and the war has commenced apparently in earnest, and the prospects—rates in fact so low that they might satisfy almost any one. The first shot was fired by the Manhattan Company, followed promptly by the Mutual, after which the younger Municipal Company wheeled into line, and, finally the old New York brought up its forces, and the firing is general all along the line in the lower part of the city. Each company seems to be acting on its own account, although they all start at the same point, viz., $2 a thousand for all consumers of less than 10,000 feet per month. From this point the price is graded down; some by per centages, some at a fixed price, per thousand for different consumptions. The Manhattan announces their intention of selling to consumers of 100,000 per month at $1.25. The other companies make their prices in such a way as to practically amount to the same thing. We give the different circulars in another column. The result of this would seem to be that the company having the greatest number of large consumers, in proportion to their total number, will be most affected in its receipts by this reduction. How for this "scale descending" will be extended before the thing is over no one can tell. Probably the company having the smallest capital, per thousand feet sold, has the advantage so long as the price is not put below actual cost of production.

Those making their gas most cheaply are also better off than the others. As to the question of quality it has practically but little to do with the question so far as the mass of the consumers are concerned. What they look at is the amount of the bill.

This is very clearly shown by the fact that one company, whose gas contains from 28 to 32 per cent. of carbonic oxide, has already obtained some six or seven thousand consumers and probably sends out four or five hundred millions feet per annum. This company naturally claim that it is the superiority of the light furnished that has obtained them the popular support; but the fact nevertheless remains that they have always sold their product at lower prices than the old companies who have adhered to the hard and fast rule of the same price to every one, and that was $2.00 per thousand. The various companies will of course do every thing they can to defend the character of their own gas, and get as many consumers as possible. This is only the beginning of the matter. The people rub their hands and say "go it," and while trade is dull, in this hot weather, the proprietors of large establishments can amuse themselves by going around "shopping for gas."

How the stockholders are to be benefited by all this is a problem containing several unknown quantities, and has not yet been solved. If we were to suggest a remedy, in a general way, for this problem, it would be to amalgamate all the companies into one—with a capital stock not exceeding $5 per thousand feet sold annually, by all put together, and then sell gas at such a price that, while it would secure a fair remuneration for the money invested, it would be low enough to prevent the starting of any other competing company. In order to do this the manufacture must be conducted on the strictest scientific principles, and the sale upon purely business principles. It certainly would be possible, with such an organization to sell gas at such a price that the consumption would be very seriously increased both for domestic and other uses, and competition defied.

The harmony and co-operation which has so long existed between the old New York and the Manhattan companies has been very seriously disturbed by the action of a majority of the board of the New York company, in purchasing the right to use the Tessie du Motay process, with the understanding that the Municipal company do not enter into competition with them in the district below Grand street. It is understood that this action was taken in spite of the non-concurrence of those members of the New York company's board who are most actively interested in the board of the Manhattan company. So radical a change as this, if they actually put the process in operation, must have had the guarantee of enough satisfactory to those who brought it about. What effect the reduction in price which has since taken place may have, on calculations based on the old price, could no better determined if it were known exactly why the process was bought. Certainly $100,000, which is the sum said to have been paid by the New York company to the Municipal company, will be a very convenient little amount of pin money for the latter to have at the beginning of the war, as it so much clear gain to start with. Whether the effect of reducing prices will make it more convenient for the New York company to pay that amount, and as much more, perhaps, should they exert works for using the process, is not quite so clear.

Thus the war begins, with "every fellow for himself"; and it is to be hoped that, after the amusement has been continued long enough to satisfy all concerned, it will be terminated by an amalgamation into one of the honest city of New York, and that afterwards the manufacture and sale of the honest article of gas will be conducted on a true business basis.

If this be the result, the fight will not have been in vain. The people will have gained permanently, and the investor will have a more remunerative return for his money invested. The only question is, whether the fight is too many months delayed. If it is, then it will be a question for Mr. Gilbert to decide whether it would not be better to pocket the loss himself, and so end to a waste and disadvantage for carrying on the business and put the same interest by all stockholders. London and Paris have both gone through the same process, and the result has been amalgamation and cheap gas.

Parliament. If the Committee thought fit to reduce the capital, the Company would have to do it; but he (Mr. Littler) would remind them that they were probably charging a London as the gas consumer some seven or eight years hence, instead of postponing it for some twelve or fifteen years. Then they said, "The difference between the two systems of charging would enable them to embark in remunerative enterprises on a large scale." Now, the Company could not apply their money to anything but the supply of gas, as his learned friend had doubtless told his clients. The next allegation was, "The Company ask for a standard price of 3s. 6d. per 1000 cubic feet, which is in excess of the highest price they now charge. Your petitioners are prepared to show that they will be able to earn their full maximum profit at 3s. 6d., and that they require, with the standard price of 3s. 6d., and without that price, a smaller capital than is proposed." With regard to that, it was almost impossible that any company on a maximum 4 shilling price that they were then charging. If they did not, every occurrence of increase in the price of coal and iron would cause them to have to apply to Parliament for powers to increase their maximum.

The Chairman: What are they charging now?

Mr. Littler said 3s. 6d., as they were only asking as a maximum, for capital purposes, the price they were charging.

Mr. Otlass: It must be remembered that you have a sliding scale.

Mr. Littler said he had mentioned that before. [Reading the usual clauses.] It, therefore, they could get down to 3s., they would earn one-half more than the standard dividend, and at the same time benefit the consumers. The sliding scale was being applied in a great many boroughs, and his clients had adopted it as the latest approved method in gas matters. Then the petitioners said, "The Company have power to create preference stock, but the maximum dividend in addition to the ordinary fixed dividend is limited by clause 26." That clause was inserted to avoid a thing which had happened in other companies. A small company a year or two ago had an explosion, alleged to be due to something for which they were liable. Two or three houses were blown down, and the Company had to pay £2000 or £3000, and the Shareholders received no dividend for a long time. If the Company had had such a fund as this, they would have been able to apply it out of the loss out of it, and not have had to go to the Shareholders for it. Then they had been obliged to come to Parliament and tell them what had happened, and Parliament, feeling it was a matter which was no reflection on the management of the company, immediately raised their maximum from 5s. to 6s. The petition further alleged that "by clause 61 the Company seek power to cover merely six acres of land, in addition to their present site, with gas-works." That was a mistake. It was proposed to move the gas-works to a convenient position, and to sell the present site, which was in a densely populated district, surrounded by railings and getting dear chemical, and where they would be built on solid foundations, instead of on soil as the consumers like very well at present. Then they said, "But your petitioners will be prepared to show that the works required to supply the limits proposed cannot necessitate the use of more land than that comprised in their existing site." Upon that point he (Mr. Littler) would like to say, if the increase was going to continue in Shrewsbury, what happens it was of anybody's if the Company bought colony more land than they required, and kept it for the future? Was it unreasonable to suppose that the Company had power to buy land, and not acquire a sufficient piece of land, they would, as had happened before, become surrounded for buildings, and it would then be exceedingly costly to buy the land. The price at present was only a little over £300 an acre, whereas if they waited till the buildings were erected, it would probably cost a magnificent sum. The owner of the land did not object, nor anybody in the neighbourhood; only the Local Board. The petitioners said, "If the Local Board have any objection, and your petitioners submit they should not be allowed to take any land in addition for gas-works." What did the Local Board mean by objecting to gas-works being removed from the population? If the Local Board had carried out their proposal to purchase the works, it would be proved that they had it in contemplation to go to a site close to the one proposed by the Company. Then, as to the two hours notice, did the Local Board seriously object to the Company having to the hour's notice the ordinary time?

Mr. Otlass: You can do anything in two hours.

Mr. Littler said that was the Act. Then a suggestion was made they generally came in the evil minds of the people who made them. He supposed the imputation was that the Company would make use of these two hours to improve the quality.

Mr. Otlass: I am only stating a chemical fact.

Mr. Littler said the next objection was that "the testing-place of the gas should be at a distance from, and not within, the Company's works." It was generally within the works, but if the Local Board wished to have a testing-place of their own in the town, or at their offices, or anywhere else, they were perfectly welcome, if they paid all the expenses of it. "The quality prescribed by clause 6 is too low, and the Company, as your petitioners submit, ought to be required to supply gas of not less than 16 candles." No doubt that could be done, but it would be at enormous cost. When the Committee were told that London and Brighton, and 80 per cent. of the whole of the southern towns, had gas of 14 candles only, they would doubtless be disposed to think that 14 candles would be sufficient in the present instance, especially when it was seen that in order to avoid the penalties, at least 16 candles, or probably 18, would be supplied; which was sufficient for the whole of the southern counties might surely be deemed sufficient for the north. Taking all the circumstances into consideration, 14 candles would be found to be a sufficient and very reasonable rate for the assistance of Parliament, submitting, as they did, at the same time, to all the obligations which Parliament placed upon them.

Friday, May 16.

Mr. Littler said that his learned friend's clients, considering the only questions between the parties were those of capital and rate, had agreed to the following terms:—The original capital, instead of being £21,000, as in the Bill, should be £20,000, with borrowing powers for £6666, and with borrowing powers for £3000. They had also agreed to a thought it was a great concession on the part of the Gas Company to reduce the standard price from 3s. 6d. to 3s.; the illuminating power to stand at 14 candles, as in the Bill.

Mr. Otlass said that after the friendly way in which they had been met by the promoters, the Committee would be relieved from any further inquiry.

The Chairman: Then the Committee find the preamble proved.

Mr. Littler said that he would now proceed to the next necessary alterations. There was only one other point—that the Company were to have the power of charging 1s. more in the out-districts, say beyond a radius of two miles from the present works.

Mr. Otlass proposed it should be "beyond the district of the Local Board;" that would prevent an undue expenditure of capital.

Mr. Littler having agreed,

The Chairman then proceeded with, and the Chairman was directed to report the Bill, as amended, to the House.

Legal Intelligence.

FALMOUTH COUNTY COURT.—Tuesday, June 22.

(*Before* Mr. H. Bere, Q.C.)

THE FALMOUTH GAS COMPANY AND THE SEXTON'S RATE.

Judgment was given in the case of *The Rev. John Wright, Rector of Falmouth,* v. *The Falmouth Gas Company,* in which the plaintiff sought to recover arrears of sexton's rate in respect of tenements used and supply pipes.

His Honour said that the clause imposing the sexton's rate directed that "the Rector and Churchwardens of Falmouth from time to time might and should assess all and every the houses, shops, cellars, and counhouses, with the appurtenances, within the parish of Falmouth, which were brought in on upon the occasion, in their several precincts of Falmouth." The first objection taken in this case was that the gas-pipes which formed the subject-matter of the Company were not rateable, because they were not houses, shops, warehouses, cellars, or outhouses, and did not come within the meaning of the word "appurtenances," and he was of opinion that that objection was well taken. The statutes which imposed the poor-rate so also 43 Eliz., cap. 2, sec. 1, and 17 Geo. 3, cap. 3, sec. 1, which imposed and overseers should levy every inhabitant and every occupier of lands, houses, &c., in certain sums as they thought fit, for the necessary relief of the poor, and if the Falmouth Act had contained the word "land," then there would be no doubt at all that the gas-pipes would be rateable. Of course, in the case of Chatham, when the statute imposing the Parochial Assessment Act was passed, gas-pipes were not thought of, and although the appeal in that case was dismissed, the point was never brought in an open manner before the Court, and in subsequent cases. The case is it was a question whether pipes were not land, it was quite clear that the Act of Parliament for the Company was rateable, because the Act of Parliament provided that the gas-pipes would be rateable as occupiers of land. In a local Act of Parliament relating to the Manchester Water-Works, for example, which came under the same category, were held not to be rateable under the Parochial Assessment Act, which made other provisions, so that the question was whether other gas-pipes or waterworks could be included in the word tenement. But in the Falmouth Act the word "tenement" was omitted; for instance, they were held to be hereditaments, because hereditament meant a thing that could be inherited, and would include the ground and soil and several yards below in which the pipes were placed. There was no doubt that most appurtenances were hereditaments, but all hereditaments were not appurtenances, and he relied upon that great point—not appurtenances within the meaning of the Act. But there was another point which was equally fatal to the claim, and that was that gas-pipes were, and rightly ruled in some par, rateable in the assessment on the pipes ought to have been taken by way of symbol. In the Act of Parliament they would see it laid down that where any person was aggrieved by any equality in the operation of the rate, "or every such case the Justices of the Peace for the County of Cornwall for the time being, at the Quarter Sessions, shall have power to hear and determine all questions and difficulties arising out of the said rate." Now, the Justices of the Peace were expected appeal, or it ought to have been if objected to at all, as there were cases showing that there must be an appeal where an inhabitant was rightly rated for some property, although wrongly rated for others. A judgment by Lord Chief Justice Ingman was very much to the purpose, as it pointed out that the benefit of exemption was lost by a rate last being appealed against. He was, therefore, in this matter, bound to find a verdict for the plaintiff, although from this he should except the gas-pipes in the streets, because of the Act; but in case of appeal the question should be taken by way of appeal, and could not be raised as a defence in the action brought by the sexton. Inasmuch, however, as the very substantial question of liability was involved, he should not give costs.

Judgment for the plaintiff accordingly, but without costs.

Miscellaneous News.

BRITISH ASSOCIATION OF GAS MANAGERS.

(*Continued from Vol.* XXXIII., *p.* 953.)

Mr. W. Cann (Halifax) read the following paper on

GAS-ENGINES.

The question of gas-engines is just now being brought prominently before the attention, not only of gas-engineers, but of the whole public, by the numerous voices of the different claimants for popular sympathy and patronage; and as these different machines promise to play such an important part in the consumption of gas in the future, I think it advisable that we should by no means neglect to give the matter our careful attention, so as to be able to answer those inquiries which will, from time to time, be put to us by those who are desirous of using gas-engines, and who trust their own judgment, and prefer to have it backed by that of a gas-person, before committing to invest their money. But as there is no good reason without some little obey, we should find that this question of amusement and useful machine will become a fertile source of complaint as it is more generally adopted; so that if it were only that we may deal intelligently with the complaints when they arise, it would be worth our while to give this matter our serious consideration.

I will not trouble you to go minutely into the historical part of the question, as I am sure you will find that fully dealt with in the day's Bill I hope you will not consider it out of place to say that if I have to what has been done by our own body in reference to this particular subject.

At the first meeting of the Association, held in Manchester in 1861, Mr. Hodkett, of Ipswich, read a paper on "The Application of Gas to Motive Power." This paper consisted of a description of the Lenoir engine, which was then being supplied by a firm of engineers in Paris, and Mr. Goddard says, "The engine is a very pretty, and, in fact, a beautiful adaptation of scientific and mechanical manipulation to believe it was difficult to conceive." He then gives a very clear and concise description of the details of the engine; but as, in spite of its beauty and adaptability, that engine has, along with others, become an instrument of the past, I shall satisfy myself with a very brief description of it, and refer any of you who desire a more intimate acquaintance, to the paper referred to.

The "Lenoir" and the "Hugon" were, I believe, the first two gas-engines ever practically applied or extensively used. They resembled in outward appearance, for the most part, small horizontal engines, and worked by drawing into the cylinder a charge of mixed gas and air during the first half of the stroke of the piston, and at the middle of the stroke this charge was exploded, either by means of a slide valve or an electric spark. The explosion which followed was intended for exerting for the moment, great pressure on the piston; but as brief was the duration of the pressure produced by this explosion, that the

THE ANNUAL REPORT OF THE METROPOLITAN BOARD OF WORKS.

The Annual Reports of the Metropolitan Board, extending now over a period of twenty-three years, afford an instructive record of the progress which has been made during those years in the improvement of the Metropolis. The machinery employed for the purpose of effecting this improvement may seem somewhat cumbrous, and the rate of advance may not be considered rapid. Still the aggregate result is imposing, and the machinery, on the whole, has worked tolerably well. Whether a point has now been reached where the existing system will be found inadequate for the task assigned to it, is a question of somewhat serious import, and suggests some misgivings. There are signs of a break-down with the Artizans and Labourers Dwellings Improvement Act, and matters also look a little ominous with regard to the Fire Brigade. In the formation of new streets the Board appears to halt, and its policy on the water question is far from happy. The Board seems of late to have misunderstood its position. It has been appointed—we might say commissioned—to perform certain duties, and to carry out certain works. Beyond the functions thus prescribed, the Board is powerless. Its nature, in fact, is that of a Commission, created for certain purposes, and capable of being employed for other purposes, as decided upon by the Legislature from time to time. Internally the Board has no power whatever. It must wait until authority is conferred upon it, before it can undertake any fresh enterprise. It is not a municipal body, like the Corporation of the City, or of Manchester, or of Hastings. In those days even Municipal Corporations, directly elected by the ratepayers, are obliged to take a vote from their respective constituencies, before they can legally enter on certain undertakings of magnitude. The Metropolitan Board is not in a position to appeal to the ratepayers. While its hands are thus tied, its responsibilities are as much the less. All it is accountable for is the due carrying out of the work confided to it by Parliament. The position may be humble, but it is safe, and may be one of eminent usefulness.

Looking at the Annual Report of the Metropolitan Board which has just been issued, we see that whereas at the close of 1865 there were simply two Acts of Parliament directly affecting the Board, there are now nearly a hundred. This shows how the Board has, so to speak, been built up. It is empirical, growing from without. Its local experience with regard to the Water Bills is startling, but instructive. In that instance we see the Board running on an errand to which it had not been sent. On this same question we have further to complain that the Board fails to do certain work which it has actually been called upon to perform. It has aimed on the water question, both by excess and defect. It has incurred an expenditure of £16,000 without result, and it has at the same time evaded its duties under the Metropolis Water Act of 1871. The error is a grave one. The Board may represent to the Government that its duties require to be re-arranged, or that some great public work requires to be carried out which it is prepared to execute. But when an obligation is cast on the Board, there is no choice except to fulfil it. The Board appears now in the aspect of a public servant which wishes to choose out of a hundred Acts of Parliament what it shall do, and what it shall leave undone. In the case of the Thames floods it goes yet further, and decides for itself how it shall do the work which Parliament requires to see accomplished. Mr. Cross seems in the case of the Thames floods to be willing to let the Board have its own way, not because he thinks that may the best, but because the Board will really work in no other. This, however, is a critical state of things for the Board, for the policy of self-will is never so dangerous as when it appears to succeed. It is necessary that the Board should be on good terms with the Government, and should show a readiness to comply with the [illegible] of Parliament.—This it has not shown of late, and it has managed on some occasions to be at variance with itself as well as with almost every other authority.

Notwithstanding its defects, the Metropolitan Board undoubtedly performs a vast amount of very useful work. Its recent conduct with regard to the Vestry of St. Luke, in respect to certain local transactions bearing on the purchase of private property for public purposes, also shows that the Board is anxious to keep itself above suspicion. That affair has ended satisfactorily, and no more need be said about it, except to commend the Board for its firmness on a matter of principle. Possibly, even in that instance, the Board went a little beyond the strict boundary of its functions; but the error—if one existed—"leaned to virtue's side," and may therefore be forgiven. In respect to the Artizans Dwellings

Act, the Board has a very responsible task to perform. The present report tells us that the Board has been called upon to consider the conditions and requirements of thirty different areas in the Metropolis, and to decide upon the course to be adopted in the case of each; "it being obviously impracticable, in view of the inconvenience of removing large "populations of the poorer classes simultaneously, to carry "into effect many extensive schemes in the same year." Of the thirty "representations" made to the Board under the Act, eighteen had been already dealt with before the end of 1878; that is to say, with regard to fifteen some kind of progress had been made, while three were considered as cases not suited for the Board to deal with, and the remaining one was that of the Holborn site, concerning which the Board and the Home Secretary were not agreed. On this subject of workmen's dwellings, it is worthy of observation that Mr. Liddle, the Medical Officer of Health for the Whitechapel district, expresses a fear that the operation of the fifth section of the Act will fail to confer the sanitary benefits expected from the statute, seeing that it contemplates retaining the working population on the old area, or close to it, thereby maintaining the population at its present density. It has been shown by Dr. Farr, that the atmosphere becomes deleterious in proportion as the population becomes more dense, that within certain limits this deleteriousness is expressed by the mortality, and that the mean duration of life varies according to the proximity of the individuals forming the population. In other words, the nearer people live to each other, the shorter are their lives. Hence Mr. Liddle contends that it is not enough to pull down and rebuild; it is absolutely necessary to "thin out" the population. "We have power," he says, "to prevent the "overcrowding of rooms, and we certainly ought to have power to prevent the crowning heights of houses on "sites of insufficient size for the healthy existence of the "inmates."

The only answer to Mr. Liddle's objection appears to be, that the structural nature of the dwellings has much to do with the health of the inmates. The working out of the sanitary problem depends not only on the extent of the area, but on the manner in which the area is occupied. But for this, the problem would in some cases scarcely admit of solution at all. It is already manifest that the practical application of the idea embodied in the Artizans Dwellings Act is much more difficult than was expected. It is much easier to pull down than to build up, and there are indications that the Act is being carried out after a fashion which for the present rather aggravates the evil it was intended to cure. The financial prospect, as depicted by Major Jones at a recent meeting of the Whitechapel District Board, is almost appalling. This gentleman states that six sites have been cleared at a cost of more than £734,000, and the sum offered for these amount to little more than £91,000, thus creating a loss of £643,000, the only set-off to which would be about £81,000, the value of the recoupment area which admirably set apart for workmen's dwellings, which the Board would retain. The statement seems almost incredible; but we fear that the case is sufficiently serious to justify grave anxiety. It cannot be deemed a sound principle that a lavish outlay should be cast upon the rates in order to provide dwellings for the working classes. Yet, unless this process is allowed to take place, there seems small prospect that the poor will be much the better for the Artizans Dwellings Act. We should be glad if this matter could be placed in a more cheerful light, for the necessity of re-constructing the "unhealthy areas" of the Metropolis cannot admit of denial, and we should like to see the Metropolitan Board dealing successfully with this important question. One hopeful feature, having a bearing on Mr. Liddle's objection, is, that in some cases the Metropolitan Board are able to provide for more occupants in the projected buildings than were accommodated in the old. Thus, in one instance 559 persons will take the place of 805, and in another 3600 persons will take the place of 1800.

The primary object contemplated in the creation of the Metropolitan Board, was the carrying out of a scheme of main drainage. This has apparently been accomplished, and yet there are complaints that all is not right. It is alleged that the sewers are not big enough, that the sewage is not altogether carried down to Barking and Crossness, and that at most an gross blither is a serious nuisance, by polluting the stream and silting up the channel. The perpetual growth of London gives rise to a state of things which accounts for some of these complaints. As for the alleged silting up of the Thames by the discharge at the outfalls, it is very difficult to prove that such is the case, so long as the volume of water going up and down the river seems to be larger than ever. Another of the great works executed by the Board consists of the cement embankments by the river-side. The Board regard this as a great work, and it is generally admitted to be worthy of the necessity in some districts—notably, in Lewisham and Brixton—and if these are not forthcoming within a reasonable period, there will doubtless be a very active agitation to obtain what is wanted.

In that part of the report which treats of the water supply, we find the Board stating that their scheme for the new supply, "on being first broached, seemed to meet with a good "deal of support on the part of the organs of public opinion," but the project "subsequently encountered considerable opposition outside the walls of Parliament," so that "the Board "came to the conclusion, in view of the disfavour with which "the scheme appeared to be regarded by most of the Local "Authorities of the Metropolis and others, not to bring it "before Parliament again in the following session." Concerning the Bill for purchasing the undertakings of the Water Companies, the Board perceived "the impracticability of successfully promoting in Parliament a measure affecting "interests of such magnitude, unless it received the support "of Her Majesty's Government." By the 10th of December last the Board learned that the Government did not see its "way to further the scheme" for buying up the Companies, and so the Board "resolved to proceed with it." The little difficulty which followed with regard to the coats of these Bills will doubtless occupy a few lines in the next Annual Report. In the present Report we find an acknowledgment of the fact that certain of the Water Companies are supplying the constant service system in parts of their districts. Four Companies are thus specified. Colonel Bolton, in his report for the month of May, speaks of six. More than three-fourths of the East London district now have the constant supply, and the system is being continually extended. There are seven Companies, the Companies who are not moving in the matter being the Southwark and Vauxhall and the Grand Junction. The Metropolitan Board, in Spa-ground Street, besides twelve in a district between Commercial Street and Hackney Road, and twenty-two in the district of the West Company. This is certainly an improvement on the practice of former years. It is also satisfactory to find the Board taking steps to utilize the hydrants which the Corporation are providing in the City.

Of the six Gas Companies in the Metropolis, we are told that three are subject to conditions imposed upon them by Parliament in 1875 and 1876, "which are more favourable "to the interests of consumers than those which previously "existed." One point is a source of trouble with the Metropolitan Board, and that is the difficulty of determining where the gas comes from in the different parts of the Chartered district, the mains being so connected as to mingle the supply from the different stations. This uncertainty might render it difficult to levy the statutory fine in the event of default in lighting power. Hence it was proposed to levy the fine at £25 per candle. To this the Chartered and the two other Companies concerned in the matter were willing to agree, providing the magistrate had a discretionary power to reduce the amount of the fine. The Board refused to confide in the discretion of the magistrate, and so are now told "the question remains unsettled for the present." The accusation pronounced by the *Daily Telegraph*, that consumers are often charged for an immaterial and impossible amount of gas, owing, of course, too late for the present report; neither do we expect that it will receive notice at the hands of the Board. The annual report is a carefully prepared document, distinguished by letting things alone as much as possible. Thus, a reference to the Water Companies is the sole allusion to be complained as to the levying of water-rates according to enlarged assessments. Credibly it is felt at Spring Gardens that if the water supply were transferred to the Metropolitan Board, the charge must necessarily be levied in accordance with the assessment. The Board would not even have the option which the Companies frequently exercise, of letting the old charge remain unaltered where there is no change in the tenancy.

The construction of new streets is an important chapter in the history of the Metropolitan Board. It is, no doubt, a troublesome business, environed with many tedious details in respect to the acquisition of property. There are critics who think that the Board might proceed more rapidly than it does, both in this and other matters. But greater speed would involve an enlarged Board, and, still more, an augmentation in the staff of officers. The fact that the business of the Board is increasing is indicated by the enlargement of the official premises at Spring Gardens. Another storey is being built, and some addition is being made laterally. The task assigned to forty-five gentlemen, of looking after the principal local affairs of more than three millions of people, must necessarily create a strain at certain junctures. The burden is not groaning lighter, although much has been done. A department is sure to make work for itself; but the Board has plenty of labour assigned to it. The most untoward part of the affair is that the Board should attempt to go out of its way to do the work of the Gas and Water Companies. For the present it may be content to leave both the gas and the water in the hands which have hitherto taken charge of these matters. The gas question has been pretty well settled by Parliament, and the water question has brought the Board into sufficient trouble already. So far as the gas supply is concerned, the Board may now carry on its warfare in a pleasant manner, by trying to develop the electric light. In this enterprise it has acquitted itself very creditably, thanks to the skilled assistance which it is able to retain.

Looking down the list of subjects with which the Board has to deal, we may marvel that they are all managed so well. In the case of parks, commons, and open spaces, the Board is promoting the public health in a manner that is eminently popular and pleasing. In the demolition of ledge cells it is accomplishing a great practical enterprise, which will work wonders both for street traffic and house property. Still more marvellous, should it ever come to pass, is the projected high-level bridge at the Tower, designed by Sir J. Bazalgette, and now under the consideration of Parliament. The obelisk of the Pharaohs—Cleopatra's Needle—is another trophy in the hands of the Board. But for the Embankment, whither would the monolith have gone? From bridges and the obelisk we proceed to the consideration of slaughter-houses, manure factories, and other unsavoury places, in the regulation of which the Metropolitan Board is preventing much public annoyance, especially in the more crowded districts. The diseases of cattle also receive the cognizance of the Board. The trade in explosives is a matter which concerns the safety of the public in a greater degree than is always apparent on the surface, and here again we find the Board exercising its protective power, as the local authority for regulating the manufacture, conveyance, storage, and sale of explosive substances throughout the Metropolis. Nearly two thousand premises for keeping explosives for sale were registered by the Board in the course of the year, and these have been periodically inspected and reported upon. The storage and sale of petroleum is a kindred subject, dealt with under an Act which the Board has long endeavoured to get amended. The Board is also the local authority for enforcing the Infant Life Protection Act of 1872, so far as concerns the Metropolis outside the City. There is much propriety in the suggestion that "institutions" where infants are kept should come under inspection, as well as the present registered houses. Some recent events show the necessity of such a provision.

A Board of Works cannot be kept going without money. The Metropolitan Board expended more than three millions sterling during the year 1878. Of this sum rather less than two millions was defrayed out of money raised by loans. The estimated expenditure for current purposes in the present year is over a million, of which more than half is for interest on loans and stock. The redemption of debt takes £213,000. The estimated income consists of a quarter of a million from the coal and wine duties, contributions to the amount of £31,000 from the Government and the Fire Offices towards the expenses of the Fire Brigade, and £101,000 in the shape of interest, rents, fees, and other miscellaneous receipts, leaving £681,000 to be raised by rate—an amount nearly equivalent to the interest to be paid on loans and stock. During the year the Board advanced, or agreed to advance, the sum of £200,000 in loans to Vestries and District Boards. "The "increased scope of the Board's operations" is mentioned at the close of the Report, with the encouraging intimation that although the work has thus grown bigger, "the consolidated "rate levied by the Board is still below sixpence in the "pound." What this amounts to, we have seen; and the growth of London, in magnitude and wealth, enables the Board to get more for its sixpence every year.

THE RETROSPECTIVE EFFECT OF THE GAS-WORKS CLAUSES ACT OF 1871.

SIR,—The question involved in the consumination of your correspondent "Glascow" on this subject, in your issue of June 2, say, I think, so far as its present position is concerned, be fairly taken as answered by your editorial note; but as it seems to me to be a subject of a very important character, and has been translated, up to now, unnoticed by your numerous readers, allow me, in such absence, to draw further attention to it, and for the reason that it appears to have a much wider range than simply affecting the procedure of gas companies and their equitable and legal rights, for the principle also applies to water-works, railways, reconveries, piers, and all undertakings which have been compelled to seek, and have obtained parliamentary powers. If I am correct in my views, the dictum of Justices Lush and Quain is on variance with our ordinary conception of equity. If, on the other hand, their decision be correctly over the Lord Chancellor, in making the Gas-Works Clauses Act of 1871 retrospective, has exceeded its functions and overstepped its bounds. In support of this view, allow me to make the following remarks:

A private undertaking requiring parliamentary powers, and consenting to submit to certain clauses embodied in a previously passed Act or Acts, applies for a special Act. Assume the Bill to have passed, and received the Royal Assent. It declares that the company "shall be a body corporate with *perpetual* succession and a common seal, and with power to purchase, hold, and dispose of lands and other property." Is not this, therefore, a right in the character of, if not absolutely a freehold; and, if so, can the Legislature, without due notice and consideration, take it, or any part of it away? In fact, is it unless with our common rights for a public Act, sitteous without notice, to annul or even to amend a private Act, without cause being shown that the undertakers had neglected to comply with the sections of their Act? In other way, where is the sanctity of a "Special Act" and its "perpetual succession"?

This there has been no error committed in the Act of 1871 by the introduction of clauses differing in significance from can be no doubt; but when it contains one clause in unison with the existing powers and usage of Parliament—namely, "That the provisions of this Act shall apply in every gas undertaking authorized by any special Act *hereafter* passed," this should surely be enough to prevent its being construed otherwise than as having a retrospective meaning.

Mr. Hatsell, Q.C., in the second edition of his very able work on "The Law Relating to Gas and Water," remarks: "There whose duty it is to administering the law very properly grant against giving to an Act of Parliament a retrospective operation, unless the intention of the Legislature that it should have so construed is expressed in clear, plain, and unambiguous language; because it manifestly shocks one's sense of justice that an act, legal at the time of doing it, should be unlawful by some new enactment." The Legislature has always strictly observed that liberals from the law, and whenever it is possible to put upon an Act of Parliament a construction not retrospective, the Courts will always adopt that construction." Further, your correspondent's illustration of giving an already incorporated person an exemption merely because the silvers of a new act have been place since his first constituted, is not only much to the purpose, but is clearly shows that the decision of Justices Lush and Quain is to be taken as a settlement of "this nice sharp quillet of the law," the "letter that killeth" (probably unknowingly) a most unjustifiable and unconstitutional act.

And, further, in support of this view of the matter, I would refer to the following twelve Acts of Parliament—namely, the Lands Clauses Consolidation Act, 1845; the Companies Clauses Consolidation Act, 1845; the Railway Clauses Act, 1845; the Gas-Works Clauses Act, 1847; the Water-Works Clauses Act, 1847; the Markets and Fairs Clauses Act, 1847; the Commissioners Clauses Act, 1847; the Towns Improvements Clauses Act, 1847; the Town Police Clauses Act, 1847; the Cemeteries Clauses Act, 1847; the Telegraph Act, 1863; and the Railways (Ireland) Act, 1851—we find that they all carefully, clearly, and decidedly state that they shall extend only to such works, &c., as shall be authorized by any Act of Parliament *hereafter* to be passed. Again, as in the case of the Water-Works Clauses Act, 1863, and the Railway Clauses Act, 1863, it is distinctly exercised it was to be incorporated "to any special Act which shall hereafter be passed."

Although it has been written that "a little learning is a dangerous thing," I hope you and many readers will excuse it by citing a quoting of the law; but the question raised was, in my opinion, so fraught with importance, not only to gas undertakings, but to the general public, that opinion appeared in unison with the exposition of giving it, especially as my quoted work says: "The opinion of the writer is that the Act of 1871 is only to apply to such companies of Parliament have been established since the date mentioned subsequently to 1871, selected its proceedings will be brought clear gas undertaking had been authorized by their subsequent special Act."

If your readers feel disposed to have a little historical episode of this parliamentary morsels—this controversies—I refer to the Journal of Gas Lighting, &c., they will find it in the 1871 volume of your Journal, pp. 216, 291, 371, 387, 388, 428, 461, 501, and 549; but we of no moment, I shall only venture to extract three from, trifling as they are, to show that the spirit of your late respected Editor (Sir. J. Clegg, Barbar), and the deference of the petition presented against the original Bill, was that the Act never was intended to have any other than a prospective effect:—

(Vide "Circular to Gas Companies," March 28, 1871.)

"We print this Bill in extenso in another column, and may produce its remarks we have to make on its provisions with more propriety. It although ostensibly intended to enable gas companies to sell their gas by meter, or otherwise, it will, nevertheless, be found to have much wider bearings than any Special Act or by any Act hitherto introduced into any Parliamentary Session, for in many instances where they apply for further powers, it is probable that they will insist on them being inserted in the Bill, therefore it is desirable that every gas company should carefully peruse the provisions of the Bill, as we have said, it is sure to affect them."

(Vide the petition on page 501, Vol. XXI.)

"Your petitioners fully admit that the Bill does not propose that clause in the Act of 1871 should be made applicable immediately to all existing companies; but, nevertheless they are of opinion that as it is the practice of Parliament to impose upon new or existing companies any new conditions which they may apply for further powers, it is probable that the clauses in question will, if the Bill be allowed to pass into a law, become a fair and reasonable subject to be introduced into a local power against its receiving the sanction of your Honorable House."

The Contest of the Gas Companies.

Those of us whom the present appears clearly as the more bridge between the past and the future find greater cause for congratulation in the recent speech declared war whilst less broken out so suddenly and so vigorously between the gas companies, than in the welcome fact that gas bills are certain to be reduced. In the first place, the final cost of gas is going to be made cheaper, for that the dollar will be able to understand a while the contest is evidently going to be of such a vigorous character that the noise it will make must excite the attention of even the most apathetic.

The spectacle, too, of these great corporations contending for the endowment of their power to tax the community will be a most instructive sight. Already society is beginning to feel that the destiny is something more than simply serving as an exploitation ground for corporations. We are no longer in the days when the hallow-day was an inquisition upon the gaze of the stick brook and the force of innovation was supposed to have reached its limit. A community like New York has become a thing of importance in the world, and recognizes that it is entitled to a share of progress but on account of its client usage to first cost. It is the best promoter of order, security, and peace there is. Put a gas light in a city's blind alleys and they cease to be the lurking-places of vice and crime. They are no longer blind alleys.

Our very language recognizes the moral power of light, and an enlightened community, to be really such, must maintain it in the public places in as much as in social and industrial institutions. We do not usually fit it as an objection to be too unobstructed for the service it requires us to be favored with. It is like an ocean to be favored for ballast, and certainly will not injure itself for its betters.

The perfect organism is made up of a combination of organs, each performing its functions, not to each other's injury but to their natural benefit. That the social body has not yet arrived at its perfection in this regard is the very context of the gas corporations shown, with some of us who can remember a few years back how harshly some of those companies disregarded the reasonable request of their workmen, as surprised at seeing them to-day overtaken by the Nemesis that regulates such matters.—*N. Daily Graphic.*

Correspondence

Sugg's Large Burners.

The American Meter Company has received the following from Sugg, which answers many anxious inquiries:

VINCENT WORKS, VINCENT STREET,
WESTMINSTER, June 27, 1879.

AMERICAN METER CO.—Gentlemen: I am in receipt of your two letters of the 16th inst., and much regret having been compelled to delay sending off your orders. As you will perceive from the inclosed invoice, a large parcel of burners, etc., have been sent off. I have had such a treadmillous run on 60-candle burners that I found it impossible to get more than four ready by the time the cases were ready for shipment, and did not wish to keep some here any longer, knowing how pressed you would be for the goods. I can well understand how unpleasant it must be for you to have been kept so long without the burners, and should have been only too pleased to have supplied you with five times the amount if it were possible. I have been very much engaged lately in professional work, which necessitated my absence from town and from England for nearly three weeks, but I forward also lithographs of large burners and bat forms, of which the globe lamp is my latest design. I hope to advise you shortly of having despatched another parcel, completing your orders. I think it would be well if you would impress on your patrons that the new lighting system being, so to speak, in its infancy, it is perfectly impossible for me to quit off more work than I do at present without running the risk of turning out inaccurate and shoreuly work, which would only result to damage my interests more than the delay in the delivery of orders. You may rely on me using diligence for the future. I am working my hands nearly day and night now, and hope to send on all the rest of your orders very shortly. I am, dear sirs, yours very truly,

WILLIAM SUGG.

Clinging Retorts.

Mr. Editor:—Now that the electric light agitation has somewhat subsided, it may not be amiss to discuss one of the means whereby the gas consumer of to-day is enabled to cheapen the manufacture of gas, as well as to increase the production of the same from a given amount of material.

By what system of charging retorts can the best results be obtained? is a question of importance to many of your readers, and one which, perhaps, every manager has satisfied to his own satisfaction, but which, as a matter of interest to all, may bear a little ventilation. The systems of charging in actual operation are, as is well known, chiefly the shovel and the charging with the scoop. Both systems have their advocates, but, which is unquestionably the best? That is the question which might be very profitably discussed. In charging with the shovel, from the fact that the shovelful of coal is thrown into the retort until it is closed, gas is wasted; and no matter how experienced the workmen may be who handles the shovel, the coal can not be charged so slowly as when the scoop is used by men who know how to use it. Nearly two years ago your correspondent introduced the use of the scoop in a works where for over twenty years the retorts had been charged with the shovel. The men were very expert in the use of the shovel—some could be more so; yet the result is justified—that the same men, using the same kind of coal and the same benches of retorts, now carbonize 26 per cent. more coal per retort in 24 hours, and get over 16 per cent. more gas out of the coal. Of course there was violent opposition to the introduction of the scoop. "It was tried before, and could not be done." "Our retorts are not large enough," etc. In fact, all conceivable objections that could be made were made; and as it will be in the case of every superintendent who may try to introduce anything new to save labor in his works. But let all who have at least three men employed about the works try the scoop, and try it under their own supervision, with proper scoops, and in a way that they should be handled; and although their gain may not be as large as ours actually was, they will nevertheless gain enough to repay them for the trial.

Some years ago your correspondent was given charge of a large retort house, in which all the work soon had gone on stolen. Having been given authority, he engaged new men, nearly all of them having never seen the inside of a retort house. Within two days therefore that company's district was well supplied with gas, although just before that time there was not enough gas on hand to light up the works. There were some 90 benches under fire. One week after this time his regular number of benches only were needed. Had the system of shovel charging been used then, the men could not have learned quickly enough to do the same.

There is another system of charging retorts which deserves far more attention, especially for large gas companies, than it seems to receive. This is charging retorts by machinery. Your correspondent had the good fortune to come in daily contact for nearly a year with a machine now for drawing and charging retorts. The machine was constructed by Mr. T. Z. Rowland, of Green Point, N. Y., and was run at the works of the New York Gas Light Co. Although, in the opinion of your correspondent, this machine was too complicated as then constructed, it seemed to him that Mr. R. was on the right track to success in this matter. By removing a few of the unnecessary parts of the machine—the ones that always gave the most trouble—and by substituting a simpler device, which was known at the time, and also by letting practical gas men, not merely good mechanics, run the same, it might now be all it was hoped it would be, and might spell some of the calculations of the electric light people. The machine charged the coal into the retort evenly and quickly, and, supposing the present requirements of the retort were used in connection with this machine (which, by the way, is saving in labor to large gas companies would probably not fall short of 60 per cent. It may be to the interest of all the larger gas companies to try and induce Mr. Rowland to finish and bring out his machine. Meanwhile let those who are not now using prejudiced give the reasons why, in their opinion, shovel charging is to be preferred, and thereby enlighten, undoubtedly, many of your readers. Yours truly,

Norfolk, Va. FREDERIC SOZER.

Shoftpville (Ind.) Gas Light Company.—

On the 7th inst. the following gentlemen were elected officers of the above company: John Hensley, President; George H. Dunn, Vice-President; A. J. Gorges, Treasurer; and G. W. EDE, Secretary.

Prices of Gas Coal.

Penn and Westmoreland,	$4.50 at New York	
"	2.50 at Baltimore.	
"	3.75 at Philadelphia.	
Dungurl,	1.25 at New York.	
Newburgh Orrel,	2.50 at Baltimore.	
Murphy Sun,	3.50	
Fairmount,		
Cherryvale & Oil,	4.00 at New York.	
Shovel,	2.25 to 2.50	
Pittsburgh Peerless,	2.50 to 2.75 York.	
Cannelton Cannel (by cargo),	2.25 at New York.	
Splint,	2.00	

The above prices are about $1 per ton below those of 1878.

GAS ENGINES.—The introduction of gas engines, says the *Engineer and Mining Journal*, has attained to remarkable dimensions in Germany and England (especially), where engines of this class, as high as 20 to 30 horse power have been built. Mr. Robert Grimshaw, reporting upon a recent visit to the Manchester Jubilee, Bazaar, notices that 5 to 6 horse power gas engines, for a land-agar factory, are in course of construction there. The gas companies, in view of large consumption, furnish gas at very reduced rates for such engines.

Fuel-Gas from Water.

Much attention has recently been directed to the Lowe & Strong processes for producing a cheap gas by the decomposition of water, which in the form of steam is brought in contact with incandescent carbon. The experiments that have lately been made in London and Boston have been attended with favorable results, and several scientific men, sense of this government officials, declare "that the gas can be readily employed for welding wrought iron, for smelting in crucibles as well as pig iron as the only fuel necessary in all those experiments have been very satisfactory as to the heating power of the gas. Only a few days after land, we can confirm the above, and it is in the employment of the gas for cooking purposes a most extraordinary saving in the household department, and that the cleanliness and convenience of its use must make it a favorite with all housekeepers."

The gas was used in a small baking and roasting stove, which required a gas consumption of only fourteen feet per hour, to maintain a heat heat of 250° and upwards.

For illumination the gas was conducted through a vessel filled with cotton saturated with benzine, and the result was eminently satisfactory.

Great Reduction in Rates.

NOTICES ISSUED BY THE NEW YORK GAS LIGHT COMPANIES.

OFFICE OF THE MANHATTAN GASLIGHT COMPANY,
No. 4 Irving Place, New York, June 27, 1879.

The Manhattan Gaslight Company respectfully informs its consumers and the public generally that on and after this date the price of gas furnished by this company will be at the reduced rate of 20 cents for 100 cubic feet to all who consume less than 10,000 cubic feet of gas per month. To those who consume 10,000 feet per month the price will be 19 cents per 100 cubic feet, or $1,90 cents per 1,000. To larger consumers a still greater reduction will be made, the price depending upon the quantity supplied. Having availed itself of all known improvements, this company will continue to furnish in the future, as it has done in the past, as pure, as good, and as desirable a light as can be obtained by any process yet invented or discovered.

JAMES W. SIMPSON,
Secretary. GENERAL ROOME,
President.

OFFICE OF THE NEW YORK MUTUAL GASLIGHT CO.,
26 Union Square, New York, July 1st, 1879.

The New York Mutual Gas Light Company has this day reduced the price of gas, and from and after this date the price of gas will be as follows: To consumers of less than 10,000 cubic feet, per month, 20 cents per 100 cubic feet, or $2 for 1,000 cubic feet. To consumers of 10,000 cubic feet, per month, 19 cents for 100 cubic feet, or $1.90 for 1,000 cubic feet. To larger consumers a still further reduction will be made.

THE NEW YORK GAS LIGHT COMPANY,
By WILLIAM H. WEBB, *President.*

Gas Companies and Electric Lights.

The following letter from Mr. Edison to the Secretary of the Manhattan Company, and the reply of the latter, will be read with interest:

MENLO PARK, June 30, 1879.

DEAR SIR,—I have the pleasure to inform you that I have succeeded in producing a perfect electric light, which is not only steady, but can be subdivided to any desired degree of feebleness, and which is entirely free from odor, smoke, or any injurious effect. It is also cheaper than the light from gas burners of equal illuminating power. I shall be ready to introduce it as a practical illuminator in the course of next winter. Before doing so, however, I desire to make such arrangements with the gas companies as will prevent any injury to their interests. I am aware that the introduction of my system will involve the abandonment of a large amount of gas fixtures, and that the companies will be subjected to a heavy loss in consequence. I propose, therefore, to pay the companies a royalty sufficient to cover this loss, and I shall be glad to know whether your company will be willing to enter into such an agreement with me. Yours truly,

THOMAS A. EDISON.

NEW YORK, July 2, 1879.

DEAR SIR,—Your favor of the 30th ult. is received, and I am directed by the Manhattan Company to say in reply that they will be glad to see you at the office of the company at your earliest convenience, when they will be pleased to hear from you in regard to the introduction of your system of electric lighting, and to make such arrangements with you as may be mutually satisfactory. Yours truly,

WILLIAM H. WEBB, *President.*

THOMAS A. EDISON, Esq., Menlo Park, N. J.

Fuel-Gas from Water.

Much attention has recently been directed to the Lowe & Strong processes for producing a cheap gas by the decomposition of water, which in the form of steam is brought in contact with incandescent carbon. The experiments that have lately been made in London and Boston have been attended with favorable results, and several scientific men, sense of this government officials, declare "that the gas can be readily employed for welding wrought iron, for smelting in crucibles as well as pig iron as the only fuel necessary in all those experiments have been very satisfactory as to the heating power of the gas. JAMES W. SIMPSON,
Secretary. GENERAL ROOME,
President.

OFFICE OF THE NEW YORK MUTUAL GASLIGHT CO.,
26 Union Square, New York, July 1st, 1879.

The New York Mutual Gas Light Company has this day reduced the price of gas, and from and after this date the price of gas will be as follows: To consumers of less than 10,000 cubic feet, per month, 20 cents per 100 cubic feet, or $2 for 1,000 cubic feet. To consumers of 10,000 cubic feet, per month, 19 cents for 100 cubic feet, or $1.90 for 1,000 cubic feet. To larger consumers a still further reduction will be made.

THE NEW YORK GAS LIGHT COMPANY,
By WILLIAM H. WEBB, *President.*

consumers a reasonable reduction from above prices will be made. Service pipe, meters, and burners will be supplied on application, without charge. This company has availed itself of all improvements in the manufacture of pure, safe and economical gas, and claim for it great superiority over any gas sold in the city. We solicit a continuance of your patronage, and that of all your friends, assuring you and them of prompt attention and courtesy.

CHARLES PLAGE, *Secretary.*

The following burlesque "ad." appeared in the daily papers on the day after the Manhattan's announcement. Who paid for it?

TO CONSUMERS OF GAS.—GREAT REDUCTION IN PRICES!!

OFFICE OF THE MANHATTAN RIBS LIGHT CO., }
RIP VAN WINKLE PLACE, NEW YORK, June 17, 1870. }

This company respectfully informs its customers and the public generally that for the past 40 years it has endeavored to supply them with light, and by the arrogance and incivility of its officers to maintain a monopoly of the lighting business. As many company having recently started to supply a gas, said to be made from water (?), this company finds it necessary, in order to try to maintain its monopoly, to reduce the price of gas, and therefore to simplify its business and to make it really understood by its customers, it has from this date adopted a scale of prices, 42 in number, so arranged that a consumer of 9,000 cubic feet of gas per month will be compelled to pay more than a consumer of 10,000 cubic feet, and so on, with a still greater reduction to larger consumers, on the principle that the poor man should always pay more than the rich man for the necessaries of life. The officers of this company having made themselves masters of the gas business some 25 years ago, feel confident that they have all the improvements that existed then, and also feel sure that no improvements of any kind have since been made in the science of making gas or in any other science, and they will always in the future, as in the past, furnish the best light that can be made by any of the processes which were in vogue 25 years ago.

PIPP-FAPP-POOH, *Secretary.* GENERAL ROOME, *President.*

OFFICE OF THE MUNICIPAL GASLIGHT COMPANY, }
Nos. 358 & 360 FOURTH AVE., July 1st, 1879. }

Bills rendered by this company after the 1st of July, 1879, will be made at the rate of 22 per 1,000 cubic feet per month. When 10,000 cubic feet has been consumed during the month, a discount of 5 per cent. will be made from that price, and a greater discount to consumers of larger quantities. The municipal company's gas is from 20 to 30 per cent. cheaper to the consumer, at the present price, than the gas of the Manhattan company. To say nothing of the 40 per cent. more light given by the Municipal gas, which is 22 candle power against the Manhattan's 16 candle. The Municipal company trusts that the public will will not lend its support to the Manhattan company in the futile effort now being made by them to crush out the opposition companies (which companies have brought about a reduction in the price of gas to this city and its inhabitants) for the purpose of regaining the monopoly so long held by them; and, therefore, appeals to all its customers and the public generally to support it and not to be tempted by the offers of the Manhattan company to sell gas at far less than it costs to furnish it, a proceeding which must lead all thinking men to the conclusion that its object is to obtain some selfish end.

PHILIP ALLEN, *Secretary.* CHAS. G. FRANKLYN, *President.*

OFFICE OF THE NEW YORK GASLIGHT CO., }
157 & 159 HESTER STREET, NEW YORK, July 1st, 1879. }

The price of gas supplied by this company, on and after this date, will be as follows: *For less than* 10,000 cubic feet per month, the price will be $2 per thousand. For 10,000 feet per month a discount of five per cent., and for a larger quantity per month a further rebate will be made.

GEORGE W. DOANE, *Secretary.* THOMAS N. LEES, *President.*

INTERVIEWS BY HERALD REPORTERS.

In an interview had with a *Herald* reporter General Roome, the president of the Manhattan Gas Light Company, who began the present war of retrenchment, gives another view of the cause for the present movement. The public will probably care but little about the real or imaginary causes of the quarrel among the gas purveyors, so long as they get good light and cheap rates, or have the prospect of performing their household cooking cool, cinders, ashes, and the better and no inconsiderable item of servants' wages. Yesterday a *Herald* reporter paid a visit to all the gas light companies in the city, and the result of his tour, printed below, will be found of interest to every gas consumer.

GENERAL ROOME'S EXPLANATION.

General Charles Roome, president of the Manhattan Gas Light Company, was called upon at his residence in West Fifty-second street, where

the gentleman was confined by a slight illness. "In the absence of data, which are at the office, I will tell you all I can," said he, "about the reduction in the price of gas made by the Manhattan Company, and the causes which led to it."

"What is the extent of the reduction?"

"The extent of the reduction which went into effect on the 1st of July varies. To the largest consumers we sell gas at $1.25 per 1,000 cubic feet, and the prices vary laterzaddicatly according to the quantity of gas consumed. To the more exact, the price of gas to those who consume less than 10,000 cubic feet per month is $2 per 1,000 cubic feet; to those who use the latter amount and over per month it will be $1.90 per 1,000 feet, and still further concessions are made in the case of large consumers, until the minimum rate I have spoken of is reached."

"How many consumers has the Manhattan Company?"

"About 27,000."

"Has the introduction of the electric light had any influence upon your company in making these reductions?"

Mr. Roome replied contemptuously and quickly, "The electric light has had nothing whatever to do with the matter. I do not think the electric light worth a moment's consideration."

"What are the causes, may I ask, which have led to the reduction?"

"I will tell you what the policy of the Manhattan Gas Light Company has been, and then the subject will be better understood. I have always been in favor of selling gas at as small a profit as possible consistent with a fair degree of profit to our stockholders. Since my connection with the company, which began in 1836, we have reduced the price of gas from $3 per 1,000 cubic feet to $2.00. Having no opposition when the war broke out, the increased cost of all materials and the enhanced value of labor compelled us to advance the price. There was also at that time the government tax of 25 cents on each 1,000 cubic feet of gas made. The increased rate at that time was from $2 to $3 per 1,000 feet. And now I will inform you of a fact which has never hitherto been made public. Mr. James Brooks, then a member of Congress from the Eighth district of this city, at my request urged upon Congress the propriety of the abolition of this tax. It was done upon giving him my personal pledge that the consumers of gas should have the benefit of the change. We at once reduced the price to $2.75. Afterward we reduced it twenty-five cents per 1,000 feet, making the cost $2.50, at which rate it remained up to the 1st of July."

"There have been complaints against your company in the past," the reporter remarked, suggestively."

WAR TO THE KNIFE.

"I will recite some of the facts of the past. Years ago the Manhattan Gaslight Company made a contract with the city by which we agreed to lay pipes wherever the authorities might direct. At that time the resolutions authorizing the use of gas by the Corporation were passed by the Common Council, the work under their provisions being carried out under the direction of the Superintendent of Lamps and Gas. Under that contract we were to light the street lamps for a price then agreed upon for a period of twenty years. The city required the company to lay pipes in streets where we could have no inducement to go, because the amount of private consumption would be very small. A large part of the money thus expended has never been remunerative to the company. We have laid pipes and lighted every street in our district, extending from Grand to Thirty-fourth street, and, before the Metropolitan Company went into operation, as high up as Central Park. Three more opposition companies have been chartered and obtained the consent of the city to lay pipes wherever they pleased on the Island. Two of these companies are under no restriction whatever as to

tured by either of the others, and that its illuminating power is reduced to effect."

"Do you think the electric light will ultimately supplant the illuminating gas?"

"I do not. The electric light is costly and unsteady. The [illegible] however, when it may be made available for purposes of display for large open spaces. Up to this time we have no reason to expect that [illegible] ever come into general use. In Paris, during the Exposition, it was [illegible] times as much as gas, and was unsatisfactory. Paris paid [illegible] use during the exhibition, because it made an attractive display. [illegible] don it has been lately tried to light the banks of the Thames, [illegible] count of its great expense they have abandoned its use."

THE NEW YORK COMPANY'S OBJECTION.

At the office of the New York Gaslight Company, in Hester street, the reporter found Mr. George W. Doane, the secretary. "Our company," he "supplies the district below Grand street from river to river. [illegible] now charges is $2 per 1,000 cubic feet. The subject of a reduction in the price of gas furnished to our consumers was agitated before the [illegible] July, and would have been acted upon before the present time, except that many of our Board of Directors are in the country and it has been impossible to convene a board meeting."

"Will you reduce the price?"

"I have no doubt whatever of it. A meeting will be held to-morrow for the purpose of taking steps toward putting into effect a reduced scale of prices. The Edison light induced the company to make a reduction."

"Edison has had nothing whatever to do with it. Competition at times have influenced the change. The reduction to be made by our company will date from 1st of July."

"What will be the extent of the reduction?"

"I cannot at present state. When it is made gas will be cheaper than ever before been in this city."

THE MUTUAL FALLS IN LINE.

"The Mutual Company," said Mr. Charles Place, its secretary, leaned back in an easy chair at its office in Union Square, "contemplates a reduction in the price of gas furnished its customers some time after the Manhattan Company put the start of us. We have made a reduction, however, since the Manhattan Company announced its intention. The directors will meet to-morrow to make still further reductions. In other words, we shall adopt a sliding scale to apply to large consumers, the purpose to sell gas as cheaply as any other company in the city."

"How many consumers does your company supply?"

"We have about 18,000 customers on our books."

"What are the influencing causes of the reduction?"

"The action of the companies in reducing the cost price of gas is caused in consequence of the spirit of competition and the lessened cost of material and labor."

"Has the electric light had anything to do with it?"

"Not a particle."

"Is it possible for the Edison light to compete with the gas companies in furnishing illumination to small consumers, as it were?"

"It has been demonstrated that it cannot. That fact has been ascertained. We have in use now a sliding scale. We sell to those who use 10,000 cubic feet a month at the rate of $2 per 1,000 feet; [illegible] who use 10,000 cubic feet during the same period we sell at the $1.90, and to larger consumers a liberal discount in prices will be made. The revised schedule to be prepared will apply more particularly to consumers, such as institutions, hotels, theatres, and similar places. The proposed reduction will make it an object of economy for people [illegible] use of gas for cooking purposes. It will work [illegible]

[illegible] Company will not be so low but I can satisfy my self that the [illegible] now paid by a part of the town is paid by the whole town. [illegible] during those hours when the [illegible] At present the [illegible] of the street lamps are extinguished. [illegible] [illegible] [illegible]

raised, renders it of great value as a fire engine in country mansions and other isolated building, where it can also be used daily for pumping, lifting, it can also be used daily for pumping, lifting, laundry work and ventilating. The gas engine appears to offer to architects a way out of the difficulty they have hitherto found in efficiently ventilating buildings for want of a suitable motor. In crowded rooms fresh air can be drawn in from the most suitable side of the building according to the season, those of day and locality, by means of a fan, and diffused and distributed where required without producing draughts, which are only a discomfort primitive, not to say barbarous, method of ventilation still in use.

[illegible] given to proper ventilation, [illegible] the want of success in the [illegible] mechanical difficulties [illegible] creditable to such a [illegible]

The destruction by fire of [illegible] buildings recently has been ascribed to the presence of a steam boiler on the premises. The danger from fire by starting or keeping the hot ashes is greatly increased when the boiler is placed on any story above the ground floor. So great is this danger that the insurance rates are often as high as to preclude the use of steam boilers by the tenants in the higher floors of a building, and often leads to the exclusion of steam power altogether on the part of the owner. This prohibition of the use of steam power has proved to be a great tax on many small industries, and in the working of crimes and holes in warehouses in London and other places where the cost of working hydraulic engines direct from the mains is too great to admit of their use. The want of a suitable motor to work in the upper floors no longer exists, as gas engines, working up to 10 horse-power, can be applied without any more risk or trouble than accompanies the use of a steam engine without a boiler.

With respect to the comparative economy of working small steam engines and gas engines, this depends chiefly upon the relative prices of steam and of coal gas. Taking the price of coals per ton, and that of gas per one thousand cubic feet in some towns in the north where coined gas is used, the relative prices are two to one, while in London they are as five to one, so that the cost of working were the same for gas and steam in Manchester, the cost of working in London would be over 50 per cent. in favor of the gas engine, a slightly smaller quantity by volume of gas being required for a given amount of work when rich coined gas is used.

The Otto gas engine is said to require not more than 23 ft. of gas per indicated horse-power per hour. At London prices this is equivalent to about one penny per hour, and therefore, working at the same cost for coal and time, would take the place of one horse power per hour. This appears at first sight a very extravagant rate of consumption even for a small steam engine, say under eight horse-power. But as the superior economy of the gas engine has been repeatedly proved where it has worked side by side with a steam engine, it may be as well to inquire into the cause of the extravagant cost of working in many small steam engines. These are used for many purposes where the resistance is very irregular, the power required varying, perhaps, from one to eight horse power. In a very great number of small steam engine and boilers over, say, four or five years old, the amount of steam lost by leakage at joints, taps, glands, slide valves, and piston rings, forms a large proportion of the quantity of steam generated, and the further great quantity of heat lost through the chimney, and by radiation from the furnace, boiler, and pipes, leans a not inconsiderable proportion of that utilised. As this waste is a pretty constant quantity, whether the engine is giving off one or eight horse power, it follows that the amount of fuel used is not at all proportionate to the power developed. When the engine is indicating two horse power, almost as much fuel may be used as when it is indicating six horse. With a leaky safety valve and steam stop valve it sometimes requires a considerable quantity of coal to raise steam and keep it up a few hours at the working pressure even with the engine at rest.

We grant this state of things is disgraceful, but we are speaking of things as we have too often found them, and not as they ought to be. There is little hope for improvement in this matter with many small steam users. As long as they have a boiler which furnishes them with a means of making up for the waste of steam and heat by wasting more coal, they prefer doing so to being at the expense of having their boiler fittings and engines put in good working order. There are thousands of small boilers and engines at work, upon each of which the judicious outlay of a few shillings annually in necessary repairs would yield a return of as many pounds.

In the case of a steam engine and boiler in fair order, and doing intermittent work, there is always a considerable loss in getting up or maintaining steam. With the best forms of gas engines the case is very different. When the engine is in fair order, the quantity of gas used is always in proportion to the power exerted. A certain volume of gas is drawn from the meter just when it is required. Should the engine not be in good order, and there be an escape of the expanding gases past the piston rings, there will be a waste and loss of power, and more gas will be required, but this has seen trenches to built. An engine only of the Otto type cannot use more gas than the quantity corresponding to its maximum power. Such an engine, working up to within 25 per cent of its greatest power, cannot waste more than 25 per cent. of the greatest amount of gas it is designed to use. When the piston rings require renewal, the defect is made manifest by the escape of the burnt gases, and in order to regain the power which the engine loses in consequence, the rings must be renewed, and as economy is mercifully forced upon the user. In a steam engine, on the other hand, the waste of steam in escaping past the piston is easily made up by burning more coal, and this waste is only limited by the quantity of air that can be made to pass through the fire-bars. The above consideration will serve to show why it is always economical to spend a certain sum in order to keep steam engines they have replaced.

Besides the economy in fuel that there is also a great saving in attendance where a gas engine is used, as there is no stoking and continuous expenditure of time and attention. When all is ready, the engine can be started up and left and started from the meter can be locked up and left to itself for hours like a steam engine. The benefit in use of the gas engine was strikingly illustrated in the Royal Albert Hall, at the recent exhibition of electrical light apparatus, by the course of the current, the engine in the body of the hall upon a seven signal was started from a state of rest, the bell slipped on to the pulley and the light produced, all in a few seconds. The engine might be left for a week or more and the same thing repeated without any preparation.

Gas engines may be often used with great advantage as auxiliaries to large steam engines. In many works a steam engine of over 30 horse power is run all night to drive a long line of shafting in order to work a small machine requiring not more than a couple of horse power. The loss in coal, attendance, and wear at tear is often very great when this work is often repeated. By using a small steam engine the evil is only partially remedied, as the friction has to be in attendance. For most such cases, gas engines have been applied with great advantage, as the man who attends little attention can start the engine and give the little attention it requires, and the cost of working is reduced to a minimum.

It is, however, in connection with small industries that gas engines will most likely engines be found in the future. Where steam is required for heating, boiling, and other purposes, the steam boiler will always look its ground, but for many minor industries we may say that the days of small steam boilers are numbered.—*Engineering.*

GAS ENGINES.

At a congress in Brussels, in 1857, of the chief engineers of the French and Belgian navies, plans for inspecting steam boilers, it was the opinion of the meeting that steam engines are not the motors for small industries. The reasons given for this opinion were that small boilers are difficult to examine, their repairs are very costly, and their life is comparatively short. It was agreed that the small motor of the future is to be found in electric, hot air, compressed air, hydraulic or gas engines. The last mentioned was justly regarded as that which has not yet fulfilled its promise.

It is only natural that the stringent laws which regulate the application and working of steam boilers on the Continent, should tend to the effect of increasing the cost of power, and to encourage the use of motors which come under lands governing more inspection with its severe tests and penalties, but we were scarcely prepared to find boiler engineers going, we might almost say, out of their way to advocate the use of gas engines, as it is evidently against their interest, in some measure at least, to do so.

Notwithstanding the favorable opinion of gas engines entertained by steam-boiler engineers on the Continent, there still exists a very strong prejudice against gas engines among engineers in general on this side of the Channel. This prejudice arose from the failure of the first gas engines introduced from France some time ago. Those engines were wrong in principle. It was overlooked by their inventors that the sudden but momentaneous pressure consequent upon the explosion of a strong mixture of coal gas and air exerted against a piston, was not so suitable as the sustained pressure of steam for obtaining a steady motion of a crank and fly-wheel. To this oversight as well as to a considerable amount of complication, necessity for skilled attendance, trouble from heating and accumulations of working, the failure of these first gas engines was mainly due. There is still about it amongst the engineers of this country, but most of those who work have been abandoning the converted steam engine, a change which their construction readily admitted.

The defect in principle has been entirely removed in the gas engines of the present day, of which we have given a description from time to time as they made their appearance.*

Nearly all the drawbacks attendant upon the use of steam, especially for small powers, are due to the risk, attention, and anxiety inseparably connected with the use of the boiler, and it must have occurred to many steam-users what a blessing it would be if the steam engines could be used without a boiler. Now, it is just this desideratum that a gas engine is designed to meet, and the success which has attended the introduction of at least one type of gas engine, renders it easy to predict with certainty that a large new field will be opened out for the employment of motive power; that many small industries will be greatly developed and extended and new industries created, now that a cheap motive power can be employed without the risk and trouble of having a steam boiler on the premises. For instance, the advantage of being able to start a gas engine at full power by lighting a jet and turning the flywheel, instead of having to wait till steam is

(From the London "Journal of Gas Lighting.")

Midland Association of Gas Managers.

At the Sixth Quarterly meeting of this Association, held at Birmingham, on Thursday, May 1, Mr. Charles Hunt, of Birmingham, the President, in the Chair, a paper was read by Mr. C. E. Jones (Chesterfield), on

PUBLIC LIGHTING, WITH SPECIAL REFERENCE TO STREETS, ETC.

The paper commenced with a few remarks on the use of artificial lights in the past ages. It then proceeds: But we pass on to treat more particularly that branch of our industry selected for to-day's consideration—viz., public lighting—the discussion of which I hope may interest and benefit each one of us. It is a subject that certainly has not received too much attention, and perhaps its unremunerative character is responsible for the lack of interest manifested in its development; but even this consideration should not deter us from endeavoring to bring to perfection every branch of our profession.

The chief requirements of public lights are—(a) steadiness of flame, not susceptible to atmospheric commotion; (b) uniformity of intensity; (c) great penetrating power; (d) great diffusive power; (e) over available without preparation, and easily lighted; (f) non-liability to any sudden or self-extinguishment; (g) *wholesome*; (h) commercially cheap.

The first of these is effected by the kind of burner used, and the form of lantern employed to shield the light. Upon the selection of the material to produce the light depend *b*, *c*, *f* and *g*; *f* is chiefly a matter of interruption in supply or mechanical defect; *g* refers to the form of support and the structure of the lantern; *h* we will consider collaterally.

In the wide range of materials from which artificial light can be produced, that which fulfills most of the above requirements is coal gas. No other source of light at present known possesses the inherent qualities of coal gas in anything like a corresponding degree, and the light-giving which the more nearly approach it have a similar composition, being hydrocarbons. Candles and oil have been tried over and over again, both remotely and recently, with the result of leaving coal gas the master of the situation. To coal gas, then, the public returns, being won back to the old love by its many excellent and unique qualifications; and if we this day advance its just claims of coal gas, and bring out more prominently than hitherto its meritorious and special features, we shall not have spent our time in vain, however imperfectly the subject may have been put before you.

To secure a successful combination of the above conditions may be considered by some to be practically impossible, the nature of the service demanded being of such a varying character, depending upon the various circumstances exceedingly difficult to effect; but if we cannot insure theoretical perfection, we must strive to secure a position as near to it as is possible in our particular and individual cases.

By a little study of the foregoing principles which I have submitted to your consideration, and careful attention to the details of their application, very great utility. Some excuse may be found for our forefathers upon the ground of ignorance; but that cannot apply to ourselves in the present day, when knowledge is universal. The ancient cry was, "Where shall wisdom be found?" Now the answer is, "It reteth on the housetops," and knowledge, says Solomon, "increaseth strength;" so that if we are already of all undertakings is safe when directed by the "excellency of knowledge." Let us, then, widen the foundations of our professional fabric by showing the public that ours is the right path to tread, the right way to use the light they pay for for street illumination, and if they refuse to follow done our duty.

Before the introduction of gas lighting, very little sound knowledge existed generally of the laws that govern the combustion of inflammable bodies; and much of the extraordinary progress made by science is attributable to the earlier efforts to light thoroughfares.

The earliest forms of oil or candle lamps that I have met with were apparently designed by unskilled people, totally ignorant of the commonest principles of combustion, and no effort was made to obtain the maximum of scarcely any air-ways, or perforated in such a manner that the carbon became deposited in graceful festoons of soot, which you will agree with me is "matter in the wrong place" in a lamp, rendering the instrument practically useless for the purpose for which it was intended. When coal gas superseded oil as a public illuminant, the old form of lantern was retained and largely used. At one of the earliest imitation of it, and to the circumstance may be traced some of the evils attending the present system of street lighting. Had we to begin de novo without such examples to follow, or vested interests to consider, far better and more suitable lamps would be produced, and the public lighting rendered much more effective.

To make matters worse, when gas works became multiplied, no portion-lap pattern of bracket or lamp column was adopted. No uniformity in height, strength, size, or distance apart was observed by engineers. Each put into practice his own ideas of taste, or what he thought the best for the locality he had to illuminate, regardless of the physical principles of light or the chemical laws of combustion. Hence we find an astonishing variety and diversity of the shapes in both lamp columns and brackets, some being designed with filagree work, called "ornamental," and so placed as to obstruct the distribution of light, and darken most effectually the same element in the immediate neighborhood of the lamp. This desire of ornamentation extended to the lanterns, and scroll-work added its shadow to that of the support, while the metallic ribs and angles were made so wide as to amount in some cases to 10 per cent. of the whole surface of the glass, and consequently augmented the evil. Uniformity in the rate of combustion was disregarded, or a quantity per hour adopted without due regard to the quality of the gas to be supplied, and when a town was well lighted, it was more an accidental circumstance than otherwise.

I have observed in many towns new lamps being put up which embodied all the defects of the old ones, and, of course, with a like result. The public lighting of the Metropolis, except in certain places, is perfectly disgraceful, and reflects no credit on the companies or the local authorities; while in Birmingham, with every deference to our valued President, a state of things exists which is little better.

In many large towns, notably in Scotland, where the street lighting does not appear to be of the slightest consequence, or else is regarded with very little interest, the effect is most disappointing, particularly when we remember the high illuminating power of the gas there as compared with places in the South. There is scarcely a town with which Scott cannot be found, though it must be confessed that there are a few in the South that are fairly lighted, and I hope before long to witness a general improvement in this much-needed direction. Of course, the change will not be a sudden one. The capital invested in lighting plant cannot be sacrificed; but when renewing broken lamps, or rearranging their situation, much can be quietly effected, whilst in new streets or districts no obstacle can interfere to prevent the adoption of suitable light-giving apparatus.

It is evident that designers and manufacturers have not paid attention to this branch of the subject, inasmuch as the designing and manufacturing of grotesque columns and brackets is still going on. In bracket lamps, instances might be advanced *ad infinitum* of intricate designing of ornamentation, and flagrant disregard of the physical properties of light, and as long as encouragement is given to manufacturers to elaborate these articles in opposition to good taste, in defiance of common sense and the true principles of utilitarianism, so long shall we be doomed to have badly lighted streets and thoroughfares, and so waste the light-giving power of the gas.

Not only is the designing and constructing of lamp columns, brackets, and lantern frames defective, but attention to the commonest glass is used for glazing, and a great interception of light takes place from this cause alone. After putting a good light into a lamp, it is not at all an uncommon thing for a lamp contractor to receive it back dim and glassy for glass.

Glass, as you all know, is manufactured by fusing silicic acid with carbonate of soda or potash. The transparent material so obtained is incapable, however, of resisting atmospheric influences, and water alone will dissolve it in time. The glass maker, therefore, has to add small portions of lime or baryte, or the oxides of iron, lead, or zinc, to enable the compound to resist the action of the atmosphere. The commonest glass consists chiefly of silicate of lime, some proportion of the silicate of alkali, and of alumina, and oxide of iron. Some kinds of window glass are very little better than the commonest bottle glass; and we shall therefore find it of service to us if we possess to consider the composition of glass, since more depends upon the quality of this material than many people suppose.

The composition of window glass is usually as follows:

Soda.....	23.3 per cent.	
Lime.....	12.9	"
Silicic acid.....	61.1	"

with a trace of alumina. Now, soda imparts a green hue to glass, so much so that in the manufacture of crown glass, the variety largely used for optical purposes, it cannot be used, and potash has to be substituted, the proportions usually being—

Potash.....	22.0 per cent.	
Lime.....	12.5	"
Silicic acid.....	65.0	"

According to an analysis of Faraday, English flint glass has the following composition—

Silica.....	51.03 per cent.	
Oxide of potassium.....	13.77	"
Oxide of lead.....	33.28	"

A small proportion of the oxide of iron gives a dark color to glass, and it is as well to remember, when selecting glass for lamps, that, next to its brilliancy, its power of resisting atmospheric influences should be considered. In manufacturing towns the atmosphere soon destroys the polish of the surface, and cheap glass is soon "etched" in this way. It is therefore more economical to use a clear, brilliant, hard glass, though its first cost may be more than many of the dull waxy varieties manufactured from gas lime, soda waste, clay, and rock salt, and largely used by spreading builders for windows, and unwise gas managers and avaricious lamp contractors for street lamps. The rougher the surface of the glass, the sooner does it become dirty, and the more readily are the rays of light intercepted; whereas a good clear, smooth glass will keep cleaner for a longer period, and allow the light to pass readily through.

Whatever media are used to inclose the light, it is inevitable that some loss will be sustained. This loss is not invariably the same for the same medium, but varies with the penetrative power of the flame, and likewise the distance from the flame. The larger the flame the smaller the loss up to a certain point; thus a strong argument is supplied in favor of larger burners in street lamps. Some experimentalists have arrived at the conclusion that window glass occasions a loss of light equal to 9 per cent.; but unless we are told what kind of window glass was used, the statement is certainly vague, if not misleading, glass of nearly all qualities, with varying powers of light-interception, being used for windows.

The following are the results of my own experiments, conducted with great care, every precaution being taken to eliminate all sources of error:

The first series of experiments were made with a pane of clear, lead 16oz. English glass, quite new, free from flaws, and possessing a good polish, but identical with the kind I use for street lamps; the only difference being that ours was used in its selection—in fact, it was the best of its kind. The illuminating power of gas used was 16.25 candles, and the loss of light by the interposition of this glass was only 1.78 per cent. Having procured from a glazier a similar sized sheet with very lines and air globules or bubbles in it—a veritable specimen, though perfectly new and clean—I found the loss of light to be 14.38 per cent.; therefore, by using this common foreign glass for glazing lamps, we sacrifice some 12½ per cent. of the light rays, which would otherwise be utilized by employing a glass equal to that used in the first series of experiments.

I next tested a pane of glass that had been in use for some time, and purposely allowed to become dirty, and to some extent also smoky. The result was remarkable, no less than 51.81 per cent of light being obstructed. The same glass, even when clean, intercepted 16.22 per cent. of light. This demonstrates the desirability of more frequent cleaning, and also exhibits the etching power of the atmosphere when charged with impurities, and the feeble resistance offered by the glass to its chemical action. By subtracting the percentages of the first-named experiment from the 16.22 lbs.: 16.02—1.78, we have 15.14 as the percentage of obstruction due to the corrosive wear of the glass when subjected to atmospheric influence in a manufacturing district containing chemical works and potteries. It would be interesting to know in what proportion of time this deterioration of glazing was effected; but that information, I regret to say, I am unable to give with strict accuracy, notwithstanding that I believe I am quite safe in this instance in putting it at from three to four years.

Red and ruby glass is frequently used for private lamps over shop doors, hotels, etc. I find their power of intercepting light varies with the intensity of color, and not so much with the thickness of the glass, as one would almost expect. A very thin specimen intercepted 61.36 per cent. of the light, while a sheet very much thicker only obstructed the light rays to the extent of 51.76 per cent.; the average of all my experiments being 48.68 per cent. Red glass is produced by the addition of suboxide of copper, and the finest ruby glass contains a little gold, 1-100th part of a grain of gold being sufficient to impart a deep rose color to a cubic inch of flint; while stain of cobalt is used to produce the magnificent blue which usually adorns the portals of police stations. Such glass, when quite pale and without clear spaces upon it, such as the word "station," etc., obstructs artificial light to the extent of 36.19 per cent. Various experiments with ground glass and other ground glass induced me to place the loss of light at 22.32 per cent., while glass covered yellow by the oxide of antimony only intercepted 11.64 per cent. of light.

In the laying of gas lamp services workmen are often either too idle or too ignorant to select good soil with which to surround the pipe. In consequence soils, such as contain the compounds of iron, lime, and some, pipes are also destroyed or "eaten away," and the least subsidence or disturbance of the surface—oftentimes the vibration of the railway caused by the passing

are not private consumers of gas in any way, I cannot subscribe to the unjust principle of selling gas to the *quasi* consumer at a lower rate than to the private and public consumer. That the buyer of the smallest quantity should be placed on better terms than the buyer of the largest quantity is an anomaly difficult to reconcile with commercial principles; but this is so whenever gas is supplied to public lamps at a reduced rate per 1,000 cubic feet.

It is obvious that the rate payer who only pays through his rates for gas supplied to the public lamps, obtains such gas on easier terms than the one who happens to be also a private consumer. Thus, assuming gas for public purposes to be sold at 2s. 6d. per 1,000 *cubic feet*, and for general purposes at 5s., it follows that A., who is only a ratepayer consuming his share of gas via the public lamps, obtains his gas for 2s. 6d., while B., being a large private consumer as well, has to pay an increased rate for his private consumption. So much money being required to pay the dividends of a company say, the larger proportion is contributed by the private consumer, and I am driven to the conclusion—and I am glad to be in a position to state that I am supported in that conclusion by many friends—that, to be equitable in price, no reduction should be made in favor of the public lighting. Another point worth remembering is that in many districts public lights are used for only four, six, or eight months of the year; whereas a private consumer is a constant customer, using gas all the year round, not even extinguishing on moonlight nights.

Of the average meter system I shall say but little. The framers of the 25th section of the Gas Works Clauses Act, 1871, were evidently neither engineers nor gas managers, or they would have put all the public lamps on meters direct, or at least have settled how many lamps were to be metered or unmetered. Whether they wished 1 per cent. or 50 per cent. of the lamps to have meters attached, they hesitate to inform us, and very graciously leave the parties interested to fight it out among themselves. As far as I have been able to learn, this "average meter indication" system is a delusion; it has been tried and abandoned. Important economical results have been reported from time to time as due to its adoption, but I venture to think that such economy is due, not to the supposed check by a meter, to so many lamps, but to the shortening of the hours of burning by the local authorities. With fair and open dealings between the officials of local authorities and the officers of gas companies, with confidence in man's honor and doing to others as you wish them to do unto you, the "average meter" system is utterly unnecessary, and the absence of its general adoption must be taken as a proof of its failure. If any member of this Association has the system in operation, I trust he will give us the benefit of his experience therewith, and show us the advantage conferred on the public by this system of supplying and charging for gas to public lamps.

Having now, sir, discharged my duty and fulfilled my promise, I must ask for forgiveness for the many imperfections to be found in this paper, considered with regard either to importance, its interest, or to its possible operation on the future of gas companies, no excuse is needed for its introduction to your notice to-day; and I venture to hope, sir, when you invite discussion, as you will do directly, upon the substance of this paper, that any member of this Association who hesitates to accept its tenor as correct, himself of the opportunity, and express his views with earnestness, with those we may be assisted to establish scientific truth, increase more and bond of fellowship.

GAS AND WATER COMPANIES.

By G. W. Stevenson, C.E., F.G.S., London.

Through the courtesy of the author we are in receipt of this very valuable work.

In the Kingdom of Great Britain all gas and water undertakings are regulated by law. While the legislation is general in its character, still, in almost every case, where a company comes before Parliament for additional powers, some special modifications of the general laws are sought, which in some cases are granted, and, in some cases, the company does not get all the powers it asks, but has conditions imposed upon it which it did not seek or desire. The result of this is quite a complicated amount of legislation on the subject, involving a great variety of special provisions.

The object of the work referred to above is to give, under appropriate heads, in a classified form, the result of this legislation; and, also, the data by which any member of the act in each case, so that those desiring full particulars as to what has been done, in any or all cases, may, by reference to this book, find exactly where to look for the details not contained therein.

It has involved much labor, and while of not so much interest to gas companies in this country just now, yet, should any company desire to obtain or oppose legislation, we know of no work that would be of so much value, from the fact that it embodies practically all the English legislation in every department of the business up to the close of 1876—giving many details, such as the capital authorized, the illuminating power and purity required, the amount of dividends allowed, the price of gas, etc., etc.

As a compendium of condensed and useful information it should merit a large sale, even at the price of one guinea, and should be in every gas library that makes any pretensions to completeness.

Gas-Works in Germany.—A German statistical paper recently published the following details relating to the gas-works at present in existence in that country:—Number of private works, 352; annual production of gas, 2,911,077,000 cubic feet; maximum production per 24 hours, 10,049,500 cubic feet; number of public lights, 51,034; number of private lights, 1,050,525; amount of capital employed, 23,715,117. Number of municipal works, 230; annual production of gas, 7,855,950,000 cubic feet; maximum production per 24 hours, 30,000,000 cubic feet; number of public lights, 86,681; number of private lights, 1,711,000; amount of capital employed, 54,748,000. Total number of works, 582; total annual production of gas, 10,767,027,000 cubic feet; total maximum production per 24 hours, 41,049,500 cubic feet; total number of public lights, 137,737; total number of private lights, 2,762,525; total amount of capital employed, 78,463,243, or at the rate of 134 6.5d. per 1000 feet of make.

THE JOURNAL OF GAS LIGHTING,
WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, JULY 8, 1879.

Circular to Gas Companies.

TELEGRAPHIC news from America tells us that Mr. Edison has devised a dynamometer, by means of which he is able to calculate the exact amount of force required to give a certain quantity of light by the use of electric machines. By the aid of this instrument, we are told, he has determined that one-sixth of a horse power is sufficient to produce an electric light, of what intensity we are not informed. The telegram further expresses Mr. Edison's confident opinion that the successful use of electricity for the production of domestic light is now decided; but he admits that a great mass of details have to be worked out before his system can be brought into operation. This is a wide admission, and we may calmly await the working out of these details, which, in our opinion, will probably occupy Mr. Edison for the remainder of his life. Presumably Mr. Edison still adheres to platinum poles for the production of the light, and it seems that he has satisfied himself that the metal may be obtained in large quantities at a comparatively cheap rate. Our present supplies come mainly from Russia; but, if we remember rightly, a few years ago it was reported that large deposits had been found in California. It is from this latter source, probably, that Mr. Edison proposes to obtain his supplies.

Mr. Edison has now filed the specification of a third patent for the United Kingdom. It includes details of what we may call his burner, which, up to a certain point, is not novel. He continues his system of winding round a cylinder of lime a fine strip of platinum foil, which is to be covered by a pyro-insulating material, the description of which is somewhat curious. For example, he professes to take the metals "zirconium, zirconium, calcium, magnesium, or other metal or material which will not be injured by a high degree of heat," and, dissolving them in acids, dip his strips of foil in the solution, and then expose them to an intense heat, by which they become coated with a layer of the oxide of the metal. This looks all very well upon paper, but probably no one knows better than Mr. Edison himself that his "pyro-insulation" is mere nonsense. Lime, for example, deposited in the way described, would speedily peel off, leaving the platinum bare. A better plan proposed by Mr. Edison is, to put layers of his "pyro-insulator" between the coils of his spiral burner, in which position the material might be expected to last. The patents propose that from a central position iron tubes should be taken, carrying within them an electric cable consisting of several strands of copper wire. From these a single wire will be taken into the basement of each house, and from this, small wires will run into the apartments, wherever the light is required. Each light is to be furnished with a switch, which will act in much the same way as a gas-tap. When every switch is turned off, it is expected that the steam motor will nearly cease to operate, and hence a great loss of power will be obviated. All this looks extremely pretty; but, as Mr. Edison himself admits, a great mass of detail will have to be worked out before the electric light can ever be adapted for domestic use.

Our readers will see in another column a letter from Mr. W. Livesey, in reply to the remarks of Mr. Warner at the recent meeting of the British Association of Gas Managers, relative to the action taken by the Gas and Water Companies Association respecting the applications of Gas Companies for powers to supply the electric light. It was always a moot question with us whether or not the thirty-four Gas Companies should proceed with the clauses intended to empower them to "supply" the electric light. It is quite true that no one of them knew exactly what they wanted; that is to say, they were unacquainted with any details which would have enabled them to carry into effect the powers they asked for. The electric light is so recent a novelty, and so little is known about the best modes of using it for public illumination, while absolutely nothing is known of the possibility of applying it for domestic use, that, under the circumstances, it certainly seemed premature for Gas Companies to apply for powers which they would not have known how to exercise. And yet there was some reason in the applications. It was like taking the bull by the horns, and announcing an intention to supply the new light wherever it might be found convenient and profitable to employ it. The report of Dr. Playfair's Committee shows clearly that the action taken by the Gas and Water Companies Association was correct. It is admitted that our present knowledge of the electric light does not justify any legislation on the matter, and that we must wait for a much more extended development of the system before Parliament can confer any exclusive powers to supply the new illuminant.

There was a large sale of shares in the Brighton and Hove Gas Company on Wednesday last at the London Auction Mart. They were 220 shares, fully paid, entitled to, and, of course, receiving seven per cent. dividend, and were sold with the dividend accrued up to June last. The prices ranged from 254 to 244. It is clear that the public lose no confidence in gas investments. That there is no fear of the competition of the electric light, even in the Metropolis, is shown by a recent rise in the "A" stock of the Chartered Company, which now touches 179—181. This stock will no doubt also go up to par rates, and fetch a considerably advanced price. We thought the price would never have been affected by the large quantity of stock thrown on the market; but our fears, we are happy to find, have not been justified by the result.

All our readers know the principles on which we have always advocated that Corporation gas undertakings should be managed. It is, that they should be so conducted that the net income over expenditure should be applied in reduction of the price of gas. This is obviously what the Lord Chief Justice had in his mind when, in delivering judgment, on the application of the Birmingham Corporation to set aside the award of the Umpire in the arbitration case between them and the West Bromwich Improvement Commissioners, he remarked that the business of a Corporation is not to make a profit. They have to supply consumers on the cheapest terms possible, and "if a profit is made, it is pointed out how it is to be applied." We rely on the words, "the cheapest terms possible," used, applying them to the Corporation of Salford, we may repeat the remark made last week, that the consumers in that borough might be supplied at a much lower rate than will obtain when the twopence reduction is made. The gas undertaking of the Corporation at the present time is, and has been for the past few years, increasingly profitable, and, in our opinion, the profits belong to those who take and pay for the gas. We do not forget that repeated reductions have been made during this period. We are aware that our opinions

are not fully accepted in this country, but they are well understood in Germany, where the gas undertaking of almost every Local Authority is conducted upon the principles we advocate. We have nothing to retract from the observations made in our last item respecting the reduction in the price of gas in Salford. A small calculation will show that if the Corporation would forego a good part of the profits they now set aside in aid of rates, the reduction might have been twice as much, and still some profit have been realized.

The Corporation of Swansea seem determined not to be on good terms with the Gas Company. A bill amounting to about £50 has been owing from the former to the latter since 1876, and repeated applications for payment of the money have brought neither reply nor cash. Under these circumstances, the Gas Company took the unusual, and we will not say legal step of withholding the payment of rates due, and till their own debt was satisfied. The consequence was the immediate issue of a summons, by whose authority seems doubtful. The Mayor distinctly repudiated that no summons should be issued, and the Town Clerk denies that the proceedings were taken with his sanction; but at this point the evidence is somewhat foggy. The moral appears to be that Gas Companies, when dealing with Corporations, especially those like that of Swansea, should act with them the same as with an ordinary consumer, and demand immediate payment at the risk of the cutting off of the gas supply. That Corporations can be as high-handed as Gas Companies is shown by the proceedings in this case, in which a summons was issued for a rate that was only due on the day the summons was taken out. We are happy to say there are not in the Kingdom many Corporations like that of Swansea, and therefore we do not know that these proceedings offer much interest.

The Dublin Gas Bill has gone up to the Lords with the expressions which will doubtless delight the Gas Company to convey the electric light, if it should ever be deemed desirable in such a city as Dublin. It is one of the last places in the world in which we think the electric light is likely to be desired. There are public spaces and squares which might be illuminated, but at the present time nobody frequents them after dark, and probably few would do so if the electric light were installed in their midst. However, the Gas Company, so far, have failed to furnish the electric light, but it is not an exclusive power. The Corporation may at any time step in by the aid of its own Commissioners, without let or hindrance; but we know that they will do nothing of the kind. They will not simply on the dog-in-the-manger principle. They will do nothing themselves, and, if they can help it, will not allow the Gas Company to do anything. This is written with a knowledge that before these lines meet the reader's eye, the Bill will be before the House of Lords. Sir Arthur Guinness appears to have done his best to prompt Earl Beaconsfield, so as to induce him to reject the clause which indirectly gives the Company power to supply the electric light; but the terms of the Act of 1868 still remain, and, unless we are greatly mistaken, they will, as they stand, justify the Company in supplying any new mode of lighting which may seem fit to them. The Bill, as has been said, went before the Lords yesterday, and in all probability will pass in its present shape.

The *Liverpool Lighting Bill* has passed a Common Committee, with an amended preamble and certain amended clauses. This Bill is one of the most important that has been introduced this session. It was originally intended to give *the Corporation of Liverpool* power to supply the electric light without limit all over their area; but the Committee have so far restricted them that they can only use the light "for the purposes of experiment for a limited period, but not "for the purposes of profit." So far so good. The Corporation could, without asking for any parliamentary powers, have supplied the electric light to all their private and public places, such as St. George's Hall, St. George's Square, the Market, &c.; but their action extended beyond this. They wished to be placed in a position to furnish the light to places of public resort, such as the Prince's Theatre, and also to illuminate the Lime Street Railway Station. To this extension of Corporation Powers the Gas Company naturally objected, and, as the Bill now stands, opposition will very properly be made in the House, the result of which, of course, we cannot anticipate. The intentions of the Corporation obviously is to launch with the dominion of the Gas Company. They will, if the Bill be passed as it at present stands, obtain power to make an experiment which is to bring them the light to theatres, railway stations, and other places of public resort. The Gas Company cannot sit still and see their ground thus wrested from them. Therefore the Bill will be opposed in the Lords, and although we are precluded from expressing my opinion as to the result, we confidently expect that it will be rejected in its entirety. The Liverpool United Gas Company have not, like many other Gas Companies, sought power to use the electric light, but they naturally look askance at any powers which may be granted to the Corporation, and which may interfere with their business. Thus they are entirely opposed to the provisions of this amended Bill, which, if it should be carried, may militate against their interests. The Company suspect that the Corporation contemplate a serious attack. It is true that the purchase clauses have been struck out, but the Gas Company are perfectly right in opposing any measure which they conceive will tend to interfere with their profits. We shall watch with much interest the progress of this and the Dublin Bill, feeling well assured that the Gas Companies concerned need have no apprehensions that their profits will be injuriously affected. Perhaps it ought to be mentioned that the Liverpool Corporation only seek power to borrow £50,000, which they can easily expend in a very short time in making experiments with the electric light.

The Corporation of Norwich seem determined to make an effort to acquire the undertaking of the British Gaslight Company. They are hardly conscious of the difficulties which lie in their way unless they make terms with the Company previous to applying to Parliament. There is, we believe, no instance on record of a Gas Company being the victim of a purely compulsory purchase. Now, the British Gaslight Company have distinctly announced their intention to hold fast by their property, and we know they will persistently adhere to that resolution. The Corporation of Norwich, therefore, if they should have the temerity to go to Parliament, will have to face a most determined opposition, the result of which will, we think, be their utter discomfiture. They should be content for the present with the reduction of price which the Company have granted, and wait patiently for further reductions, which we trust to follow.

We continue our notice of the papers read at the meeting of the British Association of Gas Managers at Newcastle. The paper of Mr. Sanderson, of Newcastle-on-Tyne, on "Economy in the Manufacture of Concrete," with reference to the construction of gasholder-tanks, we must leave to the consideration of those engaged in the works specially referred to. On this matter we cannot pretend to give an opinion. Much useful information was contributed in the course of the discussion which followed the reading of the paper, a full report of which will be found in another column. It is generally supposed that cement contracts on solidifying. Probably closer observation will show, as pointed out by the President, that expansion takes place, in either case leading to cracks; but when it is once settled whether cracks are caused by expansion or by contraction, due allowance may be made for either of these, and thereby all accidents avoided. It will be seen that a good deal of experience has now been gained in the erection of concrete structures, and we think they will come more and more into favour. Engineers, we fancy, will soon get over the backing difficulty, and that all that is necessary will have been accomplished. Of course, every one will agree with Mr. Hunter that there are cases under which a brick tank may be cheaper than one of concrete, but, as a rule, this is not the case. Mr. Sanderson deserved the hearty thanks of the meeting for bringing so important a question under their notice, and dealing with it in such an effective manner.

Mr. Wright's new form of cooler is a promising arrangement of apparatus which is credited with many good qualities not the least of which is the fact stated, that, by its means naphthalin can be kept out of the mains. It is to be regretted that unfortunately opinion does not exist among the profession as to the best form of condenser to be used, nor as to the temperature to which gas should be reduced in the process of condensation. On these points much valuable information remains to be elicited, if speakers in the course of the discussion. The remarks of the President were very pertinent. Close and continuous observation with different forms of apparatus are highly desirable.

The lecture by Professor G. A. Lebour, F.G.S., &c., entitled "Practical Notes on Coal and Coal Getting," though possessing nothing of special interest to managers, as gas makers, formed no doubt a valuable contribution to the proceedings of the meeting. A gas manager is now expected to be an educational man, and is he especially learned about the staple which he uses. The lecturer gives some useful information of a rather elementary sort, to which his audience appeared to listen with pleasure.

Some re-arrangement of the gas-testing stations of the Metropolis is, with the sanction of the Referees, about to be made, mainly, we believe, at the instigation of the Commission of the City of London. The stations at Beckton and Priendly Place will be discontinued, and in their stead will be substituted three testing-stations within the limits of the City. It has long been the contention of the Corporation of London that gas should be tested where it is consumed, and to this, we suppose, the Chartered Company have agreed.

In another column will be found an abstract of the Quarterly Report of the Chief Gas Examiner appointed by the Board of Trade, which shows, as usual, that the Metropolitan Gas Companies under his purview continue faithfully to fulfil the obligations imposed upon them by the several Acts of Parliament. The average illuminating power was considerably in excess of the requirements of the Acts, and in no case was the presence of sulphuretted hydrogen reported. As regards the impurities of "sulphur" and ammonia, the report shows that the instructions of the Referees had been fully carried out, the amounts being, in every case, far below the quantities permitted.

It is generally believed that a gasholder will not explode, nor will it, if filled with gas only. But a recent accident at Dartford seems to show that under some circumstances a real fatal season to allow that under some circumstances a real fatal season to allow that under some circumstances a real fatal explosion may take place in a holder. We must wait for further details and some explanation before an opinion can be arrived at; but it seems clear that the contents of a new holder, said to have been in use for only a week, became ignited, with most disastrous results. The holder and tank were crumpled up like a sheet of paper, and the tank was drawn to the centre of the basin. A very large quantity of air had gained access to the holder, it must have been discovered by a want of illuminating power in the gas. A strongly explosive mixture of gas and air gives very little light. The explosion occurred in the night, when only street-lamps are burning, and probably a want of power in them was not observed. [Since the above was written, we learn that the accident was caused by the bursting of the gasholder-tank, and the gas in the holder becoming ignited, both tank and holder were destroyed.]

A steam roller has been at work again crushing gas-mains, at this time at Croydon. The escaping gas, of course, mixes in with the steam, and the mixture of gas and air coming way into some houses, and the mixture of gas and air coming in contact with a kitchen fire, an explosion resulted, which was nearly destroyed two houses. Local Authorities must see that their rollers are not unnecessarily heavy. They may do that their rollers are not unnecessarily heavy. They may do that their work of crushing-in granite or gravel without being so ponderous as to make their weight felt a foot or two below the surface.

Correspondence.

[We do not hold ourselves responsible for the opinions expressed by Correspondents.]

THE GAS AND WATER COMPANIES ASSOCIATION AND THE APPLICATIONS FOR ELECTRIC LIGHTING POWERS.

Sir,—In your report of the meeting of the British Association of Gas Managers on the 10th of June, there are some remarks in the President's Address which it is necessary for me to notice. I would have done so before, but the pressure of other business prevented me.

The President states, in effect, that he thinks it his duty to say that those Companies who had Bills in Parliament with powers to supply the electric light ought to have been consulted before the petitions were presented by the other companies against the granting of such powers. On this point, I am sorry to say, I do not agree with him. When a person says he feels it to be his duty to state this or that, it implies a grave neglect of duty on the part of some one else, and as I happen to be the "some one else" in this case, you will perhaps allow me to say a word or two as to my view of the matter.

At the very commencement of the session all the Gas Bills containing powers to supply the electric light were suspended before their second readings, to give the authorities time to consider what should be done with them. It was then determined to appoint a Committee to inquire into the matter, and make a report to the House, and upon that the promoters of these Bills were informed that if they desired to obtain these powers out of their Bills they might proceed with them at once, but otherwise they must wait until the Committee had made their report.

Subsequently to this the Gas and Water Companies Association made several applications to them Companies, both through their agents and directly to themselves, to withdraw these clauses, so as to enable the Association to take some decided course before the Committee. The Association could not also, its eyes to the fact that if such powers were granted to gas companies, they could not be refused to local authorities where they were gas suppliers, and the effect of that I need not stop here to comment upon. The policy of the Companies was, therefore, clear and unmistakable—to show that electric lighting was inapplicable to private houses, and no parliamentary powers for such purposes ought to be granted in any one.

On the 12th of March I sent to all these Companies a circular containing the following paragraph:—"As it is very desirable that the Companies promoting Bills shall have some general understanding among themselves as to the course they intend to take before going into committee, the Committee of the Association proposes holding a meeting at the Westminster Palace Hotel, on Monday next, the 17th inst., at two o'clock, to consider this question, and I am instructed to say that, as your Company are promoting a Bill in the present session, they hope it will be convenient for you to appoint some gentleman to attend the meeting on their behalf." And on the 24th I sent another as follows:—"The Committee on Electric Lighting will be prepared to hear counsel from any persons who may after themselves as witnesses, but will not hear counsel. It is probable that the Committee will only sit one or two a week, and not day by day, as with an ordinary private Bill, and that the inquiry may be extended over the whole session. The issue, therefore, that there is for other causes for the Companies to take them to proceed with their Bills without the electric light clauses, and upon some general measure being passed, if it should be found expedient to do so."

The object of the meeting on the 17th of March, at the Westminster Palace Hotel, was to ascertain, if possible, before taking any interior proceedings, whether the Company really had any clear idea of their own what they meant or intended by "powers to supply the electric light"—whether the supply was to be compulsory or permissive, whether they had devised any mode of ascertaining the price, whether it was to be carried out as a separate undertaking to bear its own losses, or be worked up with the gas undertakings and the losses charged upon the gas consumers, or whether they had any plan whatever of carrying out such powers if granted.

One or two of the Companies sent representatives to the meeting, but the majority only sent their agents who, having no practical knowledge of the working of a gas undertaking, and still less of electric lighting, could give neither information nor advice upon these matters, and for all practical purposes they might as well have stayed away. But the truth is—and it is a folly to try and shirk it—that none of the parties promoting these Bills had any clear idea of what they ought to ask for, or what they would be willing to undertake if the powers were offered to them.

After the House of Commons Committee had been appointed, the Committee of the Association had several meetings to determine the best course to adopt, and decided not to oppose the electric lighting itself, but only the granting of parliamentary powers for that purpose, on the ground that the local authorities had already sufficient powers for lighting the public lamps by means of the electric light, and that it was not necessary, with our present knowledge, to light private houses; and although there were but little difference of opinion between the members of the Committee as to this being the proper course, they deferred putting it in force from time to time, in consequence of the many Gas Bills containing these electric lighting powers, and hoping they would be withdrawn. At last it was intimated to them that if they intended to give evidence at all, they must be prepared by a certain day, and thereupon, as I would have been, to say the least, a very great inconsistency for the Gas and Water Companies Association to be giving evidence that electric lighting was utterly impracticable for private houses, while a number of gas companies were at the same time actually taking for powers to supply it, and thus, in effect, contradicting the evidence, the petitions were determined upon—in fact, they became a necessity.

During these proceedings the Companies had one by one—but some of them very reluctantly, and only when they found that they could not proceed with their Bills to a second reading without doing so—withdrawn these clauses, and the very last of all was the Company which

the President of the British Association of Gas Managers himself represents.

The earliest second readings of the session were on the 24th of February; the second reading of the Bill last referred to was on the 6th of May. The Electric Lighting Committee commenced their inquiry on the 17th of April. Your readers will probably see in this the reason why the presentation of these petitions was so improper a proceeding.

It would have been a calamity to all gas companies if any individual company had obtained powers to supply the electric light, as such powers would unavoidably have been very imperfect, and in their imperfect state been copied from one Act into another, and in the end made the standard for all others. If it should ever come to pass that electric lighting can be applied to private houses, the power for gas companies to supply it must be given by some well-considered public measure applicable to all companies alike, and not by means of the special Acts of each individual company, and this is the object, so far as I know, that the Gas and Water Companies Association have in view.

As the Companies promoting these Bills did not admit any obligation on their part to withdraw the electric light clauses in deference to the views of the other companies, it is somewhat unreasonable on their part to complain of the other companies not withholding their petitions in deference to them.

The comments on the Gas and Water Companies Association generally are legitimate, and the suggestions would, I think, produce beneficial results if acted upon; but no Association can have much weight if its individual members persist in taking their own course, regardless of the views of the majority. An Association would but make itself ridiculous if, every time one or two of its members adopted a course they disapproved of, they were to abstain from taking the course which they thought the proper one. They would be neglecting the interests the other members if they failed to do so.

I do not think the President's good faith in thinking it was his duty to remonstrate against the presentation of these petitions, although I do not agree with him; but if I had been in his position, I should most certainly have felt it to be my duty to put the boot on the other leg. I am quite sure it would have pinched that better.

So much has been said about electric lighting, that I fear your readers must be heartily tired of it. There is, however, still one point upon which information is very much wanted, and which I, with many others, have been unable to obtain, and that is, What is meant by supplying the electric light? Will any gentleman connected with either of these 24 Companies condescend to inform us how he intended to carry out such powers, if granted?

I am, Sir, your obedient servant,
W. LETCHER.

Gas and Water Companies Association, 6, Victoria Street, Westminster Abbey, S.W., June 28, 1879.

GAS CONSUMERS AND GAS PRODUCERS.

[1223].—To still simplify and enlighten a great deal of your correspondence on this subject I your readers will divide the consumers hitherto into the sheers division, Consumers and Producers, and the latter division, I have no doubt "Fellows," and many others belong. Supposing that I hold gas shares to the hundred, and supposing I hold a retailing [illegible] as trader and chemical adviser to a few gas companies, and supposing I might write as many of your readers as I might wish to keep fillings or they are; but seeing that I am a gas consumer, and can at present paying four times the value of what I receive as gas, I am a long way from being convinced by anything yet advanced by any of your correspondents, and think at the duty of every consumer to try and bring about a better state of things.

In my last letter I named some of the causes which in my opinion helped to make bad gas. The name to have acted like a "red flag" to [illegible], and brought forth a storm of abuse and bad words.

The fact of wet coal being used is one which I can vouch for, having seen it used in the retort, and noticed that a air weather block of coal was burned in an open yard, exposed to all the vicissitudes of the weather, and a convenient corner assumed to serve as a store—for the use of thirty or forty men—and being a long winter. Perhaps in "Figgin's" opinion the resulting gas would be all the richer for that addition.

As to the other cause I named, "the admission of air," against telling the trouble in order to say how much chemical work will find that this very thing is caused as a danger, and very possible.

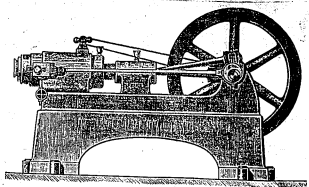
There are numerous causes at work in a large works that might lessen the height of the water in the hydraulic main, and supposing that to be the case, I or [illegible] would favour quickly if atmospheric air or gas gain admission without detection.

If any one can tell me as many of your correspondents seem to think, as to suppose that "atmospheric air and aqueous vapour" cannot pass the water in the mains, I am all ears. The evil shows itself in the resulting compounds of gas and air, and with the action of the water on the [illegible] with the action of the [illegible] with carbonic acid and carbonic oxide. The nitrogen is [illegible] and [illegible] "is provided" as a diluent.

Certainly our fact is very significant, and may point to a solution of the present question, and that is the complaint as to bad gas and [illegible] and [illegible] of [illegible] since the wonderfully increased [illegible] of "works products." The problem seems to be with those to whom the accused that will yield the most by-products, and not that which gives the best gas.

As a question of interest to all the gas companies, and ask them and the public at large, to [illegible] a smaller over-use or two facts, and they [illegible] their own conclusions.

The present [illegible] furniture in this country is exactly [illegible] to say that it was fifty years ago; the schoolboy's copy-book is [illegible] with pen-nib and pencil, and the [illegible] represents exactly the process on the larger scale. The [illegible] companies on the larger scale. The [illegible] of [illegible] every other trade or [illegible] all first gas engineers and gas consumers have [illegible] article is simply there made 60 or 70 years ago, and at the present time that was [illegible] of [illegible] [illegible] [illegible]



CLERK'S PATENT GAS ENGINE.

Progress, July 1879

ATTENTION is steadily directed to the price of gas in the great cities and on further examination I find that the neighborhood to the coal, which is a necessary ingredient in the production of this illuminating element, is a controlling factor. There are three companies in Brooklyn, where the price ranges from $2.00 to $2.50 per thousand; three in Baltimore, where it is $1.50 and $2.00; three in Pittsburg, where it is as low as 75 cents and $1.50. In New York city the movement for cheaper gas is pressed with a determination that is sure to produce good results.

Soon July 1879.

GAS LIGHTING EXPERIMENTS.—Colonel Haywood, C.E., the engineer in the City Commissioners of Sewers, has reported in favor the results of an experiment now being made in a portion of Queen Victoria Street, between Mansion House Station and the Poultry, with new gas burners, by the Gas Light and Coke Company, at the Company's own expense. The experiments commenced on the 6th March. The new lamps are fitted with the "Sugg London Argand" burners, with glass chimneys. They are of two sizes—one consuming 10 cubic feet of gas per hour, the other 30 cubic feet. The gas is consumed in the smaller burners in two concentric columns or rings of flame, and in the larger burners in three rings. The burners are so arranged as to be self-lighting when the gas is fully turned on. They are in lanterns of the ordinary description, the smaller in the form of a hexagonal in plan, and the larger in twelve-sided lanterns. The lanterns are larger than those generally used, and have the upper parts glazed with a new kind of white glass, which partly reflects and partly transmits the light. The lower portions are glazed with ordinary clear glass. Proper means are provided for ventilation, and preventing down-draughts. There are 30 of the smaller and 5 of the larger lamps, and they supersede 35 ordinary lamps. The length of the street lighted is 1,100 feet. The burners consuming 10 feet of gas per hour have an estimated illuminating power of 80 candles, and thus 30 lamps are equal to 2400 candles. The 30-feet burners have a power of 200 candles, and five lamps are thus equal to 1000 candles. The 5 large lamps temporarily superseded 35 lamps of 720 candles, or 25,200 candles. The 30 small lamps. The cost of the 35 ordinary lamps superseded is £1 17s. 6d. each per annum, or the large £21 0s. 0d., or £777 0s. 0d. in all. The cost of the smaller experimental lamps is £10 0s. each per year, and of more costly then she did. The general result, therefore, is nearly three times larger as much light as that in general use, and lasts about three times as much. It should be added that the experiment is being conducted at the sole cost of the company.

Engineering 4th January 1879 Gas Lighting in Public Streets

Gas Stocks.

New York, Friday Evening, July 18, 1879.

We note a steadier market for gas stocks, a slight improvement being reported in the stocks of the Manhattan and Metropolitan companies. The stock of the Municipal is down 82 per share. The Metropolitan Gas Company publishes the following advertisement, which, it will be observed, contains many valuable suggestions, and we are free to predict that this war of the gas companies of the metropolis, if continued, will ultimately result in great good, both for consumers and the companies themselves.

OFFICE OF THE METROPOLITAN GAS LIGHT CO.,
BROADWAY, corner 29th st.
New York, July 16, 1879.

From the 1st inst. the rates for gas will be as follows: Those using less than 5000 cubic feet per month, $1.75 per 1000; 5000 to 10,000 cubic feet per month, $1.50 per 1000; and to those using larger quantities, a further reduction is made.

We constantly take advantage of and adopt every improvement in the manufacture of gas and endeavor to furnish a superior light, which shall, at the same time, be pure and safe to the consumer.

We also call your attention to the utility of gas as the above rates for power, cooking, etc. No ashes, no coal, no ashes, and less labor.

Indianapolis Gas Works.—The contract for building the gas works at Indianapolis, Ind., will be awarded on the 25th inst. to Messrs. Coppell & Co.—The company will sell of 2,240,000 feet during the year just ended—a falling off in quantity corresponding to the previous year—which gas is chiefly responsible.

Gas Consumers Gas Question.—At the meeting of the Gas Consumers' Association, held on Tuesday, June 24th, a report by Mr. Bennett was read, which referred to a Committee of the Whole. It fixed the price of gas at 3s per 1000 feet, net, at which rate the city would be saved £25,000 per year.

The Tillsbury Gas Co. has declared a dividend of $2 per share.

ADVERTISED RATES:

Leavenworth (Kan.) Gas, Co.—20 shares, at 40.
Owensboro (Ken.) Gas Co.—40 shares, at 71.
Lawrence (Mass.) Gas Co.—5 shares, at 135.
Lowell (Mass.) Gas Co.—5 shares, at 141½.
Lowell (Mass.) Gas Co.—5 shares, at 141½.
Portland (Maine) Gas Co.—10 shares, at 110.
Saco (Maine) Gas Co.—6 shares, at 90.

The following list of companies in New York and vicinity is reported weekly by Messrs. Hunter, Dimmick and Dodge in this STAR, No. 52 Broad street:

Engineering July 1879

Gas at Boston.—The sales of gas effected in 1878 by the Mutual Company for Lighting and Heating by Gas were united to 7,310,319 cubic metres, or more than 260,000 cubic metres in excess of the sales of 1877. The net profits realized by the company in 1878 were 90,283l., or 15,037l. more than the corresponding net profits in 1877.

Miscellaneous Items.

METROPOLIS GAS SUPPLY.

The following is an extract from the report of Dr. Williamson, F.R.S., the Chief Gas Examiner to the Metropolitan Board of Works, for the quarter ending the 24th of June:—

I. *Illuminating Power.*—The maximum, minimum, and average illuminating power in standard sperm candles at each of the testing-places were—

	Max.	Min.	Aver.
The Gaslight and Coke Company—			
Beckton	17·5	16·3	17·0
Friendly Place	17·5	16·3	17·0
Hilly Fields (barrel gas)	19·4	18·2	18·7
Ladbroke Grove	17·8	16·6	17·3
Lewis's Mews	17·8	17·0	17·4
Curtain Square	17·8	16·6	17·3
Tyssen Street	17·8	16·6	17·3
Graham Road	17·8	16·6	17·3
Commercial Gas Company—			
Barrel Road	18·2	16·2	17·3
Old Ford	18·2	17·4	17·8
South Metropolitan Gas Company—			
Hill Street, S.E.	17·3	16·7	17·0
	19·4	16·2	17·6

At all the stations of the three Companies the average for the quarter has been above the parliamentary standard, especially at the Beckton, Ladbroke Grove, Lewis's Road, Camden Street, and Graham Road stations of the Gaslight and Coke Company, and the two stations of the Commercial Gas Company.

II. *Impurities.—Sulphur.*—Sulphuretted hydrogen has not been present in the gas at any of the stations. The proportions of sulphur in other forms than this were—

Grains of Sulphur per 100 Cubic Feet of Gas.

	Max.	Min.	Aver.
The Gaslight and Coke Company—			
Beckton	11·5	9·1	10·2
Friendly Place	11·5	9·1	10·2
Hilly Fields	11·5	9·1	10·2
Ladbroke Grove	11·5	9·1	10·2
Lewis's Mews	11·5	9·1	10·2
Curtain Square	11·5	9·1	10·2
Tyssen Street	11·5	9·1	10·2
Graham Road	11·5	9·1	10·2
Commercial Gas Company—			
Barrel Road	12·1	9·7	10·8
Old Ford	12·1	9·7	10·8
South Metropolitan Gas Company—			
Hill Street, S.E.	12·4	9·1	11·8

From these results it will be seen that at all the stations of the three Companies the maximum has been within the requirements of the Act of Parliament, and that the average in all cases considerably better than required by the Acts.

III. *Ammonia* has been present in the gas during the quarter, in slight quantities, at all the stations of the three Companies, with the exception of the Hilly Fields station of the Gaslight and Coke Company, situated in the Kingsland Road. The Chief Gas Examiner to the Board on the 23rd of May last, that, in consequence of the ammoniacal liquor from the Hilly Fields station not being mixed with the Gas Referees on the 16th of May, and a letter has since been received, in which the Referees state that they propose to prescribe, as a testing-place for the gas manufactured at the works in question, the testing-station already fitted up and used by the Company, and which is situated in the Kingsland Road, from the works. The Chief Examiner states that he will shortly examine the place on being satisfied that the gas supplied to the proposed testing-station is identical with that supplied from the purifiers works. The Referees, at the same time, intimate their concurrence in the views of the Board as to the selection of the testing-place at Beckton; and that they also propose to establish the testing-place now prescribed, by them at Friendly Place, Bow, and to establish three testing-places within the area of the district recently added to the limits of the Metropolis.

The Chief Examiner has no early intimation thereof should be given to the officer engaged in the testing of the gas supplied from the Beckton works, recommended—That notice be given to Mr. Young of the intention of the Gas Referees to discontinue the testing-place at Beckton, near Barking, to which he was appointed Gas Examiner by the Corporation of London and the Board conjointly; and that he be informed that, on the discontinuance of the testing-place, his appointment as Gas Examiner on behalf of the Board will cease."

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, JULY 25, 1876.

Circular to Gas Companies.

THE Alliance and Dublin Gas Bill has passed a Committee of the House of Lords, but the influence of Sir Arthur Guinness has so far prevailed with Earl Redesdale that all clauses in the Bill which would directly or indirectly give the Company power to supply the electric light have been struck out, or amended so as to prevent the Company from having any authority in respect to it. Of course, it was never intended that the Company should have any exclusive power to furnish the electric light. It was settled long ago that no such exclusive privilege could be granted; but the Company were fairly entitled to make experiments with the light, as it promised to lend itself to their service. There are questions behind, which would, of course, require consideration. For example, whether the Company supply capital, granted to them for the purpose of supplying gas, to making experiments with the electric light? The answer of their opponents would, of course, be a very ready one: No such power can be conferred. As for a monopoly to supply the new light, no one dreams of such a thing. The Company might demonstrate the feasibility of illuminating public spaces and large interiors, but the making the slope of a monopoly could be granted. We may take the Bill as it is now amended, and as it will pass, with the remark, that it will be long before Dublin rejoices in the exhibition of an electric light. The impecunious Corporation could do nothing, if they had the will to do anything. Adventuring inventors may come from all quarters to exhibit their lights; but if they are successful, who is now to take them up and make them render public service? The Corporation never will, and now the Gas Company are prohibited. Who, then, will introduce the electric light to Dublin? We look on the fate of this Bill as in every way unfortunate. It was promoted with the best possible intentions, and if it had been carried in its form in which the Company proposed, it would have given them the opportunity of employing the light or not as it seemed convenient in them. As it is, it is left to the Corporation or a new Company to promote a Bill when the electric light has been so developed that its exploitation promises to be interesting to the public and advantageous to investors. We know very well that the Corporation will never do anything, and as for a new Company, the chances of raising capital for any public purpose in Dublin are very remote indeed.

In other columns we publish a report of the proceedings on the Liverpool Lighting Bill before a Select Committee of the House of Commons. The evidence was of a very interesting character, and fully bore out our opinion that the object of the Liverpool Corporation was to gain a foothold for the supply of light for public and private purposes. In this attempt, however, they have been disappointed; but sufficient power has so far been given us will enable them to make a series of experiments to ascertain whether or not the electric light may be made permanently available. The Bill, as we said last week, will be opposed in the House of Lords, with what result we know not. It is curious to note that the Corporation do not show their hands, or give us any idea of what they intend to do if they should gain the power which is now withheld. What system of lighting do they propose to adopt? Is it the Jablochkoff, the Lontin, the Rapieff, or the Werdermann? or do they intend to rely upon Mr. Edison's inventions, of which as much is now being written? It seems probable that as long a time will be taken in considering the light to be adopted, as has been consumed in arriving at a decision as to the sites and a new water supply. In this case, the five years which the Committee have granted to the Corporation will be occupied in perfectly useless discussions, without a single electric light being displayed. Corporations never very slowly, and, considering the vagueness of the propositions for electric lighting now before the public, we shall not be surprised a see the five years pass without any decision from the Council as to the best light to be adopted. But our speculations are at present premature; we must wait the result of the deliberations of the Lords Committee before we express any further opinions.

The cause of the explosion at the Dartford Gas-Works, to which we referred in our last issue, is now made tolerably clear. The cast-iron tank, standing about 16 feet out of the ground, gave way under the pressure of the water, which ran in torrents all over the works, and, as a matter of course, the seal being removed from the holder, the gas escaped. There can be little doubt the first explosion occurred in the open, but as the gas escaped from the holder, air, of course, got in, and thus there resulted an explosion within the holder. It is quite clear that nothing but a violent explosion, caused by the ignition of mixed air and gas, could have wrought so much destruction, and how the air got into the holder is now perfectly explained. The moral of the accident, so far as we can see, is that managers should look after the strength of their cast-iron tanks.

A majority of the Town Council of Hanley are waking up to the fact that a gas-lamp is generally under a policeman for the preservation of social order. The respite in the town of "sans-and-dog fight" celebrity are solicited to committing assaults on the police and innocent passers-by during the dark hours. Hitherto the Town Council have not lighted the lamps in the borough during the months of June and July, and it would appear that it is just in the dark hours of these months that most burglaries and assaults take place. It is an old remark with us that gas has contributed more than any other agency to the safety of our streets, and we feel certain that the Town Council of Hanley will never regret the small expense they will incur by lighting the streets during the dark hours of the summer nights this year exceptionally dark.

The Directors of the Commercial Gas Company have given notice that from and after Midsummer-day but the price of gas will be reduced from 4s. 6d. to 4s. per thousand feet. The standard price of the Company, subject to the sliding scale, is 3s. 9d. per thousand; thus they might, during the past half year, with a charge of 3s. 6d. per thousand feet, have paid a dividend of eleven per cent. As a matter of fact, however, they have only paid ten and a half per cent. Now that the price is reduced by another twopence, they will be enabled to pay eleven and a half per cent. Supposing all things to go well, we may expect that the first dividend declared by the Company next year will be eleven per cent., which will make them the best paying Company in the Metropolis.

65 Coal trade Journal

PRICES FOR GAS COALS, AT NEW YORK.

Penn and Westmoreland, $4 60; (At Amboy $4 20, at Philadelphia, $3 75.)
Staten Coal Company, $4 50; (At Philadelphia, $3 75; Staten Is. $4 50.
Wurster Youghiogheny, $4 60; (At Baltimore, $3 75.)
Murphy Run, Newport, Pittsburgh, Monongahela, Newburgh Crest, Tyrrconnel, Palestine, Pittsbridge, etc., etc., $4 25 at New York; $3 25 at Baltimore.
Cannelton gas coal, $4 60; (At Richmond, $4 75.)
Cheapeake and Ohio Agency, 5-6 coal $4 00.

Pictou and Cumberland Canmel, quoted at $9 per ton at New York—shipped at Richmond Va. 2nd Bank Cannel, $5 50 per ton,—$4 00 f. o. b. at Philadelphia.
Newcastle $5 00. Liverpool Steam Orrel, $11. Iron Hall Cannel, $11—for gas $5 00
Scotch, $7 00. Nova Scotia, $3 75 to 4 00 as to quality, nominal.

A company called the Municipal Gas Light company of St. Louis, has applied for permission to lay gas mains in that city. It apparently intends to manufacture gas by the same process as that used by the Municipal Company of this city. It offers to furnish gas at a lower pressure and candle power for $1 per 1,000 feet, and to light the city lamps for not over 200 a year each. The price of gas in St. Louis is now $2.50 per 1,000 feet, and the city pays $27.50 a year for its street lamps.

THE GAS AND WATER COMPANIES ASSOCIATION AND THE APPLICATIONS FOR ELECTRIC LIGHTING POWERS.

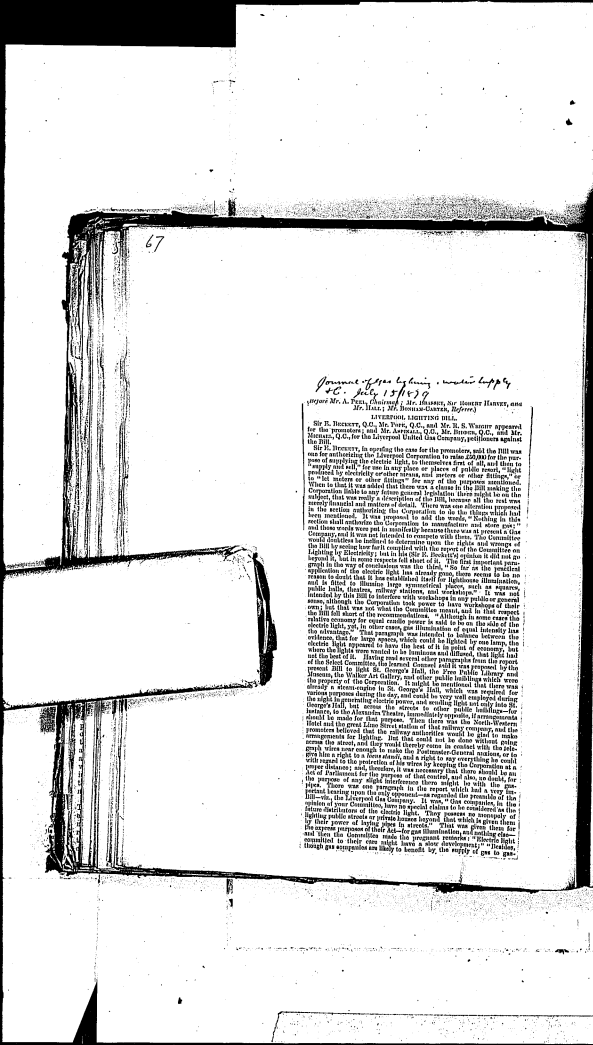
SIR,—In replying to Mr. Livesey's letter, which appeared in the last number of the JOURNAL, relative to my remarks at Newcastle upon the Gas and Water Companies Association, I will not discuss the question as to whether the action of the Committee was right or wrong in the matter of the electric light clauses. That was not the principal object of my remarks, though Mr. Livesey has thought it right only to dwell upon this. My remarks were intended to be of wider scope, and of a more general character. They referred rather to the constitution of the Association, the general conduct of its business, and the support given to it by the Companies.

That which I aimed at was even by yourself, as in your "Circular" of the 17th ult. it is said: "The Gas and Water Companies Association may not in all that could be desired; but wherever they fail, it is no reason, entirely the fault of the Companies, whose interests are identified over with the most zealous care by the energetic Secretary of the Companies Association, who is, we believe, left almost entirely to bear their deficiencies. A stronger combination, as Mr. Warner proposes, is undoubtedly desirable; but it can only be effected by the more hearty co-operation of the Companies themselves." Mr. Livesey himself says the same in some thing, but in other words, thus: "The remedy rests in the Gas and Water Companies Association generally are legitimate, and the suggestions would, I think, produce beneficial results if acted upon."

Though I know nothing of the actual position of the Association, I have an impression that what is most needed is a greater interest to be taken in its working, and a higher appreciation of the value of its work. More like attendance on occasion of members, which doubtless is greatly needed, would quickly follow. The members of the British Association of Gas Managers render good services by pressing the matter upon their chairmen, and discussing it before their friends. The Gas and Water Companies Association has a special claim upon us, too, just now, from the good work it has done through the present session. It effectually in my other way. An Association feebleness must have, if properly established and fairly managed, greater influence than any private combination for guarding our common interests when attacked, and, further, the Association can grow in experience and influence, and it has its machinery always ready for work.

Now the subject has been opened up, I do hope that the estimable Secretary will be encouraged to renew his efforts to place the Association in the position it should fill.

South Shields, July 10, 1876. W. J. WARNER.



Journal of Gas Lighting, Water Supply & &c. July 13 1869

REPORT MR. A. PAGE, *Chairman*; *Mr. Hargreave*, MR. GEORGE HARVEY, AND *Mr. Hall*; MR. HOUSE-CLERK, *Reporter*.

LIVERPOOL LIGHTING BILL.

Sir R. Bickersty, Q.C., Mr. Pope, Q.C., and Mr. R. S. Wansey appeared for the promoters; and Mr. Archibald, Q.C., Mr. Bidder, Q.C., and Mr. Morgan, Q.C., for the Liverpool United Gas Company, petitioners against the Bill.

Sir R. Bickersty, in stating the case for the promoters, said the Bill was for the purpose of enabling the Corporation to raise £250,000 for the purposes of supplying the electricity, to themselves first of all, and then to "supply and sell," for one in any quantities, to any persons, any light produced by electricity or other means, and motive or other force," light to "let meters or other fittings" for any of the purposes mentioned. When the Bill was first introduced there was a clause in the Bill making the Corporation liable to any future general legislation there might be on the subject of electric lighting, but a deputation of the Bill, because it did not merely benefit and matters of detail. There was one alteration proposed in the section which limited the powers of the Bill to the places which had been specified. It was proposed to add to the words, "So-thing in this section shall authorise the Corporation to supply light to any place or district and those words be put in specifically where was at present a clear Company, and it was not intended to compete with them. The Committee of the Bill's coming here fairly complied with the report of the Committee on Lighting by Electricity Bills (Sir F. Peckston's opinion it did not go far beyond it, but he was content to let him stop at it. The first important paragraph in the way of competition was that which refers to the practical application of the electric light that already exist, there seems to be no reason to doubt that it has established itself for lighting large manufactories and be fitted to illumine large symmetrical places, such as squares, public halls, theatres, railway stations, and workshops." It was not intended that it should interfere with warehouses in any public or general areas, although the Corporation took power to have warehouses of their own; but that was only to meet a particular case. The Bill did not in that respect relative economy for equal candle power in the case of the electric light, gas, in other cases, the illumination of equal intensity has the advantage. That paragraph was intended to indicate generally how competition was to be carried on, and it was proposed by the Bill that large spaces, which could be lighted by one lamp, the electric light appeared to have the best of it in point of economy, but where the area was limited to a hundred and fifteen feet radius of the not the best of it. Reading over several other paragraphs from the report of the Select Committee, it would be seen that it was proposed by the Bill to illumine the Walker Art Gallery, and other Public Library and the property of the Corporation. It might be mentioned that there were already a steam-engine in St. George's Hall, which was required to work pumps during the day, and could be very well employed during the night in generating electric power, and sending light not only into St. George's Hall, but also to the streets or other public buildings—for instance, to the Sessions House, immediately opposite, if arrangements could be made for that purpose. The Bill was for the North-western Hotel and the great Lime Street station of that name, and the North-western directors believed that the railway authorities would co-operate, and the arrangement would be for the benefit of the public, as they could not do those with the electric light. The cost of supplying light by the means proposed by the Bill would be much greater than the present cost of supplying gas by existing electricity to illuminate. Look at those which they could not light by gas. Gas Company's Hall and the area of the Exchange, and other places connected with them. They could creating a subterranean communication between the Exchange buildings, and they hoped they could erect steam-engines at each of those Railway Company could not be expected to go to the expense of laying down pipes for the purpose of supplying gas to the Corporation, and permission to do so by merely laying a pipe, according to the Corporation, and the Bill was one principally to enable the Corporation to do what they could not do without it. The Bill was opposed by the Liverpool Gas Company. It was, "Gas companies, to the opinion of your Committee, have special claims to be considered in the lighting public streets or private houses, which is given them by their power of laying pipes in streets." That was given them for the express purposes of their Act—for gas illumination, and nothing else; and then the Committee made the proposal somewhat ridiculous—"although compelled to their care might have a slow development," "electric light though gas companies are likely to benefit by the supply of gas to gas-

opinion, when you were called as chairman for producing electric light, as general principle, if gas manufacture and supply are under public control for the production of electricity as a source of illumination." That having any right of control over gas or future, to have anything to do with electric lighting, using it in the most remunerative sense. Then they went on to say that they "do not consider that they can arrive at any general powers to control gas companies in the interest of the local authorities," but they would be willing to grant to the Corporation "power to purchase the undertaking of any gas company, on such terms as may be agreed upon between the progress of invention brings a demand for facilities to transmit electricity for the purposes of gas, and makes it necessary to consider the question of the public interest." That was an important remark—"then, no doubt, the Corporation" that was an advantageous for a monopoly of the supply of electricity for illumination. The Liverpool Corporation were willing to take to the Bill if it was to say, if the Corporation already possessed the power to supply and make the company—the monopoly of the supply of electricity for illumination, compensating advantages. It was to take that the public should receive notice upon the public illuminations, and there could be no conflict between them and any company as to the supply of electricity. It was very difficult, whenever the time arrived, to enable, so as to obtain, through its corporation, the compensating advantages. It was directed against anybody who had a right any gas streets, and that was the case called a monopoly for the whole the electric light. It was not a monopoly for the whole, but somebody must take the lead in the matter, and there was no corporation in England more fitted to do so, and there was no corporation in Liverpool or Manchester, and possibly others in Corporation as that of the Liverpool Corporation were willing to take the leading them out, if experience had already conveyed for the benefit of the town and the company—the company—for the benefit of the town in some instances Liverpool had taken the lead, for it was the first to lay down in 1866, in Dublin, power was given for the express purposes of using the electric light, founded upon the Liverpool Act, and the Liverpool Act was also similar. That was the case of the Liverpool Corporation, and if there were any gas companies there was no reason why the Corporation should not have power to deal with the electric light in connection with the additional light which had grown up of the Liverpool Corporation had before them two agreements which had been entered into between the Corporation and the Gas Company. The first was with reference to the electric light, and that, generally, parity with reference to purchasing the undertaking was entered into between the Corporation and the Gas Company. The second agreement inserted other matters had been arranged and also the purchase price of the undertaking. The first agreement was to the Corporation the exclusive and other powers were granted (Sir R. Bickersty thought that was not necessary, and, for it was the first time in the Bill as it originally stood, that paragraph was written with a view to include the present Bill; but it could hardly be applicable so far as mean that, especially as his learned friend had already fully understood in the Bill was an important one, as it was the first time that the Corporation had taken powers to supply electricity. When they said, "We undertake to exercise electricity authority," they had to do with the undertaking of the Corporation character." In some cases it was true, but in another it was not; it had been a long course in particular cases, and it was not to be supposed that the Corporation would not have such powers. It was not to be supposed that the Corporation would not have such powers. It was not to be supposed that the Corporation would not have such powers. It

of each. I am advised that we require this Bill to empower us to take up the pavement. We have not tried to do so, and been stopped from proceeding. I am aware that competent authorities have advised that we have the power, and that evidence was given before the Select Committee to that effect.

Mr. Bidder: I see that the marginal note to clause 2 of your Bill is, "Power to supply electric or other light to public streets and places;" so that you not only contemplate illuminating St. George's Hall from the approaches to the landing-stage, and possibly some other avenues, but also supplying electric light for private purposes?

Witness: I do not think that at all likely.

Mr. Bidder: The words in the Bill are, "In any place or places of public resort."

Witness: That means railway-stations, theatres, and music-halls, but I do not know whether they are contemplated, although there is no reason why some of the rooms in the large hotels should not be lighted by electricity.

Mr. Bidder: When you come to light the theatres, music-halls, and hotels to any quantity, what is going to be the effect upon the business of your present clients?

Witness: I do not think that such lights as are likely to take place, having regard to the state of the invention up to the present time, will permanently depreciate the value of gas shares.

I did not ask you anything about the effect on gas shares; but it is not obvious, if you carry out your intentions, you will deprive the Gas Company of a considerable part of their public places of resort?—The use of gas in the particular places we might have provided the electric light would, of course, be gone; but, to counterbalance that, there would, I believe, be a very large use of gas in gas-engines for driving machinery, the machines, I am inclined to think, also, that the time is coming when there will be a demand increased illumination generally in all places of great traffic. I am satisfied that when gas companies find that their 10 per cent. is not forthcoming from them, they will discover other uses for gas, in the way of heating, which it is not now applied.

The Chairman: I think that will have anything to do with the effect of this upon the Gas Company or the gas shares.

Mr. Bidder said, with great respect, that the whole question before the Committee was whether the Corporation were entitled to ask for parliamentary power to do a thing which would injure the Gas Company, which had a parliamentary position; or, if granted, upon what terms, so as to protect the interests of the Company. Before many Committees there had arisen questions as to the supply of water and gas under tidings into the hands of corporations, and in some cases with most important question which the Committee had had to deal with was upon what conditions and with what terms, for the protection of the existing parliamentary company, they would grant the power asked for.

The Chairman: They only consider we have to consider is whether the existing rights of the Gas Company are interfered with, and their property and their business; and we have nothing to do with gas pipes, or interfering with their supply to their customers. I do not see how the Engineer can go into those questions.

Mr. Bidder: I must lay a foundation of fact with the Engineer. You, Sir, were the Chairman, I think, of the Committee on the Stockton and Middlesbrough Bill, the opinion there being practically, though it was fought out in a different form in different years, whether the Corporation should be allowed to supply water to the ships. They ultimately obtained it, but only upon the condition that they should purchase the rights of the existing Water Company at rates which were to be settled by arbitration, or precisely in the same position as the Water Company were. We are, under the authority of Parliament, the Lighting Authority of the town of Liverpool, and nobody else can light that town. With the sanction of the Town Council themselves, and with the sanction of Parliament, our capital is practically unlimited for the purpose, and I do not hesitate to say that the most important question for you to consider in this case—when one of the two parties to that bargain is about to commence a new trade under parliamentary power that may ruin us with our business, and asking you for powers which it is admitted will make it difficult for us to earn our dividends—is upon what conditions you will grant it.

Witness: I do not admit that.

Mr. Bidder: I am assuming that lighted existing companies are preserved. This is not a screwed on the part of the Corporation to light the whole of Liverpool with the electric light.

Mr. Bidder: It is a proposal to light the streets and places of public resort, and thereby to take the cream of our business away from us.

Mr. Pope: It is no more a proposal to take the cream of your business away from you than the proposal to make a railway from Manchester to Liverpool is a proposal to take away the cream of the coaching traffic away.

The Chairman: We will leave it to the learned Counsel to pursue his own course.

Cross-examination resumed: As a matter of fact, we break up the streets ourselves, and give permission to others to do so for certain purposes. We have express statutory powers to give authority to lay down rails across the streets in places in which both sides of the streets are occupied by houses. Under those powers I have no doubt we have given authority to the Telegraph Company to lay their wires under the footpaths, but they had the consent of the Corporation.

Mr. Bidder: If they had power to do so they would not have asked you to allow them to do it.

Mr. Pope: They had authority to do it with the consent of the Street Authority.

Mr. Bidder: They had power to lay their wires either overhead or underground, and I submit the Street Authority have power to lay them underground, if they like. A different power is given to others, and it is proper to take them overhead, and not underground.

Re-examined by Mr. Pope: If we have the power to do any mischief to the Gas Company without an Act of Parliament, our obtaining that Act will not do them any harm. Another point is that, supposing, only for the sake of argument, the whole of the public lighting in Liverpool were done away with, there would be a mere trifle in the accounts of the Gas Company. Since the report of the Select Committee I have had a letter from a gentleman from Messrs. Siemens Brothers with reference to the advantage of placing the electric light at a high elevation, instead of on a level with the eye, so as to diffuse the light over a larger area, though diminished in intensity. On that point I may, however, say that there are some practical difficulties in placing an electric light very high in a town; but I think they difficulties may be overcome by diminishing the intensity of those lights which are placed at considerable heights, and making the rays, therefore, very intense as you approach them—by means of gas screens, which will not obstruct the light passing to greater distances; and then, if above the light properly constructed reflectors are placed, the whole of the light may be utilised that would otherwise be lost by passing upwards, and it may be thrown to a great distance and also downwards.

The Chairman: It is not very clear what the provisions of the Bill are. What I understand is that you propose to limit the effect of the powers in this Bill upon the Gas Company's business, at some future time to be, to petition there is a clause pointing out the effect which it is believed would be produced upon those sources by the passing of this Bill, and, therefore, that point is before the Committee. Now, as to that petition has been lodged, I understand an allusion has been made to the petition which is the foundation of my remarks—that is to say, that the Corporation should supply and sell by agreement for use in any place or places of public resort. How can anybody be injured if there is an agreement necessary?

Mr. Bidder: By agreement with the persons to whom the place of public resort belongs; not agreement with us. It means, for instance, that we should not be able to supply electricity away from the Company.

Mr. Pope: No doubt, assuming that to be the true construction of the petition, it would be competition between the electric light and the Gas Company.

The Chairman: Is there any compulsory power given to interfere with the mains of the Gas Company?

Mr. Pope: None whatever.

Mr. Bidder: That is conceded.

The Chairman: I think the Gas Corporation it would enable the new mode of lighting to enter into competition with the existing lighting by the Gas Company. If it turned out satisfactorily, without the passing of this Bill, of course electric lighting would be used instead of gas; but if it turned out unfortunately, still the Gas Company would hold their own. It is nothing but the competition of a better mode of lighting with the present mode of lighting, and not interfering in any way with the powers of the existing Company.

Dr. C. W. Siemens, examined by Mr. Pope.

I know the open spaces round St. George's Hall, Liverpool, and the approaches to the landing-stage, and I consider they are very favourably situated for trying this experiment of lighting by electricity. The result of those experiments would prove the comparative advantages and the comparative cost of the one system and the other. The question of cost is one of two elements—the one is the cost of the machinery and everything to produce the effect, and the other is the (incidental) expenses connected with its application. With regard to the first, the necessary expenditure of energy to produce light by gas and the necessary expenditure of energy to produce light by electricity are at present pretty well understood. We know how much energy is necessary, how much expenditure of coal is necessary, to produce a given amount of illuminating power by gas, and we know pretty nearly approximately how much would be necessary in obtaining the same amount of light by means of electricity. But the second question, how the new mode of lighting could be best applied under given circumstances, is a matter that can only be finally determined by experience.

Mr. Pope: We have heard something about the wastefulness of the electric light, by reason of the necessity in obscure it to make it even approximately fit for the purposes of lighting, that the greater part of it is wasted, so as to avail yourself of the whole quantity of light?

Witness: I have considered that question, and I think that the electric light should be treated very differently as regards position from gas light, which must be placed near the object lighted, because its illuminating power is limited; or even if oil or candles were used, they would have to be placed still nearer the object to be lighted. Solar light diffuses itself through space, and the sun is far removed from the surface of the earth, though the sun is far removed from the surface of the earth, its solar light, being nearly of equal intensity to the solar light, should be placed at a considerable distance from the objects lighted; otherwise the light would be in intensity artificially, to be brought to the same level, or nearly so, as gas lighting, because if that were not done, it would be intolerable to the eye. I have considered the question of electric lighting as an engineering question, and I have come to the conclusion that, looking at the practical results by means of the electric light, that light must be placed at considerable elevation, in which case it is not necessary to obscure any large portion of it by means of opal or semi-transparent bodies, because the light will be removed above the lines of vision. On the other hand, if the light were too much subdivided, it would have to be placed near the spaces lighted, and the inconvenience would arise of bringing the source of light within the range of vision of the eye of the spectator.

That would seem to me to point rather to the utility of electric lighting for large spaces, where you can diffuse the light over a large area from an elevated position, rather than for domestic use, where it would be required immediately upon the object sought to be lighted?—Decidedly. It is generally supposed that the rays of the light diminishes as the square of the distance at which it is placed; and a good deal of misconception exists in consequence of that supposition. If a certain amount of light is placed at a greater distance, less practically is produced in consequence of that distance. The portion of that light which falls upon a square foot of space, diminishes as the square of the distance, but it will be found that if the source of light is placed at double the height, it will light four times the area. Therefore, the total amount of light which is utilised is exactly the same, whether the light be placed at a considerable or an insignificant height above the ground. Those views, I think, great deference to be tried experiments such as those proposed in the large open spaces at Liverpool.

By the Chairman: The height at which the electric light should be placed depends upon the breadth of the place; is the particular locality mentioned, I should say about 60 feet. I have spoken with the previous witness that the distribution of power might take place through the same wires as the light was carried, and that it could be used at the same time.

Mr. J. Dewey, examined by Mr. Pope.

I am a member of the firm of George Forest and Co., engineers, Liverpool, and a Town Councillor and a Justice of the Peace. I have given very considerable attention to the subject of electric lighting, in the interests of the town. I desire to see all our public squares and open places lighted by the best possible means. Practically the electric light consists of the evolution of power, which will, by a building effect in so ordinary manner, be expensive and vitiates more air than the human beings in the building do.

Cross-examined by Mr. Aspinall: There is nothing to prevent the companies lighting their stations by electricity, if they wish to do so, providing they do not interfere with the public streets. I do not think it would be a fair stretching of the term "places of public resort" to include railway-stations. I have not considered the question whether those words take anything but what would be their fair and natural meaning. The purchase of the property of the Gas Company has been a subject of debate, but it has been opposed by the great bulk of the Corporation.

Mr. Pope: When the Bill was introduced it was during the "scare," when it was supposed the electric light would supersede gas. It was then suggested that a Parliament might say, "If you will not supply us with electricity, you must buy up the Gas Company," and therefore we took that power.

Mr. Aspinall: You had a Committee in 1877 to confer with the Gas Company in respect to the purchase of the works?

Witness: Some questions were asked; that was all.

Was not this the action of the Committee: "In order that this question may be determined by the Council, your Committee recommend that they should be empowered to negotiate with the Gas Company for the purchase of the gas-works at a price to be agreed on between your

and still introduced a contested special powers to the Corporation to establish the Gas Company, and to buy their property, by agreement. The Bill was originally a company one, asking for powers to use the electric light for certain purposes, and for other powers as large as they could get them from Parliament. There were a number of clauses in the Bill with regard to the purchase of the Gas Company, but they had been struck out; but it was clear that, subject to the provisions of this section, they would be for ever at the mercy of the Corporation if this section were not amended, if they manufacture, lay, or rent, and may sell or let any gas or fuel, or other matter power, and any materials or articles necessary for the purposes of this section." That clause prohibited the Corporation from manufacturing gas; but it gave them power to lay it without limitation, and to sell it for certain purposes. If the Corporation thought it desirable to set up works of their own, they could do so. It was now framed, gave them power to lay down gas mains in any district, and to supply gas to any person as they pleased, and it gave them the power to compel the transfer of undertakings, as the Bill stood. What it was a Gas Bill. That showed the great ingenuity with which the ingenious gentlemen who conducted those matters on behalf of the Corporation, Bill those things. He (Mr. Aspinall) wished particularly to impress upon the Committee that the Bill originally was a power absolutely to enable them—by agreement, certainly—to buy up the works of the Gas Company, and to carry on the business. That was the case in every borough in the country in its experiments for the purpose of seeing whether the electric light was a good thing or not, or did it point to the real intention on the part of the Corporation of Liverpool to get before everybody else, to anticipate general legislation, and to obtain by a private act of Parliament powers which should give them a footing against the Gas Company, which powers, in the first instance, would be limited, but which, if they found that the light was a good one, would also place the possession, as it undoubtedly would do, in a far better position to negotiate with the Company for the purchase of their undertaking, than if there had been no such legislation? A great amount of criticism might be offered upon the extraordinary words, "places of public resort," including possibly as much as the Town Clerk had to select those words would extend to, then being hardly anything, in fact, which they might not be empowered to light under the powers. As the Bill now stood, it was limited to the purposes of experiment, and the words to that end, and if they had gone out of the committee-room with those words as they stood, unlimited, it would have been found that they were dwelling in the first place, with the supply of the public lighting; and then, finding that the supply of electric lighting was a success, and that it was a complete it probably, they would, without further legislation, have been empowered to include themselves the various places of public resort, and so do the Gas Company irreparable injury. That was the argument to be used against the Bill. The Bill was not now in the form in which it originally they required it, it would not be necessary. If they had refused it, they might have had all their valuable buildings lighted up; they might have had a wire from the top of St. George's Hall to the top of the Exchange Building-Room, or they might have taken it under the street without the slightest danger that any gas they would be subject to as to that case which was for their benefit was for their disadvantage. The absolute want of any provision for the protection of the Gas Company was the only way in which it could be said that the Bill was framed. In conclusion, the learned Counsel said he had tried to impress upon the Committee that the proposed Bill might work a serious injury to the Gas Company, and that the anticipation of that general legislation which must take place upon the subject, and which he ventured to suggest the Committee had intended to recommend; which might possibly be quite inconsistent with the proposition which was now before them, and which was, under the Bill as it now stood, to enable the Corporation to apply the electric light to any purpose they pleased, and to place them in a position to negotiate with the Company for the purchase of their undertaking, then if there had been no such legislation? A great amount of criticism might be offered upon the extraordinary words, "places of public resort," including possibly as much as the Town Clerk had to select those words would extend to, then being hardly anything, in fact, which they might not be empowered to light under the powers. As the Bill now stood, it was limited to the purposes of experiment, and the words to that end, and if they had gone out of the committee-room with those words as they stood, unlimited, it would have been found that they were dwelling in the first place, with the supply of the public lighting; and then, finding that the supply of electric lighting was a success, and that it was a complete it probably, they would, without further legislation, have been empowered to include themselves the various places of public resort, and so do the Gas Company irreparable injury. That was the argument to be used against the Bill. The Bill was not now in the form in which it originally they required it, it would not be necessary. If they had refused it, they might have had all their valuable buildings lighted up; they might have had a wire from the top of St. George's Hall to the top of the Exchange Building-Room, or they might have taken it under the street without the slightest danger that any gas they would be subject to as to that case which was for their benefit was for their disadvantage. The absolute want of any provision for the protection of the Gas Company was the only way in which it could be said that the Bill was framed. In conclusion, the learned Counsel said he had tried to impress upon the Committee that the proposed Bill might work a serious injury to the Gas Company, and that the anticipation of that general legislation which must take place upon the subject, and which he ventured to suggest the Committee had intended to recommend; which might possibly be quite inconsistent with the proposition which was now before them, and which was, under the Bill as it now stood, to enable the Corporation to apply the electric light to any purpose they pleased, and to place them in a position to negotiate with the Company for the purchase of their undertaking, then if there had been no such legislation as had now proposed.

The committee-room was then cleared. After some time the Counsel and parties were called in.

The Chairman said the Committee had to pass the preamble, with some reservation, but the object the Committee had in view was simply to enable the Corporation to make experiments with regard to lighting by electricity, and the Committee are of opinion that the clauses of the Bill should be scrutinised with the view of effecting that object, and that the preamble should be amended accordingly.

After some conversation, in the course of which Mr. Aspinall intimated that the opposition would be reserved in the House of Lords, the Committee adjourned till Thursday, by which time the clauses to be amended in accordance with the decision announced by the Chairman.

THURSDAY, JULY 4.

Mr. Aspinall said he understood that on Monday the Committee had decided to pass the preamble of the Bill, provided certain clauses were added. The memorandum furnished to him was to the effect that the Committee had decided, and that the Committee had decided to enable the Corporation to make experiments with respect to the electric light. The Bill, however, as he drew from being amended, was not limited to experiment, but been made indefinite more objectionable. The amendments, in point of fact, were the merest evasion, and, considering this circumstance, he certainly would appeal to the Committee to say that the preamble of the Bill was not proved.

An adjournment then took place in order to consult as to the clauses. Subsequently,

Mr. Aspinall he ventured to think that the alterations which had been made had brought them nearly within the decision of the Committee, who had decided to pass the preamble with amendments. The object of the Committee in passing the preamble was solely to enable the Corporation of Liverpool to make an experiment; and he gathered that that decision was illustrated, if not expressed, by the Committee saying that what they desired to avoid was giving the Corporation power to enter into a commercial undertaking and competition with the Gas Company, but to set them experiment in electric lighting without making a profit by the transaction. The object of the Corporation would not be to make a profit, but to try the experiment for their benefit, but they desired that the clauses of the Bill to enable them to carry out that experiment should be such as to make it worth carrying out. If some fabled new electric light on the top of a post was not an experiment; and the question was, how far it would be economically used for the purposes of public lighting, and that experiment, he understood, would be tried by the Corporation. If the Committee would refer to the preamble, they would find that the second section in it was as follows:—"And whereas it was expedient that the Corporation should be empowered to undertake and carry out such supply for means of electricity in the borough;" had they proposed to amend the evidence—? Whereas it is expedient that the Corporation, for the purpose of experiment, be authorised, for a limited period, to manufacture, provide, and supply light for the purposes in this Act mentioned, but not for the purpose of private lighting by means of electricity." The words "for a limited period" were inserted for the purpose of experiment; they would not be entitled to enter into a permanent arrangement, but they must have a limited period to enable them fairly to carry out the experiments that were necessary. Instead of saying "public and private purposes," they said "for the purposes in this Act mentioned." In the preamble they had inserted the words "five years from the 1st of September, 1878," as being the limited period for the purpose of lighting the streets. The Committee had also struck out the clauses which referred to the Corporation from any control. And the result he power of the Corporation to establish the Gas Company, and to buy their property, by agreement. The Bill was originally a company one, asking for powers to use the electric light for certain purposes, and for other powers as large as they could get them from Parliament. There were a number of clauses in the Bill with regard to the purchase of the Gas Company, but they had been struck out; but it was clear that, subject to the provisions of this section, they would be for ever at the mercy of the Corporation if this section were not amended, if they manufacture, lay, or rent, and may sell or let any gas or fuel, or other matter power, and any materials or articles necessary for the purposes of this section." That clause prohibited the Corporation from manufacturing gas; but it gave them power to lay it without limitation, and to sell it for certain purposes. If the Corporation thought it desirable to set up works of their own, they could do so. It was now framed, gave them power to lay down gas mains in any district, and to supply gas to any person as they pleased, and it gave them the power to compel the transfer of undertakings, as the Bill stood. What it was a Gas Bill. That showed the great ingenuity with which the ingenious gentlemen who conducted those matters on behalf of the Corporation, Bill those things. He (Mr. Aspinall) wished particularly to impress upon the Committee that the Bill originally was a power absolutely to enable them—by agreement, certainly—to buy up the works of the Gas Company, and to carry on the business. That was the case in every borough in the country in its experiments for the purpose of seeing whether the electric light was a good thing or not, or did it point to the real intention on the part of the Corporation of Liverpool to get before everybody else, to anticipate general legislation, and to obtain by a private act of Parliament powers which should give them a footing against the Gas Company, which powers, in the first instance, would be limited, but which, if they found that the light was a good one, would also place the possession, as it undoubtedly would do, in a far better position to negotiate with the Company for the purchase of their undertaking, than if there had been no such legislation? A great amount of criticism might be offered upon the extraordinary words, "places of public resort," including possibly as much as the Town Clerk had to select those words would extend to, then being hardly anything, in fact, which they might not be empowered to light under the powers. As the Bill now stood, it was limited to the purposes of experiment, and the words to that end, and if they had gone out of the committee-room with those words as they stood, unlimited, it would have been found that they were dwelling in the first place, with the supply of the public lighting; and then, finding that the supply of electric lighting was a success, and that it was a complete it probably, they would, without further legislation, have been empowered to include themselves the various places of public resort, and so do the Gas Company irreparable injury. That was the argument to be used against the Bill. The Bill was not now in the form in which it originally they required it, it would not be necessary. If they had refused it, they might have had all their valuable buildings lighted up; they might have had a wire from the top of St. George's Hall to the top of the Exchange Building-Room, or they might have taken it under the street without the slightest danger that any gas they would be subject to as to that case which was for their benefit was for their disadvantage. The absolute want of any provision for the protection of the Gas Company was the only way in which it could be said that the Bill was framed. In conclusion, the learned Counsel said he had tried to impress upon the Committee that the proposed Bill might work a serious injury to the Gas Company, and that the anticipation of that general legislation which must take place upon the subject, and which he ventured to suggest the Committee had intended to recommend; which might possibly be quite inconsistent with the proposition which was now before them, and which was, under the Bill as it now stood, to enable the Corporation to apply the electric light to any purpose they pleased, and to place them in a position to negotiate with the Company for the purchase of their undertaking, then if there had been no such legislation as had now proposed.

The committee-room was then cleared. After some time the Counsel and parties were called in.

The Chairman said the Committee had to pass the preamble, with some reservation, but the object the Committee had in view was simply to enable the Corporation to make experiments with regard to lighting by electricity, and the Committee are of opinion that the clauses of the Bill should be scrutinised with the view of effecting that object, and that the preamble should be amended accordingly.

After some conversation, in the course of which Mr. Aspinall intimated that the opposition would be reserved in the House of Lords, the Committee adjourned till Thursday, by which time the clauses to be amended in accordance with the decision announced by the Chairman.

THURSDAY, JULY 4.

Mr. Aspinall said he understood that on Monday the Committee had decided to pass the preamble of the Bill, provided certain clauses were added. The memorandum furnished to him was to the effect that the Committee had decided, and that the Committee had decided to enable the Corporation to make experiments with respect to the electric light. SOCIÉTÉ TECHNIQUE DE L'INDUSTRIE DU GAZ EN FRANCE.

As lately recorded in the last number (see *Journal des Gaz*, p. 64), the Annual Meeting of this Society was held in the Salle des Ingénieurs, the Sixth (boulevard Sébastopol, No. 62), on the 16th and 17th of June, under the presidency of M. Mallet.

The proceedings opened on the morning of the 16th with the transaction of the usual business of the meeting, and the admission of new Ordinary Members and Associates, 22 of the former and 9 of the latter having sent in applications.

The Secretary then delivered an address, in which he referred to the growth of the Society, and the work of the past year. The experiments that had been made in electric lighting during the past year, frequently occupied their attention. They had instituted a series of trials of the Jablochkoff candle, especially investigative the various systems in use, and were on the point of entering commencing experiments to be undertaken, when one and by the City Engineer, assisted by the Municipal Council of Paris by M. Contamin, Engineer-in-chief of the Northern Railway, and the work of M. Sautiaux, the public. Those experts having failed to agree upon the terms upon which the question had arrived, and given the exact cost of electric lighting by the various apparatuses, it was necessary to put the Society in considerable and interesting position. He then referred to the loss the Society had sustained by the death of M. Pecqueur, one of whose last Magazine had been known not only in connection with the *Télégraphe au Gaz*, and was well director of several gas-works in France and abroad, but as the managing financial position of the Society, he stated that an improvement had been effected over the previous year, by means of additional grants from gas companies and other sources, bringing the amount then placed to the credit of the Society from 1875 to 1877 (inclusive). While acknowledging the Society's financial position, he urged, there was still much to be effected in the way of technical progress, and that the Society must not rest on a single paper 2300 fr., which had been offered to the meeting by the Presidency, amounting to, unequal upon the maximum, especially the younger ones, and to be awarded to such members their ideas to the Committee for the general benefit of the Society.

The Secretary then referred to the question of the illuminating power of simple coke—illuminating power not necessarily to be kept constant; a few —might have considerable influence on the future of the industry. The many practical questions which had been started in connection with the Society's establishment. It was the fate of the Society to have to struggle against difficulties due to the subject of increased illumination, either by electricity or gas—the subject which, for more than a year, had occupied the thoughts of the Society's members, and which, in 1878, would be the question of the Exhibition of 1878. Whether private minds had been greatly troubled by the enlightenment of the electric light, he was not prepared to say, but a few months ago a considerable fall took place in the value of gas securities on the principal Bourses and even the American companies had not escaped the panic. The question of electric lighting, as put forward in a very few years to the place to electricity, not only for the illumination of the public thoroughfares, but also for the lighting of private houses. However, since several gas companies, foremost among them being the Paris Gaslight Company, which occupies a high place in the industry in France, had come to the front, and their establishment in the Rue Caumartin to furnish a most resplendent light in a very simple, practical manner, and at considerably reduced cost. Their system had been carefully studied and proved to the minds of others. The President concluded by announcing that a premium of 2000 fr. had been awarded to M. Bérard, Engineer of the Paris Gas Company, at the last year's meeting, and that the Committee proposed to set aside the sum of 2300 fr. for the next meeting, to be awarded as the Society in 1876.

The usual annual business of the meeting was then proceeded with, including the election of the Committee for the ensuing year, when the following gentlemen were elected, the first two being re-elected, and the sitting closed.

The ensuing gentlemen were appointed Committee for the ensuing year:—M. Jordan, President; M. Rilleux, Vice-President; M. Rousset, Treasurer; and M. Lencauchez, Secretary.

The members re-assembled in the afternoon, and again on Tuesday morning for the purpose of reading and discussing the following papers:—

"On the Influence of the Hygrometric State of Air, Barometric Pressure, and Temperature on the Illuminating Power of Gas," by M. Bérard.

"A Constant Water-Level Gas-Meter," by M. Edmondson.

"A New Regulator for Gas-Burners, and Cock with India-Rubber Closing," by M. Guitton.

"Simplified Method of Work on Electric Lighting written at the request of the Committee by M. Durand," by M. Mimbelli.

"The Recent Improvements in Lighting Thoroughfares," by M. Sugg, Jun.

"On the Value of the Jablochkoff Candle in comparison with the Sugg Regulator," by M. Sugg.

"On the High Power Burner employed at Havre in the Comparative Trials of Gas and the Electric Light for Lighting the Port," by M. Goulier.

"On a Burner of High Power tried at Toulouse," by M. Mallet.

"Photometrical Trials made with Cylinder-coated Lamps and Argandin Burners," by M. Giraud.

"A Self-registering Indoor for Gas and Water Meters," by M. Benjimmyer.

"Facilities of Transport," by M. Jacquet.

"Leroy's New Coke-Breaker," by M. Chevalet.

"A New Apparatus for Heating and Ventilating by Gas," by M. Roger.

"On Pressure in Gas-Mains," by M. Abervelve.

"On Coke Ovens Turbine, and its Application in the Manufacture of Gas," by M. Vee.

"Bibliothèque to be established between Gas-Works," by M. Cutsoent.

"On Gas-Works Accounts," by M. Ch. Fouard.

On Monday evening the members of the Society were entertained at a banquet given by the Imperial Continental Gas Association in the Hôtel Continental, Rue de Rivoli, and presided over by M. Dereeq, the Association's representative at Lille, and the Chairman of other establishments honoured the assembly by their presence. After the toasts had been proposed, the Eagle Gas-Works, which were brilliantly decorated and illuminated for the occasion. In the yard were displayed a number of gas-burners of high illuminating power, mounted upon candelabras, so as to show of their respective merits being justly estimated. Refreshments were provided in a tent, and dancing was kept up to a late hour.

On Tuesday morning a second banquet took place, by invitation, under the presidency of M. Mallet, at which the members of the Society and several guests, including M. Dorrets, were present.

In the afternoon of Tuesday the members inspected the gas-works at Bercy, Vaugirard, Auteuil, and on the following day an excursion was made to Bruneau, for the purpose of visiting the large works belonging to the Municipality. The party, which numbered about 100, was headed by the Engineer-in-chief, and M. Aerts, the General Manager, whose valuable guidance a thorough examination of the works was made, and no one could fail to admire the colossal proportions of this magnificent establishment, which does honour alike to the Engineer who designed it and to the Municipality who, to a large extent, have provided the funds for its execution and maintenance.

On the return to Asnières of the rowing closed, and, on separating, a hearty vote of thanks was accorded by the members to the President of the Society, for the manner in which he had conducted the affairs of the Society during its term of office.

After the excursion to Bruneau, several members of the Society came on to London with the object of visiting the gas-works here, and studying the manufacture of gas lasting apparatus now so largely used in England, on their arrival in the Metropolis, they were met by Mr. W. H. Maw, the Secretary of the British Association of Gas Managers, who kindly placed himself at their disposal, and arranged for their visiting such works as the principal London works, especially the Phœnix, which members were very cordially received by Mr. Corbet Woodall, the Engineer and Past-President of the British Association of Gas Managers, and the Beckton works of The Gaslight and Coke Company, where Mr. G. C. Treweby, the Engineer, did the honours. On following day the visitors were entertained at dinner by Mr. Woodall, who hospitality to express their appreciation of the kindness with which the members of the British Association regarded the Société Technique, and to promote they would always experience in meeting any of their number who might be accessible the very kind welcome accorded to those members of the Association who visited Paris on the occasion of the Society's meeting in 1878. Mr. Woodall dwelt particularly upon the interest aroused by the arrival from a frequent interchange of communications concerning the very important questions which were brought under discussion, and the circumstance might further contribute, and expressed an earnest wish that this was shared by every member of the British Association of Gas Managers. The visit was of purely an scientific character, and the members expressed their thanks to Messrs. Woodall, Treweby, and Bennett for the cordial welcome they had received.

THE PROPOSED SUBSTITUTE FOR CANDLES IN TESTINGS FOR ILLUMINATING POWER.

The following is the letter referred to in the "Circular to Gas Examiners" of the 1st inst., as having been recently addressed by Mr. A. G. Vernon Harcourt, one of the Metropolitan Gas Referees, to the Assistant Secretary of the Board of Trade:—

Sir,—I desire to call the attention of the Board of Trade to the unfortunate state of the standard candle, and to the practical inconvenience which it causes to the Gas Referees, to the Companies and Corporations they supply, and to the Gas Examiners.

Under the Acts of the seven named Companies, the Gas Referees are charged with the duty of testing the illuminating power of the gas supplied by each of the Companies by comparing it with the standard candle, and of certifying such testing every 4 months to the Board of Trade. I have been for many years engaged in this duty, and have been also by appointment, in 1872, an arbitrator on the Gas Referees, in the question of examining upon the effect of heating gas with a view to the satisfactory final solution, the inaccuracy of the usual photometric tests was brought home to me very forcibly. In 1871 I began a series of experiments, which I continued during a space intentionally protracted, which have led me to the conclusion that with occasional interruptions, I have had occasion to make a large number of testings with candles of the kind ordinarily employed, and also with candles differing in diameter and in the circumstances connected therewith, but coming within the definition of "sperm candles of six to the pound, consumed 120 grains of sperm per hour."

Metropolitan July 19 1879

The London Gas Companies.—The appearance simultaneously of the official return of the accounts of the Metropolitan Gas Companies of the year 1878, and of Mr. John Field's admirable analysis of the same, affords us a very favourable opportunity for laying before our readers a few figures in regard to our gas supply, as at present administered (which at the present juncture may not prove altogether uninteresting reading, especially to those whose duty it has been in the past to give attention to this subject in the interests of the consumers. The accounts of each of the companies mentioned have already been given in this column more or less in detail, and, therefore, on the present occasion we propose to confine ourselves to general results, and to a comparison of these results as shown by the several companies. First, with regard to capital. The subjoined is a statement of the amount of capital each company is at present empowered to raise, the amount of capital employed in each case during the past year, and the capital employed per 1,000 feet of gas sold during the year :—

	Capital authorized.	Capital actually raised.	Capital Employed per 1,000 feet of gas sold.
	£.	£.	s. d.
Chartered	10,800,000	8,638,500	16 6
Commercial	1,130,000	690,000	11 0
London	1,256,666	1,256,666	11 0
Phœnix	1,012,000	1,012,000	14 1
South Metropolitan	1,000,000	1,000,000	11 8
Surrey Consumers	300,000	290,000	11 0
Total	15,587,666	12,887,511	13 15 9

The first point which strikes one in glancing at the above table is, of course, the magnitude of the amount shown in the case of the Chartered Company under each heading, and to this matter we shall allude hereafter. Of the total employed capital of £12,334,514, no less than £7,162,360 is entitled to a standard dividend at the rate of 10 per cent. per annum, and £1,295,029 is loan capital. The remaining sum of £3,877,125 consists of preference and other shares bearing interest at rates ranging from 4 to 7½ per cent. It is worth while considering for a moment what might have been the result if the several companies had been compelled to raise the whole of their present capital by auction. The interest now payable upon the seven millions odd entitled to a standard dividend of 10 per cent.—which, of course, means the payment in some cases of 11 and 111 per cent.—whereas, at the lowest estimate, a sum closely approaching £700,000 a year. Had this same capital been raised by auction, and at the same prices been obtained as at the recent sale of the Chartered Company's stock—and it should be borne in mind that for many years past similar prices have been obtained, although, of course, we well know that there were times when the London gas companies were not quite so prosperous—the consumers of the metropolis would have been relieved of an annual charge of something like £700,000, which represents the produce of a rate of nearly 4d. in the £. We quite admit that these calculations have only an approximate value, but in the main they are reliable, and constitute an all-important evidence of the correctness of the view—so far as the public is concerned—that has always been urged in this journal. We have also invariably contended that amalgamations, unless effected under exceptional circumstances have never resulted to the advantage of the consumers ; and we find in the above table a very significant fact, proving the accuracy of our opinion as to the inexpediency, from a financial point of view, of such gigantic concerns as that at present presided over by Mr. Hedley Thomas. The capital employed by the Chartered Gas Company amounts to no less than 16s. 6d. for every 1,000 feet of gas sold—a sum in the absence of that employed by any other company for doing precisely the same amount of work. It is not very difficult to see that, where in one case the price charged per 1,000 feet of gas has to provide interest, on 16s. 6d. of capital, and in another case on only, say, 11s. of capital, all other circumstances being equal, the consumer in the first instance must necessarily be placed at a very considerable disadvantage ; and when it is borne in mind that the Chartered Company supplies a district far in excess of that provided for by all the other companies put together, the importance of this point can scarcely be overestimated. Indeed, it is somewhat singular to notice how this proportion of capital employed per 1,000 feet of gas sold indicates the general condition of each company as far as the price charged, and the dividend it declared are concerned. The following table will show this at a glance :—

	Capital employed per 1,000 feet of gas sold.	Price charged per 1,000 feet.	Dividend per cent declared for 1878.
	s. d.	s. d.	
Chartered	16 6	3 6	10½
Commercial	11 0	3 3	10½
London	11 0	3 3	10
Phœnix	14 1	3 6	10
South Metropolitan	11 8	3 6	11½
Surrey Consumers	11 0	3 6	10

The Surrey Consumers' Company, as everybody knows, is somewhat exceptionally situated, while the Phœnix and the London Companies are not under the provisions of the sliding scale ; and when these circumstances are remembered, it will be seen that the point to which we have alluded is a tolerably correct index. Coming to the results obtained by means of the employment of this capital, we have prepared a table showing the quantity of coals carbonised during the past year, and the quantity of gas made and sold.

	Coals Carbonised.	Gas Made.		Gas Sold.	
		Thousands.	Per Ton.	Thousands.	Per cent. of gas made.
	Tons.	Cubic Ft.			
Chartered	2,208,000	11,126,993	10,089	10,634,890	95·61
Commercial	131,069	1,385,731	10,106	1,253,618	90·39
London	130,000	1,310,414	10,080	1,251,068	95·48
Phœnix	154,360	1,551,018	10,050	1,491,765	96·19
South Metropolitan	154,360	1,551,018	10,050	1,491,765	96·19
Surrey Consumers	34,211	343,092	10,031	324,253	94·51
	2,812,431	28,268,255	10,181	16,951,358	95·92

The results shown above do not differ very materially from those obtained in the previous year. There is an increase in the quantity of coals carbonised by about 100,000 tons, and in the quantity of gas made by over 1,000,000 thousands. We confess, however, that we are somewhat surprised to see a falling off in the quantity of gas obtained from each ton of coal carbonised, in respect of four out of the six companies. With all the improvements and inventions that are continually being brought forward for extracting the very last ounce of gas from the coal, one might have expected a change in the other direction. It is just possible, however, that a true economy may not lie in the employment of these inventions, which, in some cases are of an exceedingly costly character, and this view is somewhat strengthened from the fact that the Chartered Company, which is notorious for its extravagance, shows, as a result of its very large expenditure, a slightly increased make of gas per ton of coals carbonised. At the same time, we certainly think that a decrease in the make should not be shown. The Surrey Consumers' Company, for instance, last year made a smaller quantity of gas per ton than in either of the three previous years. In considering this point, there are, of course, other circumstances to be borne in mind ; but, in glancing over the figures before us, these comparisons do strike one, and they are of some value as illustrations of the general results obtained from time to time. The make of gas per ton in 1877 averaged 10,137 feet, in 1878 10,069, and in 1879 9,892. The only other matter to which we propose referring this week is the cost of coals, and on this point, we should explain, our information is obtained solely from Mr. Field's book. The accounts of the companies simply state what was paid for coals in the course of the year, and no means whatever are afforded of ascertaining for any purposes of comparison the practical value or effect of the figures given. We have, therefore, compiled the subjoined table from the figures contained in Mr. Field's analysis.

	Cost of Coals.		Less Residuals.		Net Cost of Coals.	
	Amount.	Per Ton.	Amount.	Per Ton.	Amount.	Per Ton.

Comparing these results with those shown in previous years, we find that the cost of coals in 1877 averaged 16s. per ton, in 1878 17s., and in 1879 19s. 4d., as against 15s. 6d. in 1876 ; while the net cost of coals in 1877 averaged 6s. 6d., in 1878 6s. 6d., and in 1879 6s. 10d. One would have thought that the Chartered Company, with its extraordinary facilities for handling material at Beckton and elsewhere, and with its enormous consumption, would have been able to secure contracts for coal at prices which would compare favourably with those paid by any other company ; but instead of this we find that the price paid during the past year by the authorities at Horseferry-road, was not only not the lowest, but was actually above the average price paid by the whole of the companies, while the net cost of their coals was, with one exception, higher than that shown by either of the other companies, and nearly 4d. above the average. It may be that, in the opinion of the directors, the extra yield of a hundred feet of gas per ton of coals carbonised fully compensates for this difference in price, notwithstanding the fact that their receipts by the sale of residuals were 9d. below the average ; but it may also be a fact, as in the opinion of some competent judges is the case, that the company is not particularly anxious, as a matter of policy, to increase its condition of prosperity much beyond that at present attained, for fear that unreasonable and extravagant profits may again excite the feelings of the public in regard to their proceedings. Our own impression is that those who hold this latter view are not very far wrong. We cannot persuade ourselves that the company is striving to carry out the spirit of the Act, nor can we think that the company is disposed to give to the public that advantage in the form of a reduced price, which it was manifestly the intention of the Legislature the public should secure. We cannot of course say how long the metropolis will be prepared to put up with the present state of affairs ; but, as we have repeatedly said, while the inhabitants of places like Birmingham and Manchester can obtain good gas at prices ranging from 2s. to 2s. 3d. per 1,000 feet, it is a monstrous thing that the inhabitants of London —the metropolis of the world—should be compelled to pay these monopolists 3s. 6d. and 3s. 9d. for an article that is enriched and beautified for its purpose in the extreme when compared with that supplied to many provincial cities and towns. On a future occasion we hope to be able to return to this subject, and to submit further extracts from the accounts before us, but for the present, probably we have been able, in the figures given above, again to place before our subscribers information on the most important subject, which may prove most useful

Hardware July 15 1879

Webster's Improvements in Gas-lighting.—At the present time if may, perhaps be affirmed that more efforts are being made for the improvement of artificial light than at any other in the world's history. Within the memory of men still living the same form of lighting was employed as well anterior for 1,000 years. Within this century coal gas, having slumbered since the creation of seas, has become our willing handmaiden, and it may be fairly said that it has withstood the efforts lately made against it by the electric light with triumphant success. This contest has, however, not been without its effects upon lighting by coal gas: we have discovered that gas may be burnt to yield no light, and that to obtain perfection in gas-lighting we must leave the most perfect supervisory indeed, it is not too much to say that the economical consumption of gas depends almost entirely on the form of burner and shade used. It is for this purpose that Mr. G. E. Webster, C.E., of Nottingham, has directed his attention, and after thousands of experiments, simple, and practical experiments, has produced the improvements we illustrate below. The first of

these, figure 1 and 2, is the Improved Duplex Burner, by which the gas is caused to flow equally, and, by means of the small orifices placed at certain angles to each other, to form—first, a hollow flame, which, by inducing a current of air through the burning gas, gives the advantage of having an Argand chimney supplied by limited air; secondly, by the arrangement of the holes the principle of diffusion is made use of, and the black and heating zone so familiar to all in the gas flame is done away with. The global accompanying this burner is made with a larger opening at the bottom than the top, and thus the light which is ordinarily thrown up to the ceiling and wasted is reflected downwards, where most wanted. Where a paper shade is used an improvement termed a

"protector" is applied. This prevents the shade from being burnt or blackened, and consists in having a ring of tin fixed on the wire frame at a little distance from the shade, so that a current of air is induced between the shade and the protector, cooling both and preserving the shade. A triangle or gallery for supporting the globe consists of a cast tripod, which is shadowless; it fastens in a very simple and secure manner with one screw. Mr. Webster also manufactures a burner which is novel and peculiar in its action. It consists in a burner with a loose cone, having a hollowed conical top with a slit in it. When burning the flame takes a direction exactly across the slit. The shade is of opal glass, and combines the advantages of a globe and paper shade. The improved street lamp is triangular in plan, and has an opal top. Its advantages are—less first cost, and more economy in use, there being one less pane of glass to clean, &c.

Hardware July 1879

Messrs. Barwell, Son & Fisher, of the Worcester Works, Birmingham, will make a principal feature in their exhibits at Sydney of their new system of lighting by the patent duplex burner, and a new form of shade and shade-holder. The duplex burner (already illustrated in our "Novelty" columns), has four holes, which produce two flames, so inclined to one another that they blend into one. The air entering between the flames at the openings in the burners causes perfect combustion, so that a maximum of light is produced with a minimum of heat and smoke. A five-light chandelier, fitted with duplex burners, and with suitably-shaped globes, carried on holders which intercept hardly any of the light, will be shown side by side with a similar chandelier, fitted with Bray burners of the fish-tail type, and the ordinary shades and shade-holders. The comparison as to the illumination is decidedly in favour of the new system; while the introduction of the Bunsen photometer shows that there is a saving in the quantity of gas consumed to the extent of about 25 per cent. The firm will also show a new shade, with flat plate underneath for Argand burners. It is an idea borrowed from the method of enclosing the electric light, and is well adapted for offices, banks, and shop windows. A burner, which is constructed on the most approved "Bellenes" system, will also be shown, as well as a collection of metal chandeliers and miscellaneous goodsings. Ironmonger July 1879

PRICES FOR GAS COALS, AT NEW YORK.

Penn and Westmoreland, $1 90 ; (At Amboy $1 80, at Philadelphia, $2 75.)
Boston Coal Company, $1 80 ; (At Philadelphia, $2 75; Manhattan $1 80.
Waverley Youghiogheny, $1 80 ; (At Baltimore, $2 25.).
Murphy Run, Newport, Fairmount, Monongahela, Newburgh Crest, Tyrconnell, Palatine, Pinnickinick, etc., etc., $1 65 at New York ; $2 25 at Baltimore.
Canaston gas coal, $1 65 ; (At Richmond, $2 75.)
Chesapeake and Ohio Agency, gas coal $1 50.

Peytona and Gauley Coal, quoted at $2 per ton at New York—shipped at Richmond Va. Red Ash Cannel, $4 50 per ton,—$4 50 f. o. b. at Philadelphia.
Newcastle $3 50. Liverpool Orrell-Arley $11. Dove Hall Cannel, $15—for gas $4 50
Scotch, $7 50. News, nov'ls, $2 75 to 4 00 as to quality, weight, &c.

Engineer July 12 1879

The eighteenth annual meeting of the North British Association of Gas Managers has been held at Edinburgh, under the presidency of Mr. Alex. Smith, of Aberdeen, who, in the course of his address, gave it as his opinion that gas was hardly yet beyond the age of its infancy, and had nothing to fear from the electric light. Mr. Peter Watson, of Stirling, gave the results of his experience of the effects of frost on gas apparatus during the recent severe winter. Mr. Wm. Young, of Chopens, contributed a paper on "Gas Engines and Gas Motors," and Mr. Carpenter on "Illuminating Gas," and "The Percentage of Non-luminous Gas in relation to its Illuminating Power." Mr. Jas. Colville, Dalkeith, read a paper entitled and described his meter gas governor; Mr. Neilis, of Forfar, spoke in favour of gas engines and governors, letting out gas to consumers free of charge; and Mr. Jas. Gilchrist, of Dumbarton, read an interesting paper on "Circumstances affecting the Price of Gas." A committee was appointed to confer with a committee of the West of Scotland Association of Gas Managers, with a view to the amalgamation of the two societies. Mr. Jas. Reid, of Islington, was elected president for the ensuing year. Subsequently, Mr. Thomson, of Messrs. Laidlaw and Sons, read a paper on "A Gas Compressing Engine for the Recovery of the Light Spirits in Waste Shale Gases." Mr. Wm. Cowan, of Hillsborough, exhibited and explained his automatic pressure changer—a machine which is found to do automatically an important part of the work hitherto performed by the gas manager or his deputy. Next annual meeting was fixed to be held at Perth.

Cheap Fuel and Light. 1879

American Gaslight Jour

We have before us a report lately made by Gen. Herman Haupt, on several patents and processes for producing cheap hydrogen for light and fuel and utilizing it in a wide range of metallurgical operations. Gen. Haupt has made extensive investigations as to the working of these processes, and has prepared a valuable report, from which we make the following extracts, and will continue them in a future issue.

REPORT.

These patents embrace a very wide field, and the operations which they include may be divided into several classes.

1. Processes for the manufacture of illuminating gas.

2. Processes for the manufacture of a combustible gas for heating and culinary purposes.

3. Processes for the manufacture of cheap hydrogen, or combined hydrogen and carbonic oxide, for metallurgical purposes.

4. The use of hydrogen, carbonic oxide, carbonic acid, carbureted hydrogen gases, air, hydro-carbon vapors and super-heated steam, in various regulated proportions and combinations, for a wide range of metallurgical operations.

WHAT IS CLAIMED AS CAPABLE OF ACCOMPLISHMENT BY THESE PROCESSES.

1. The production of illuminating gas of superior uniformity, brilliancy and purity, at lower cost than by any other process, and not poisonous.

2. The production of a heating gas of uniform composition, possessing greater heating power, at a cost not exceeding that of the inferior gases produced by other processes.

3. By the application of gases and vapors as proposed it is claimed as results :

The dessiliation of ores of iron.

The production of sponge iron of great purity directly from the ores, which will need recalcine in cooling.

The production of iron and steel of all the various grades directly from the ores, and of determinate and uniform composition.

The production of bar iron, steel, boiler and armor plates directly from the ores.

The hardening of the surfaces of iron manufactures to add to their durability and usefulness.

The softening or annealing of the surfaces of cast iron and steel manufactures, to increase their toughness and ability to resist percussive and other forces.

The treatment of manufactures of iron to give them a permanent property of resisting all corrosive influences, including that of salts and acids, enlarging greatly the field of specialties and opening up new manufactures.

The production of steel from ores or from crude cast iron without the use of spiegeleisen.

The removal of impurities and the preventing of oxidation in the processes of heating and forging masses of iron for the manufacture of shafting and other machinery, in the processes of re-heating and rolling iron and steel plates and bars, of annealing iron wire and its plates, and manufactures of sheet iron with smooth and bright surfaces that will effectually resist corrosion.

The reduction of refractory and titanic ores.

The separation of impurities, the desulphurizing of ores of the precious metals, and the manufacture of superior iron and steel from inferior stock.

The attainment of all these objects by processes more economical than those now in use.

These claims cover a wide field. In reference to them I will observe:

First. As to the processes for the manufacture of illuminating gas.

These processes are very numerous at the present day. A large number of machines have been set up in our large cities which depend upon the use of gasoline vapor diluted with air. They are used extensively for suburban residences, and give satisfactory results.

A water gas produced by the decomposition of super-heated steam is now coming into very general use under the name of the Lowe gas. The process has been improved upon by Strong, of New York, who claims the ability to produce 1,000 cubic feet of gas from 10 lbs. of coal, at a cost of eight cents. This gas is not suitable for illuminating purposes, but by the use of naphtha, petroleum, or hydro carbon vapors it can be enriched at a cost, it is claimed, of 27 cents per 1,000 feet, and yields a gas said to be superior in candle power to ordinary coal gas.

The Gill process claims similar results, so far as concerns cost of production, but a gas of greater uniformity, brilliancy and heating power, consisting largely of hydrogen, while the principal constituent of ordinary water-gas is carbonic oxide.

To understand on what this claim is based a brief description of the process is necessary.

The Strong and Lowe gas is produced by passing super-heated steam through a furnace containing incandescent carbon, previously heated, by which means the steam is decomposed, the oxygen absorbed by the carbon forming carbonic oxide with some carbonic acid and hydrogen liberated, so that the resulting gas is a combination of which the following is said to be the average composition of one pound, as given in a printed report on the Lowe and Strong process:

OVER

Oxygen	.0174
Carbonic Acid	.0627
Nitrogen	.8690
Carbonic Oxide	.7007
Hydrogen	.0747
Marsh gas	.0466

The oxygen, carbonic acid and nitrogen have no heating or illuminating properties, and the carbonic oxide, of which there is 71 per cent., develops in combustion only 4225 units of heat per pound, while hydrogen, of which there is only 7½ per cent., yields 62,000 units per pound.

In this process, moreover, the temperature is constantly changing, the incandescent coal is gradually cooled so that its power to decompose steam is less lost, and the operation must be suspended while the furnace is reheated.

The Strong gas requires for combustion 69 pounds of air, and develops 7727 available heat units per pound.

The steam coming in contact with 50 pounds of incandescent coal carries off a much larger proportion of sulphur and other impurities than if the quantity of coal were less.

In the Gill process for producing gas from the action of super-heated steam or incandescent coal, the production of gas is represented as continuous and not intermittent, and the product uniform instead of being variable. It differs from the Lowe and Strong in this, that the coal required to decompose the steam is contained in close fire clay retorts, heated from the exterior and not from the interior, and the heat maintained with uniformity. The steam or air come in contact with not more than 20 pounds of coal or coke per 1,000 cubic feet of gas inside of the retort, and the fuel required outside is 20 pounds of coal. The total amount of coal, therefore, is less than in the Strong and Lowe process, but there should be no very material difference in the cost of the water gases for equal volumes. A pure water gas, produced from the decomposition of water and the complete combination of the liberated oxygen with the carbon, should consist, by weight, of 1 part hydrogen, 8 of oxygen, and 6 of carbon, thus being the constituting equivalents, and the resulting gas should contain 6.6 per cent. by weight of hydrogen which is nearly the per cent. given in the analysis of the Strong gas. The specific gravity by calculation is .912.

The specific gravity of hydrogen is .07, and the heat units developed in the combustion of 9ss pound 62,000.

The specific gravity of carbonic oxide is .972, and the heat units developed in the combustion of one pound — 4225.

But, .0742500 — 4240 units,
And .9722 4225 — 4241

So with equal volumes the heat units are nearly equal under equal pressure.

It is necessary to distinguish between quantity and intensity of heat, and I was surprised to find so much confusion of ideas and diversity of opinion amongst practical metallurgists and scientists on these subjects, and especially in reference to the temperature of furnaces. Mr. Gill claims to have discovered the errors of the usual theoretical formulæ for temperature, which give carbonic oxide an intensity in combustion of over 3000°, and hydrogen of only 4000°. The absurdity of this result is apparent from the fact enunciated by Bunsen, that carbonic acid is dissociated or resolved into its elements at from 1832° to 2192°, and consequently at or above this temperature carbonic oxide cannot undergo combustion at all, which contains in conversion into carbonic acid. Vapor of water is also said to be dissociated at 4532°, which is the highest temperature from combustion of hydrogen, and the highest possible in a furnace.

Further, the average heat of a furnace must be less than the maximum heat of combustion of the gases, for all the heat communicated to the substances acted upon must be deducted from the source of heat, the combustion of the gases. The temperature of combustion given by writers is purely theoretical, and would appear to be erroneous.

Mr. Gill claims to have demonstrated, not only theoretically, but practically, that the intensity of combustion of hydrogen is much higher than that of carbonic oxide, and has deduced formulas which give results consistent with experiment and observation, and which he proposes at a proper time to publish.

I will only add that I am unable to perceive any flaw in the reasonings and conclusions of Mr. Gill, who impresses me as a thorough expert on the subject of temperatures.

Admitting that the same quantity of heat may be developed by the combustion of equal volumes of carbonic oxide and hydrogen under equal pressures, it must be observed that a gas consisting chiefly of carbonic oxide is poisonous and too dangerous for domestic purposes, while for metallurgical purposes the intensity of combustion and the affinity of hydrogen for sulphur and the phosphorus as well as for oxygen render it a more useful fuel than carbon or oxides.

Plumbers & Sanitary Engineer

April 1879

The following are the debts of three English cities, and the proportion due to establishment of gas works:

	Total Debt.	Spent on Gas Works.
Bolton,	£1,655,000	£164,700
Bradford,	2,266,132	341,577
Leeds,	3,237,059	505,939

George Westinghouse, inventor of the air brake, has proposed a new method of lighting railroad cars. His air-brake plans a supply of compressed air at disposal; current of this is passed through carburetters placed under the cars so as to produce an air gas, which is used for lighting the passenger cars.

The semi-annual meeting of the New England Association of Gas Engineers will be held on the 13th and 14th days of August. The members and guests will meet at the Narragansett Hotel, Providence, R. I., visit the Gas Works, and have an excursion productive of the usual quantities of pleasure found at those meetings.

Last month the Dartford, Eng., Gas Company's new gasometer, 74 feet in diameter and 26 feet in height, blew up, the whole falling with a tremendous crash, the columns and massive sides being carried a great distance. The night watchman was seriously injured and had his collar bone broken. The gasometer had been in use only a week.

Philadelphia wants gas cheaper, to judge by the papers. There is plenty of grumbling against the Gas Trust there, editorially and by letters from the people.

The Gas and Water Committee of the Ramsgate, Eng., Local Board have decided upon letting gas cooking stoves on hire on the three-years' purchase system.

From the annual report of the Metropolitan Board of Works of London, Eng., it appears that during the last year the number of gas meters tested was 80,447.

At a late meeting of the Philadelphia Public Building Commission, a proposition from a gasoline company to erect gasoline lamps and keep them in order for $20 per lamp yearly was postponed.

The Providence, R. I., *Dispatch*, of July 6th, contains an article of some length describing one of the Otto gas engines at work in Kelleg's printing office, 19 Washington Street, in that city, and giving a short interview with Mr. Kelleg.

Dr. Samuel S. Cruy was, trying in the beginning of July, to introduce a process of making gas from crude petroleum into the gas works at Glens Falls, N. Y. It is the same process in use at the Delavan House, Albany, N. Y., already noticed in the Meteorites.

Coatsville, Pa., Gas Works are to be improved by substituting clay for iron retorts.

The Common Council of Plainfield, N. J., has suspended lighting the street lamps for three months.

The property of the Fall River Gas Light Co., was bought in for the creditors of the company at the beginning of the month for $30,000.

Progress July 12 1879 82

In New York city gas is now furnished at $2.00 a thousand feet; in Lancaster in this State it is supplied by a private company at $1.80; in other towns at equally moderate rates. In Philadelphia, the Gas Trust, a corporation existing under the city government, and controlling an influence up to this time stronger than public opinion and the press, demands and receives $2.15 for every thousand feet of gas. No support, no competition, no argument, affects this defiant monopoly, and in self-defence many citizens are trying other processes to light their dwellings and factories. Hence the deep interest with which Edison's magnificent movements are watched by hard-working, enterprising Philadelphians.

Progress July 12 1879

THE JOURNAL OF GAS LIGHTING,
WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, AUGUST 6, 1878.

Circular to Gas Companies.

It is extraordinary to notice the opposition shown to Gas Companies as regards their obtaining powers to supply the electric light. It would be difficult to explain the reasons for this antagonism but for the statements made by Mr. D. Chadwick in the House of Commons on the 29th ult. This gentleman argues that every additional privilege granted to a Company will enhance the value of their undertaking when a question of purchase by a Local Authority is considered. We shall not attempt to controvert this argument; still it appears to us to tell nothing against the right of a Gas Company to possess the privilege. As matters stand at present, the day appears distant when the electric light will become a thing of profit to either Gas Companies or Corporations. It might, therefore, have been safely left for time to settle the relative positions of those bodies. But as the Committee on Lighting by Electricity decided that Gas Companies should not possess the exclusive right of supplying the electric light, we must accept our position with the satisfaction of thinking that our interests are not at all interfered with by the refusal. Local Authorities are perfectly welcome to expend the ratepayers' money in making experiments with the electric light, which, for the most part, will prove abortive. Gas Companies may, therefore, patiently wait, and quietly pursue an industry which, with careful management, is always profitable, and capable of development as their district extends. There is then, in our opinion, no reason to regret the decision of the Committee of the House of Commons; on the contrary, we think Gas Companies may be congratulated on the result.

The Liverpool Lighting Bill has now passed the third reading, and will, no doubt, receive the Royal Assent this week. All Town Councils are now up for the holidays, and we do not suppose that we shall hear until next year what steps the Liverpool Council intend to take to carry out the exceptional powers they have obtained.

The Preston Corporation are angry with the Gas Company for remunerating the Directors for their labours in preparing and seeing through Parliament their Act of the present session. The Corporation, it is said, spent between £1000 and £2000 in opposing the Bill, and no doubt a part of this sum went—and, it is true, into the pockets of some of the Councillors, but to the advantage of some of them. Of course, the Council have no power to vote themselves any money reward for the labours they perform, but they ought not, on this account, to envy the Gas Directors the remuneration which the Shareholders have awarded them. Matters of this kind are a constant source of squabbling between Local Authorities and Companies. The former look with a jealous eye upon every appropriation of profits which is not made to the direct advantage of the consumers. In the long run, however, we think it will be found that the Preston Gas Act will operate favourably to the interest of the public. Some members of the Corporation threaten an attempt to make a compulsory purchase of the Gas Company. They will find this a difficult and very expensive process, and if they should succeed, the troubles of the Council will only be begun. It must be admitted that Preston is extremely well served with gas at a very moderate price, and nothing but forbearance and courtesy are required to establish relations which would prove beneficial to both parties. Nothing is to be gained by violent opposition on the one side, and dogged resistance on the other. Let each party approach the other in a friendly spirit, and gas and electric will come in Preston.

The half-yearly meeting of the Cambridge University and Town Gaslight Company was held on Thursday last. It is hardly necessary to say that the Company are still in a highly prosperous condition. The revenue account shows a large excess of income over expenditure, and, considering the prospect of a continuance of cheap coal, the Directors have resolved to reduce the price of gas threepence per thousand feet from Michaelmas last. While having regard to the consumers interests, the Directors are not unmindful of their duty to those Shareholders who invested their money when it was less productive than it is to-day, and they accordingly set aside 10 per cent. for the payment of back dividends to the proprietors of consolidated stock. It ought always to be remembered that the first Shareholders had to bear the burden and heat of the day. They obtained but little for their investment, and now that times are become more propitious they deserve to be rewarded for the sacrifices they made in earlier days. At the meeting a doubt was expressed by a Shareholder not interested in the latter distribution, as to the legality of the payment; but we may assure him that there is no doubt whatever about the matter. The Directors have not only the right, but, in some respects, it is a duty to allot unappropriated balances for the payment of back dividends. We miss on this occasion one of those admirable speeches with which the Chairman so commonly gratifies the whole gas world. There is, however, no "burning topic" on which to expend his eloquence, and, with stone regret, we wait for an occasion which may once more induce him to speak.

The annual meeting of the Reigate Gas Company, Limited, was held last Thursday. In a thriving and rapidly improving district like that occupied by this Company, it is not surprising that a high degree of prosperity should be enjoyed. It appears that from the workings of the past year a dividend of 15 per cent. might have been paid; but although a limited Company, who could pay what dividend they pleased, they keep back some of the profit for the benefit of the consumers, and make a reduction in the price of gas. The Company pay 10 per cent. dividend, and put £300 to the contingency fund, carrying forward £201 to the next account.

We omitted last week to remark upon the half year's working of the gas undertaking of the Birmingham Corporation.

Concluded from page 1.

In the two last volumes of Encaustica, considerable space has been devoted to the description and illustration of the various methods that have been proposed or adopted for the purpose of adapting electric lighting to the illumination, not only for large spaces, but also for the halls, work-shops, and private dwellings. Our columns have afforded abundant statistics and reports on that question. For the present there is no doubt but that the electric light stands on its trial. It has been put into competition with gas, especially in a financial point of view. The gas companies throughout England become alarmed, and to some extent, when in the shares of these companies sustained heavy depreciation. But, as will the Gas Companies' for 1878, presented last June pursuant to Act of Parliament, they have had as little to fear as they have had to suffer.

The business of the gas companies in the "Gas Light and Coke," which supplies about two-thirds of London, embracing also the City proper. The following statistics relate to the half-year ending December 31, 1878. The varieties of capital, and the Acts under which they were created, are numerous for detail. It appears that the total paid-up capital amounts to £5,705,000 and there remains £1,160,000 to call up; giving a total amount of authorised capital of £6,865,000. In regard to the loan capital, it is allowed of £1,681,260 having £1,000,000 to be borrowed. Of this loan capital, £981,300 is paid at the rate of 4 per cent. interest, and £937,200 at 3 per cent. The total expenditure on capital account amounts to £8,424,421, leaving a balance to capital account of £305,918 or a grand total of receipts of £8,726,000.

The receipts to revenue the half-year ending 31st of December, 1878, amounted to £1,728,932. Of this £178,315 was produced by the sale of gas, £1,455,000 from sales £861,307 was derived from common gas at 3s. 6d. per 1,000 and £593,944 by the sale of cannel gas at 4s. 6d. Lighting under public Acts produced about £60,000. The sale of residual products afforded £85,000, of which coke amounted to £124,027; tar, £36,571, and ammoniacal liquor, £56,382. The remainder of the income is derived from various sources. On the side of expenditure is charged £857,070, the chief items of which are:—Coals, £135,772; repairs, £145,271; salaries and wages, £89,000; cost of purification, &c., £36,012. The cost of the distribution of gas amounted to £56,621; meter rentals, £11,000; rents and taxes, £11,100; general management, £36,212; besides minor items, leaving a balance of £370,213 to be carried to net revenue account. It is stated that the reserve fund account amounts to £137,788 and the insurance fund to £12,250.

The total amount of coals carbonised during the half-year was 657,339 tons of common and 41,000 tons of cannel. Of coke 229,236 chaldrons were made, 148,141 used, and 150,761 sold. In regard to quantity of gas there were made (in thousands of cubic feet) 5,246,556 of common, and 328,648 of cannel. The total quantity sold was 5,219,117 of common and 317,648 of cannel. There was an unaccounted for loss of 256,751 of common and 14,208 of cannel gas. The total number of public lamps was 50,000.

The usual annual dividend of 10 per cent. was paid on the ordinary share stock.

The remainder of the London Gas Companies may be briefly dealt with, as they have not as a rule a small consumers trade to extend and developed, and it is more than probable that amalgamation will speedily reduce their number to unity.

The accounts for the half-year ending December 31, 1878, of the South Metropolitan Company were as follows:—Total paid-up capital, £500,000; loan authorised, £700,000; total of loan capital established but not borrowed, £500,000; total expenditure on capital account, £482,725. The receipts from sale of gas, &c., was £78,995; of residual products, £20,738, and the total expenditure was £71,400, leaving a balance of £28,270 to net revenue. The total of coals carbonised was 56,120 tons; the quantity of gas manufactured is 518,113 thousands, of which 302,611 were sold and 40,000 not accounted for.

The Commercial Gas Company's accounts for the half-year ending December 31, 1878, were as follows:—Paid-up capital, £200,000; authorised, £210,000; loan, 670,000, paid out of £700,000 authorised. Total expenditure of capital, £658,107. Revenue from gas, &c., 118,081; residual products, £21,707, leaving a balance of £18,900 to net revenue account. The total of coals carbonised was 70,469 tons; of gas made, 7,000 thousands, of which 29,879 were not accounted for.

The accounts of the three following companies are made up for the year ending 31st of December, 1878.

The London shows a paid-up capital of £709,462, with £878,812 authorised; of loan £160,543 paid up, and 673,205 remaining to be borrowed. The total expenditure of capital was £842,175, revenue from gas, &c., £216,460, residual products, £61,209. The total expenditure was £206,158 leaving £71,681 to carry to net revenue account. The amount of coals carbonised was 132,122 tons, of gas made 1,312 114 thousands.

The Phœnix Company had a capital paid up of £1,137,000, authorised £1,241,000, and of paid up loan £76,000. The total expenditure on capital account was £1,122,518. The sale of gas brought in £277,856; of residual products, £77,460. The total expenditure was £356,463, and of net balance carried to revenue £107,121. Of coals 174,200 tons were carbonised, and the quantity of gas made was 1,701,038 thousands, of which 81,902 were unaccounted for.

The Surrey Consumers' Company shows the following results: Paid up capital, £230,000; authorised, £250,000; and of loan, £60,000 paid up. The total expenditure of capital was £248,932. The sale of gas produce d £94,850; of residual products £25,467; the total expenditure was £93,150, leaving £31,633 to carry to net revenue account. The amount of coal used 54,912 tons, and of gas made 544,898 thousands, of which 29,393 were unaccounted for.

The following was the revenue charged per 1000 feet at the end of last year for common gas by the

Gas Light and Coke Company	3 6
South Metropolitan	3 6
Commercial	3 6
London	3 6
Phœnix	3 6
Surrey Consumers	4 0

For the present we shall make no further remarks on the above statistics, except in observing that with the exception of water shares, there seems no more safe or profitable investment than in gas companies' shares. In our last volume reports of the half-yearly meetings of each of the above companies were given, and it will be found that in most cases, the directors have resolved to extend their operations to lending by gas for domestic purposes. This will doubtless still further add to the prosperity of the companies.—*Engineering.*

We regret to notice the serious illness of G. B. Mansel, a leading coal operator of the Lehigh region.

The Pierce colliery, near Archbald, Pa., has resumed operations after a month's strike. The dispute was about dockage and unfair weight, which has been amicably arranged.

WATER-GAS AND THE GAS WAR.

Every one knows that a short time ago the price of illuminating-gas was unexpectedly reduced to $1.50 per M by one of the large New York companies. So unlooked-for an event as a gas company voluntarily reducing the price of gas was at once interpreted as the proof of a break in "the ring," and we need now no longer doubt that "honest fellar" was likely to have some show for their rights. The primary cause of the rupture was, no doubt, the Municipal Company, which, manufacturing a water-gas by the Tessié du Motay process, that far exceeded in illuminating power the coal-gas of the old companies, was making serious inroads upon the business of its near neighbor, the New York Company. The old and so often successful policy of the great monopoly over which the pre-Adamite Father Roosne has presided from time immemorial, and which consisted in "squelching," as he beautifully expresses it, all those "upstart schemers" who propose to reduce the cost of gas by introducing improvements in its manufacture, or in substituting electricity for gas in illumination, could not be applied in the case of the Municipal Company. There was too much capital behind that enterprise, and it distinctly declined to be "squelched," but, on the contrary, "carried the war into Africa" (the dark domain of old-fashioned 12-candle gas), and threw a new and popular (23-candle) light upon the gas question. The "squelchers" had to come to terms and, we understand, have bought out the Municipal processes at the handsome figure of $200,000 cash. This, however, would not dispose of the water-gas question. The Lowe-Strong process, a simpler, more economical and efficient system, has attained in so many districts that success which we have in these columns always predicted for it, that it is no longer possible effectually to confound the "squelching" process so long and vigorously applied to it by the monopolists. Water-gas alone can fight water-gas. So, we shall doubtless see the old companies, whose managers have long and violently abused this greatest improvement of the age in gas-making, forced to seek its aid to save their heavy investments from impending annihilation.

As the ENGINEERING AND MINING JOURNAL years ago pointed out to those gentlemen, the great question of the future—ay, and of the present—is the distribution of a cheap fuel-gas, and those who are wise will shape their course toward accomplishing this. The electric light, though still in the experimental stage, and not yet adapted to domestic purposes, will doubtless become the light of the near future. Enough has, we believe, already been done to justify this prediction; but, aside from this source of anxiety and danger to the gas interests, the fuel-gas question will be a far more important industry than has ever been that of manufacturing illuminating-gas, while the benefits which will result from it can not be overestimated.

The general use of cheap fuel-gas will indeed create a very revolution in the industries of the world and will produce results of the extent and importance of which here as yet scarcely been conceived in the most sanguine of the most sanguine advocates.

When water-gas practically pure hydrogen and carbonic oxide) can be manufactured at a cost of about ten cents per thousand feet, as can be done by the very simple and efficient Strong process, it would seem as though no further improvement in that direction were needed to secure its general adoption as soon as its economical distribution is secured. That the gas companies should so long have not only neglected, but actually discouraged and opposed, the use of fuel-gas, seems incomprehensible to the unprejudiced, and indeed, without a knowledge of the vested interests which revolve in the gas-ring, it could be accounted for in no more rational way than that "whom the gods wish to destroy they first make mad."

NORTH BRITISH ASSOCIATION OF GAS MANAGERS.

Meeting held in Edinburgh on Aug. 1, 1878.

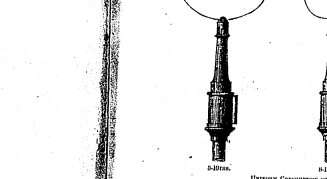
Mr. D. Bruce Peebles (Edinburgh), after reading the address of the chair, which was most satisfactory and was unanimously approved of, made the following remarks on

THE SIEMENS CONVERTER, ETC.

I beg to be allowed to state that I intended to read a short paper to-day but having been from home for some time past, the date of the meeting having gone from my memory, and I was too late in sending the title of the paper to the Secretary, he having sent out the notices of the meeting before my head for the day. I am sorry for not having a paper, therefore, I would simply ask you to allow me to make a few experiments, which, I think, will interest you, although I should have preferred having spoken with less gaseous, or steam, on the odor of the proceedings in any way, without your permission.

I may explain that I had the honour, some time ago, of reading a paper before the Royal Scottish Society of Arts here, the subject being "The Needle Converter, and its application to Gas Illumination." Several members of that Society, who were also members of this Association, desired me to take this opportunity of bringing the subject before you to-day, as being interesting and instructive in connection with the development of the illuminating power of coal gas; and seeing that our esteemed member, Mr. Yorke, has chosen a subject to which that point will play a very important part, I should be glad if he had an opportunity of seeing those experiments, as they have in reale his pair, and if you are there and in next there, he may give us, say not, in a certain degree, locally some of the ideas regarding the enrichment of gas, which he will bring before us in connection with the illuminating power, and you may be better able to discuss what I am sure will be a most interesting paper.

The first thing I wish to show you is a simple arrangement by which two rat-tail burners may be made to come together, so that the flames may combine and form a centre jet, which arrangement may be useful to any of you who may be giving lectures, &c., and may wish to show how two long flames may be made to change their shape and combine to form a compact



Uniform Consumption of Five Cubic Feet per Hour, at Varying Pressures.

We have here four needle governors, with different sized burners and to which the pressures at the point of ignition given in Mr. Mitchell's table. The first is adjusted to the 5-inch pressure, the second at 8-inches, the third at 13-inches, the fourth at 17-inches, and each of them passes exactly 5 cubic feet per hour. Now, gentlemen, you will see by the table that the light increases as the pressure is increased, and you will also see that when I saw this for the first time, I would not believe that the fourth burner was really passing 5 feet per hour, and it was only after I again and again tested each burner, and the rate per hour, that I was convinced.

The results are so startling that I think if the public could only see the experiment as we see it here to-day, that the Gas Companies would gain and save many complaints about bad gas. With the present burners the results are quite as convincing as these, but they are open to doubt by those who do not understand the method of testing the illuminating power. With the four lights burning simultaneously, the first giving a 5-inch pressure, the second the same, the second third descending by two-inches, the fourth has a thin white and feeble flame, all doubt as to the deleterious effects of low pressure is removed. Now, gentlemen, we are hardly justified in these gas companies should so long have not only neglected, but actually discouraged and opposed, the use of fuel-gas, seems incomprehensible to the unprejudiced, and indeed, without a knowledge of the vested interests which revolve in the gas-ring, it could be accounted for in no more rational way than that "whom the gods wish to destroy they first make mad."

clearly flame having a much greater illuminating power. The apparatus usually made by fixing down two union jet burners in the direction of the length of the box of the small boiler is left; then forming "each fixed into a tube, and making them work on a pivot, so that the Bunsen can be expanded or screwed up at will, and can be used certainly. Wires brought together or separated, have the same effect produced, with a great increase of light from the same quantity of gas.

The next experiment is the bringing together of two small union jet flames, and we see that the moment they are brought in contact there is a great increase in the illuminating power. I am inclined to think that the cause of this increase in the illuminating power is that when the flames are separate there is a certain amount of cooling effect produced by the air. When brought together there are only two sides that expose. Less egress, therefore, is applied to the hydrogen, and more carbon is liberated, which, being raised to whiteness by the increased temperature, gives a corresponding increase in the illuminating power.

The next thing I have to bring more particularly before you, and to show you by experiment, is the different rate at which the pressure at the burner is increased. Dr. Wilson, of Leeds, has made a number of experiments, and Mr. Mitchell of the Barnsley Gas Works, has made experiments in connection with this, and tabulated the results, which prove conclusively that gas should be burned at a low pressure. This paper read by Mr. Mitchell last year at St. Andrews may be found in the minds of many of you here, and the experiments in the table because he adopted a certain stated delivery of gas per hour at the burner in all his experiments. Here is Mr. Mitchell's table giving the results of burning 5 cubic feet of gas at different pressures:—

5 cub. ft. of gas are at 0·5 pressure	28·25	candles illuminating power.	
"	" 1·0 "	29·07	"
"	" 1·5 "	27·27	"
"	" 2·0 "	11·25	"

The only difficulty in making the experiments here in getting a burner of the exact size to burn the exact quantity at the given pressure, and then to be sure that there is no leakage. This difficulty is by a number of fixed different sized burners from one gallery, and succeeded in getting the exact quantity at a given pressure, and by the aid of the needle governor I had no difficulty in maintaining that pressure.

I would have the greatest tendency to deposit carbon, simply because that flame is nearest the smoking point. With ordinary English coal gas the difference between the flames would be more apparent than it is here, because with cannel gas of 28-candle power we can afford to use a lighter pressure without losing light. When we come to gas of 14 or 15 candle power, the loss of light by the increase of a few inches pressure is much more apparent, and consequently the difference in the flames is more marked.

Mr. Mitchell: I understood that the slab was to be held over the flame at the same level in each case.

Mr. Peebles: The only effect of bringing the slab down would be to cool the flame, and the carbon burning at the low pressure would be more readily cooled than that at the high pressure, which is partly burned as it goes.

Mr. J. McGlashan (Penicuik): Where does the carbon go to? If it is collected on the slab from a burner at low pressure, and escapes in the other, it is not burned, and it is not collected. Where does it go to?

Mr. Peebles: Dr. Menzies's explanation answers your question. In the one case the hydrogen and carbon do not separate, but are burned as a gas, there being a full supply of air; in the other case, the hydrogen is burned by itself, the carbon being heated to whiteness by the burning of the hydrogen and escapes as a solid particle.

Mr. Macfarlane: Is there a new gas formed in that flame.

Mr. Peebles: Certainly not.

Mr. Macfarlane: Am I to understand that oxygen and air combined with carbon form a new gas?

British Association of Gas Managers.

Annual Meeting at Newcastle-upon-Tyne.

Mr. W. Sugg (London) read a paper on

Lighting by Gas and Electricity.

In the early part of last year it was proposed to light the Avenue de l'Opéra in Paris by means of electricity instead of gas. Already the Jablochkoff electric candle had been shown to a few scientific men, and a new incandescent light—Werdermann's—was apparently producing an electric light which, in simplicity, rivalled—if not surpassed—the well-known Serrin electric lamp, to which scientific men had long pointed as the point of departure in electric lighting, and as such it was hailed by many men.

It was not at first seen that electricity would enter into competition with gas as a means of street lighting, but as soon as the company was formed for the new exhibition of the new electric light were given at the works of the company in the Avenue de Villiers, and comparisons were instituted between the new light and gas light. The comparisons, as I then saw, were most unfairly made, the gas being placed at about 15 feet from the floor of the room in which the trials of the lights were conducted, while the electric light was only 7 feet from the ground. Four of the new lights were placed on 6-foot standards, and two large chandeliers, each having a number of common iron burners of the most gas-destroying type, were hung from the ceiling; the lights being, as I have said, about 15 feet from the ground. Supposing the two chandeliers were hung from the ceiling so that the lights were at the same level as the electric lights, I think the amount of light given by them would have been equal to that given by the electric light. But it is clear that in the comparison made, at the distances I have mentioned, the gas was most heavily handicapped. I do not mean to infer that the electric light company designedly selected the worst burners to try against the electric light; on the contrary, I have reason to believe to the contrary, as such as might be bought anywhere in Paris, and, in fact, were still as were generally used in cafés and other large public rooms. As gas is but of an ordinary type, it was fair to take them as samples. The only other part of the comparison was the manner in which the gas was placed in the competition with electric light. I more particularly mention this circumstance, because I have found since, in almost every case in which experiments have been made by electricians against gas, there have been equally unfair means taken to depreciate gas and show an untrue effect with electric light.

Similar experiments made in this manner are bitterly unworthy of scientific men, and the effect of such one-sided work is to debase science in the eyes of the general public. Gas and electricity must stand or fall by their merits, and it is of no more use to endeavour to bolster up a defective system of lighting by false statements and one-sided experiments than to stand idly by and let the public be misinformed without an attempt to put them in possession of the true facts of the case.

One thing is certain, and that is that, after the preliminary trials I have referred to, both scientific men and the public, overlooking all its defects, were said to be of a temporary character, were entirely carried away with their enthusiasm for the new light. It was resolved by the Municipality of Paris to place leaving lamps with the new light during the Exhibition, and a fixed price having been agreed upon between the parties, this magnificent new street was at the opening of the Exhibition supplied with 62 of the Jablochkoff candles.

Notwithstanding the lamentable mistakes of the electric light, it found favour with the public, because it was immensely superior to the ordinary yellow gas lights. It evidently fulfilled a latent desire on the part of the Parisian public for more light in their most frequented thoroughfares. The oxygen light of Tessie du Motay, which had been without a short trial, had left them unsatisfied, and till the advent of the electric light a considerable time had elapsed without any imitative having been taken by the Paris Gas Company to show an improved system of gas lighting.

Therefore it was, I think, that the electric light, thus answering to the great desire on the part of the public, met with a more enthusiastic reception than it otherwise would; more even than it merited, for the light was not of a few minutes. Indeed, it cannot be said that even for a single hour it was constant. A large gas light working on a very bad meter or electric light than anything else. The illuminating power of these lights was stated to be equal to that obtainable from 700 or 800 candles. I know that this was a gross exaggeration, but it illustrates how much

scientific men were carried beyond the power of reason by their enthusiasm for the new light. As a mode of street lighting it failed in a most important requirement: It was not continuous between the hours of sunset and sunrise. At midnight it was extinguished, and the regular gas lamplighters were called into requisition to carry on the lighting till sunrise. The double system of gas lighting and electricity had to be maintained.

Some among us had the pleasure of visiting Paris after the meeting of this Association last year, in company with three American gentlemen—Messrs. Greenough, and Pownall have left behind them as set agreeable memories as we have. We now feel that in all our meetings they will be present with us in thought, and in our work and discussion we address ourselves to them as well as to those who are present. In company with these gentlemen, and others, including your late president, Mr. C. Woodall, who has devoted considerable amount of time and trouble to the investigation of the most of electric and gas lighting in use, we made a careful examination of all the systems of electric lighting in use in Paris at the time of our visit. We stated to be given by the electric lights did not appear to be proportionate to volume of light fell far short of our ideas of what it ought to be, if the statements made by the electricians were correct. We soon came to the conclusion that they were not correct, and subsequent experiments, by M. Tolmer, the Chief Gas Examiner of Paris, have confirmed us in our idea of the small illuminating power given by the electric light. We thought that the amount of light could not exceed at any time more than 150 candles. The public were therefore misled by the statement made at the first presentation of the electric light.

I regret to have to say that even at the present time electricians do not seem to have made up their minds to state with anything approaching to accuracy what is the real illuminating power of their lights. It is next to impossible to obtain any reliable information as to the cost or illuminating power of any of these systems. I will mention an example of the nervousness of electricians as to this question of illuminating power. At the recent exhibition of electric lighting apparatus at the Albert Hall, there were two electric light photometers exhibited—one by Mr. Keates and the other by myself. Although the authorities invited the electricians to bring their lamps to be tested, so far from illuminating power, and Mr. Keates' assistant kindly attended to try them, yet it was found impossible to get the electricians to be ready simultaneously with the exhibitors of the engines which worked the electric machines. When the engineers were there, the electricians were not, and vice versa; so the trials had to be given up. I have, therefore, in the interests of this paper, compared the sometimes slightly conflicting evidence of those who have made trials of the electric lights in various places, in order to give you the best idea of the relative positions of the two lights as they stand to each other at present, and I then propose to make some remarks upon the future of the gas and electric light.

First I will take the Avenue de l'Opéra. There are in all 62 electric lamps in the Avenue. The machines setting in motion by gas engines strictly producing the light were what are called the "Double Gramme." The length of the Avenue is nearly 1,000 yards; the width of the road from house to house is 90 feet; the width of the carriage-way is 30 feet. The Place de l'Opéra, at its intersection with the Boulevards, is 200 feet by 150 feet, and 450 feet long.

This Place is lighted by 22 Jablochkoff lamps, and the machines producing the electric current creating the lights is worked by a 25-horse nominal engine fixed in the basement of the Opera House. The next section of 16 lamps is worked from a Double Gramme machine, driven by an engine of 20-horse power fixed in the Rue Caulles. The next section, also of 16 lamps, is worked from a Gramme machine and a 20-horse power engine fixed in the Rue d'Argenteuil. The last section consists of the lamps in the Place du Theatre Francais. They are 14 in number, and the engine and the machine for them are fixed in the basement of one of the houses of the Avenue. Each of the lamps is provided with four candles, only one of which is burning at a time. The whole four are inclosed in an alburine or white glass globe, about 18 inches in diameter. One of these candles burns a little over an hour. At the end of that time the current must be switched off from the one which has been burnt down to the fresh one next it. So it is necessary that an attendant shall go to every lamp once in an hour, and turn on the current to the new candle. The lamps are lighted at about an hour after sundown, and are all extinguished at midnight. They are not already lighted up, must then be put into requisition to carry on the lighting till sunrise.

According to the official report, from the 30th of May to the 10th of October, 1878, a little over four months, there were no less than 60 extinctions, lasting from 1, 2, 3, 5, or 10 minutes up to 15, 30, or 45 minutes. The Company, it is said, hopes to do better. There are no fines to pay if they do not

...gas at present consumed, it would be possible to give more light ...ation of improved burners, and more effective illumination by abol... among the shadows. He was quite sure, however, that there would eventu... ally be an increase in the consumption of gas in the public streets. Of course, it would not come all at once; no public improvement ever did. First the crossings would be improved, and then other places would by degrees receive attention.

[The other papers read will follow in due course.]

Gas Companies and Consumers.

For several weeks a discussion, has been going on in the *English Mechanic* on the question as to whether economy affects the consumers' accounts. Writing on the subject, Mr. J. B. Warren says:

From the tone of "Lofluman's" last letter I am led to infer that he objects to reduce his pressure by the main tap, on the assumption that the pressure being reduced before the gas enters the meter, the gas expands and is increased in volume by the reduction of the pressure, so causing the meter to register in favor of the company. I do not say that this is not the case, but I will endeavor to show him the increase in volume is so very small that his gas bills cannot be effected thereby.

It is a well-known fact that the volume of gas is inversely proportional to the pressure to which it is subjected. If we increase the pressure the volume is diminished, and by diminishing the pressure the volume is increased. If we take a volume of gas measuring, say, 100 cubic feet—the pressure being equal to a column of mercury 30 inches high—then, according to the above law, if the pressure is reduced to 29 inches, the volume will be increased to 103·4 cubic feet. I need scarcely inform "Lofluman" that to distribute gas it must be subjected to a pressure greater than that of the external atmosphere, or it would not flow through the pipes and escape through the burners for combustion. This pressure to which the gas is subjected is measured by the height it will support in a column of water, expressed in 1-10ths of an inch. And in correcting the volume of gas for pressure, this pressure should be reduced to its equivalent height in mercury and added to the pressure given by the height of the barometer. Mercury is 13·6 times heavier than water; therefore, a column of water 1-10th of an inch high is equal to a column of mercury 0·00741 inch in height. We will now assume "Lofluman" to have his main tap turned full on, and that the pressure at the inlet of his meter is 15·10ths, the pressure to be regulated anywhere he thinks proper beyond the outlet of his meter, to 1·30ths, and that his meter has indicated a volume of gas equal to, say, 1,000 cubic feet. We will now suppose he takes the advice given by the gas man, and reduces the pressure at the inlet of his meter, by means of the main tap, to 2·80ths, all the burner taps in use to be full open. His gas is now passing through the meter at a pressure equal to 10·30ths less than it was in the first instance, which will cause the gas to expand, and to have increased in volume to *x* cubic feet, which, of course, his meter will indicate. We can easily find the value of *x* by the law given above—taking the barometer as standing at 30 inches—as follows:

$$\frac{(30+5\cdot10\text{ths})\times30\cdot10\text{ths}}{(30+15\cdot10\text{ths})} = \frac{32\cdot11115}{30\cdot11115} \text{ or } \frac{1\cdot0667}{1\cdot000}$$

$$\therefore x = \frac{1\cdot0667 \times 1,000}{30\cdot0665} = 1,002\cdot46$$

"Lofluman" will thus see that by taking the advice of the gas-men his meter will have registered 1,002·46 cubic feet, which is ·2646 per cent. in favor of the gas company; but I think he will agree with me that this is not worth a single sou very much on the stretch after all, and that his economy will not suffer to so great an extent as he imagines by taking their advice, especially when we take into consideration that the "Sales of Gas Act" allows a meter to be stamped as correct with a range of 5 per cent. in its registration, namely, 3 per cent. slow and 2 per cent. fast. We also see from the above that, practically, it does not signify whether the pressure is reduced before the gas enters the meter or after it has left it. It is best to use a governor for the purpose of regulation, because the governor, being self-acting, requires no attention. Where a governor is not used I should advise the regulation to be made by the main tap; I see no objection. I always advised the regulation to be made by the main tap; it answers to perfection, and saves the expense of having an extra tap fixed elsewhere.

I think I have now said enough to convince "Lofluman" that he is in error in charging the gas-men with fraudulent intentions, the increase in the registration of the meter being too small to justify him in bringing such a pretension I made, that consumers would gain largely by taking their advice. I have adopted the same premises I used in my previous reply, because I consider 15·10ths to be a more than sufficient maximum pressure to be given by any gas company at their consumers' meters, and for the minimum of 5·10ths, because it is the standard pressure used under the "Sales of Gas Act" for testing meters, and, further, it is the least pressure that can be used with economy for illuminating purposes where common burners are used.—*Journal of Artificial Light and Sanitary Gazette.*

Coal Gas versus Water Gas.

The recent gas controversy has brought to mind many important matters connected with its consumption and relative cheapness, as compared with other illuminating substances, as well as its safety under its several forms of manufacture.

—With a view of determining the position that the gas companies occupy with regard to the general public, we propose to show, in brief, the value of the claims set forth by the water gas companies with respect to the wonderful illuminating power obtained for the substance distilled from hard coal and petroleum or the products of the latter.

In a circular recently issued by one of the companies organized under patent having in view the manufacture of gas by such means, it is boldly set forth that their gas has very much greater illuminating or candle power than gas manufactured by the ordinary process from bituminous coal, and that by their method a saving was effected to the consumer of from 25 to 50 per cent.

This is truly a wonderful discovery. It calls to mind the anecdote of the miserly farmer who, after repeated experiments, thought he had hit upon a plan for keeping his stock in good condition at a very small cost. He tried the experiment first upon a favorite white horse. This animal was fed upon nothing but bean straw for several days without any apparent loss of strength. The farmer was in high glee over the experiment, and invited his neighbors to come and view the result. The barnyard was sought and by the assemblage, when lo, and behold! old White was found in a horizontal position, stiff and dead.

"How is this?" asked the farmer of Dick, the hired man, as he turned his eyes up with unmixed sorrow at his loss.

"Don't know," said Dick, "but I gave him all the bean straw he would eat."

"Aye, I see," said the farmer, with a sigh and a moan, "you must be more careful next time, you fed him altogether too bountifully!"

It only requires one more discovery—patented, of course—on the part of the water gas companies to save the lucky consumer the remaining 50 per cent., and his gas bill would be wiped out altogether.

But what are the facts? Take, for instance, the Manhattan gas at a nominal standard of 100, flowing through a four foot burner, and the Municipal at a standard of 75, passing through the same-sized burner, the average candle power is 16 for the former, and 22 is claimed for the latter, but allowing for the difference in gravity and actual illuminating realties and the Municipal gas is actually only about an average of 12 candle power. The two being in every case equal, the result must prove substantially correct.

The apparent difference that the water gas company's claim arises from the different-sized burner, less volume of consumption, greater impurities, the shape of negative illuminant properties, and a marked difference in specific gravity as compared with coal gas. For instance, coal gas contains six per cent. of illuminants will furnish 16 candle power, while water gas with 18 per cent. of illuminants, will give only 22 candles, showing that it requires 200 per cent. increase of illuminants for 87 per cent. increase of light.

All the rest of what almost proves beneficial is acquired by the large proportion of carbonic oxide and other impurities, which enters into the elements of its production. These non-illuminants are absorbents as is related by a pale blue flame.

An actual loss of about 20 per cent. takes place in bringing water gas to a good standard of excellence. Gas made from bituminous coal contains about five per cent. of carbonic oxide, while water gas contains, by analysis, from 20 to 30 per cent.

If this statement is true, as is vouched for by eminent chemists, the question of illuminating power is not the only one to be considered. It is repeatedly been ascertained that about five-tenths per cent. of this poison will kill birds and small animals, while its presence in slightly increased quantities is likely to prove very injurious to human health, and even destructive to life.

This is especially very likely to happen with persons of weak habit, as those fields to affections of the heart, or laboring under pulmonary difficulties and affections of the throat and air passages.

Water gas is no new thing; patents for its manufacture date back to 1830, and it has at various times been introduced both in Europe and America, but generally with doubtful success. Selligue obtained permission, in 1840, to use the gas in the towns of Dijon, Strasburg, Antwerp, and also in Paris and Lyons.

At Strasburg an accident occurred which put a stop to its use. The gas

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, JULY 25, 1882.

Circular to Gas Companies.

The Metropolitan Board of Works have, in compliance with the application of the French Société Générale d'Electricité, agreed to make a more extended trial of the electric light. It is proposed to have twenty more lights, some in Northumberland Avenue, if the consent of the Vestry of St. Martin's-in-the-Fields can be obtained, and some on the Waterloo Bridge. The charge for the lamps, after the expiration of the present contract, is to be only threepence per hour per light. The French Society wished to have the experiment continued for twelve months; but the Board determined, at their meeting on Friday last, that a six months experiment would be sufficient for their purpose. The fall to threepence per hour per light is a considerable drop; but it will scarcely induce the Metropolitan Board to continue the experiment unless better results follow than have hitherto been obtained. We are not told for how many hours in the evening the light is to be used, nor how far it will require to be supplemented with gas. Hitherto, wherever the light has been applied, it has been extinguished early; and, for the illumination of the really dark hours, gas has always been employed. It says but little for the new light, that it cannot be made continuous; but if it could be, the expense, even at threepence per hour per light, would militate against its general employment.

Sanguine expectations are, however, now entertained that the electric light is the public light of the future. It seems that the twenty new lights which are to be installed by the Metropolitan Board will be actuated by the same 20-horse power engine as was employed for the original twenty lights, but with an enlarged Gramme machine. With this addition or substitution, very long circuits, it is alleged, may be maintained. Some, indeed, have an opinion that all the principal streets and open spaces in London may be illuminated by a common centre of force at Charing Cross. Others prudently recommend that several centres should be established. It is perhaps premature to express any opinion as to the complete success of this large extension of electric lighting until we have the results of the experiments about to be made by the Metropolitan Board. We have said all along that much, if not all, would depend on the relative cost of electricity and gas. An opinion seems to be gaining ground that, light for light, electricity may in a short time be able to hold its own against gas; but the fact has yet to be proved. We have at present no four of witnessing gas supercedid in London streets. It will not be until we have seen the electric light maintained in operation during all the hours requiring artificial lighting, that we shall have any apprehension of gas being supplanted in our thoroughfares. Supposing, however, such a result to happen, Gas Companies, as we have said before, have nothing to dread, and public lighting, we all know, brings an infinity of trouble and very little profit. Perhaps if all the streets of London were lighted by electricity, the Gas Companies would not regret the change. Their strongholds lie where electricity is not likely to penetrate for a very long time; and if they be only true to their own interests, the consumption of gas will go on increasing as fast as it has done during the last few years.

From New York we learn that Mr. Edison has, after all, but yet perfected his invention, or rather brought it into a condition for general use. He still finds platinum too dear for his purpose, and is now hunting all over the continent of America for new supplies of the metal. California will, of course, receive a large share of his attention, and by-and-by, some years hence, we may hear that the metal has been found in sufficient quantities to make its use in electric lighting remunerative.

The Liverpool Lighting Bill has passed a second reading in the House of Lords, and stood for Committee yesterday. Rather late in the day, the Gas and Water Companies Association issued a form of petition which Companies were recommended to sign and transmit forthwith for presentation. The Bill, as it left the Commons, gives the Corporation of Liverpool power to supply the new light to places of public resort, such as theatres, music-halls, &c., and to private establishments, such as railway stations, &c.; and it is against the granting of such powers that the Gas and Water Companies Association very properly protest. They further set forth in the petition that the Bill, as it now stands, will only confer power to make experiments with money which must, in the long run, come out of the pockets of the ratepayers. The Corporation of Liverpool have large private funds, but they do not propose to expend any of them in experimenting with the electric light. It is the ratepayer who is to pay for all, and he is forbidden to profit by it, while he will be required to make good any loss the Corporation may sustain in the course of their investigations and in their pretended endeavour to provide a better illuminant. The Bill is so far inimical to the interests of the Liverpool United Gas Company, that strenuous opposition will be made to prevent its further progress. More than this, if it be passed it will constitute a precedent of a most dangerous character. It will be the first time that a Corporation have been granted power to make experiments at the expense of the ratepayers, for the purpose of bringing to a successful issue a purely commercial undertaking. We regret that this petition was not circulated at an earlier date, and very extensively signed. Gas Companies have a special interest in endeavouring to restrain power being granted to Local Authorities to encroach on their rights and privileges.

[Since the above was in type, we have learnt that the Lords Committee passed the preamble of the Bill.]

It would appear that no alterations in the *locale* of the Metropolitan gas-testing stations, which would remove them beyond the distance from the works now prescribed by Act of Parliament, can be made without the authority of another Act; and therefore the Board of Trade have recommended that the Corporation of the City of London should confer with the Metropolitan Board of Works, and promote a Bill to which the Central Authority have promised to give their support. It is, of course, the thousand yards distance, prescribed by previous Acts, which stands in the way of any change of situation. We do not know how far the Gas Companies concerned will be inclined to give up the limit, which was established after long and careful investigation. It seems

[illegible] position they were in at [illegible] The 10th [illegible] seen, and they [illegible] the same [illegible] relating to the [illegible] into the Bill as the Metropolitan [illegible] the principal [illegible] against the Staffordshire Gas

tions to share, in the prosperity of the gas undertaking, because, when that prosperity enables us to make a reduction, we make a proportionate reduction to Northfield and Yardley; and we have, since the undertaking passed into our hands, reduced the price of gas in those two districts. We finished here a little to deal contrarily and liberally with a public authority, and made the price for the public lamps in Northfield the same as we charge in the city of Birmingham.

Two who attend the meetings in Birmingham and those outlying districts to be added together, and the Corporation will have a majority. I never some sort which effected periodically the consideration of the Bill. Cases which has been brought to the notice of the Committee in that of the Great Western Railway, and there the Committee sat from day to day after the sittings within the district of supply of the Birmingham Corporation Gas Company, and the same course pursued, and the same reward obtained, as I have taken pains to negotiate every small case required for these local sittings. That was a great saving of time, and the Committee, I am sure, appreciated the trouble to which we were thereby relieved in the loss of our professional.

Another important case, where a tradesman living in Birmingham was interested, was on his consumption in Acock's Green, to come up to the amount of consumption which would entitle him to the allowance, and we have included the whole of Acock's Green in the district. In that case he was charged at rates according to the local consumption, and he was charged at a differential rate with regard to it supply in Acock's Green.

Examination continued: With respect to the Hilton Company, my reasoning a very considerable quantity of coke in their disposal; and when the negotiations commenced, the Corporation were very much troubled with the question, what their object was in obtain a sale to their Company. In the course of the negotiations it was suggested that they would take their gas specially from us, and that they would be in a position to be able to use the coke during the daytime, when they were not employed for any considerable consumption, to convey the gas to Hilton, and they would have a stock of gas for use at night, and in the evening, and it would be no increase of expense to us to supply them in this way. We have supplied them in this way, and we have made a profit upon it. With holder, at the time we made the agreement, and we said, under all the circumstances, if they would take gas[illegible] we would supply them at the lowest rate in bulk. It was a specially from us, we would supply them at a differential rate.

Mr. Macnay: In your opinion, are there any circumstances which would make the sale of gas in Northfield and Yardley, supposing a separate district were constituted for the purpose, objectionable for the supply from the Birmingham district at ballast?

Witness: Yes. The Corporation come to Birmingham, and could get their gas at a[illegible] there were very careful calculations showing that the maximum cost in those districts would be 2s. 6d. per 1,000 feet; and at the differential rate charged to Northfield and Yardley, and filled them with the greatest possible profit to the Corporation, and the greatest benefit to themselves on behalf of the inhabitants, that we had no power to charge the differential rate in those districts, because they were not such districts as we could, and they were obliged to charge the rate to that within the borough. Respecting the necessity, which there is for the rate to that within the borough, the necessity which there is for the rate to that within the borough, is supplied at a higher rate than that charged to Northfield and Yardley from the works, I have caused inquiries to be made, and I believe that before the Corporation of Birmingham came to the city, and in fact, they were charging at as low as two miles from the works, while the higher rate is charged at a distance of three miles from the works. That is the reason for that.

Mr. O'Hara objected to the evidence, as each of those cases was under an Act of Parliament which specially dealt.

Mr. Macnay said he would not press the point. (To witness:) There is the maximum prices charged over the Corporation Act make any difference in the[illegible] Yes, it did; it reduced the maximum price.

Mr. Macnay: Then it reduced the maximum price to 2s. 6d. It was 3s. 6d. and 4s. 6d., and lower in and 5s.; but the actual price was 2s. 6d. when the Act was passed?—Yes.

Cross-examined by Mr. O'Hara: My impression is that the maximum price with the Corporation was 3s., and with the Staffordshire Company 4s. 6d., and with the Staffordshire.

Mr. O'Hara: You have said you think it fair to charge a different rate for all persons residing distant. Did you not think it fair that representation to the Committee in 1875?—Certainly not.

Mr. O'Hara: Did not the Committee inquire that what you charged locally by the Corporation you should charge outside?—No; it was put in what the Corporation charged, and it was offered by me personally and by the[illegible] according to premises.

Mr. O'Hara: Is it not the fact that you were only asked to supply Northfield and Yardley are no better off than all the other districts?—I[illegible] I have no means, no matter what it was.

By the Chairman: The capital invested in the gas-works does not belong to us, and we do not pay interest upon it. We have borrowed 42,000,000, and have made somewhere about 2½ per cent against that sum, and a little more. In how many years will you be obliged to put something by towards the[illegible]?—Is there not a sinking fund?

Mr. Macnay: We are bound to repay the whole of the capital in a certain time.

You said you looked for an increase of profits, and you hope you will gain more and more every year?—I said I expected, and you hope you will gain more. The Bill was under consideration by the Committee of the two Houses of Parliament for eight days.

—Did you not think it a very good bargain?

—I did not think it a bad bargain.

Mr. Macnay: Mr. Sheridan: If we were obliged to give up any portion of our[illegible] to a[illegible] municipality, it would be a[illegible] sell it this week as[illegible] a parliamentary title which would be[illegible] Corporation was in full possession of all the facts.

Mr. Macnay: I had some extracts from the evidence given in 1875, and which I thought it was evident that the whole matter was before Witness said that was so.

Mr. Macnay: And the Committee themselves pointed out the[illegible] Mr. Sheridan: And you said that the[illegible] Witness: Yes; and taking it away at the time would involve a loss of £25,000 to the Corporation of Birmingham, either as representing the ratepayers, or as representing the consumers.

If taken away, might it not be[illegible] to have been taken away when they would have let you claim a corresponding sum[illegible] from the Gas Company?—Yes.

Mr. H. Hack, examined by Mr. Michael.

I am one of the Gas Engineers of the Corporation of Birmingham, and was formerly Engineer to the late Birmingham and Staffordshire Gas Company, and I was one of the Engineers who prepared the Bill which was passed in the third Session of the Birmingham Corporation Gas Act, 1875, under which the Corporation purchased the undertaking of the Company. The Bill was opposed by the Corporation of Birmingham, and I was one of the witnesses called in support of it. The Birmingham and Staffordshire Company had a trunk main for the supply of Yardley and Northfield. Enough being conveyed in order to supply those districts. The purpose of the Company to expand that money. But for that in. I should have recommended the Company to go to King's Norton, which is a populous district, and so is Northfield and Yardley, except in certain small districts, which are not suitable for the supply of gas. The total length of mains laid to the end of that year was 630 miles, and the total length of mains laid to the end of the year was 1,000 miles. The number of lamps in Yardley in 1876 was 16,563,500 cubic feet, and the number of lamps was only 673. The consumption per mile of main there was 26,000 feet. I have made an estimate of the cost of the mains, meters, and services, and I estimate the cost at £1,000 per mile. I estimate the cost of the mains at £1,000 per mile. I estimate the distance from the gas-work to the nearest boundary of Northfield at 2½ miles. The consumption there is 26,000 cubic feet, and the number of consumers 250, giving a consumption per mile of mains of more than 1 million cubic feet. On the basis of the consumption there at Northfield £500 has been expended, equal to £937 per million feet a year. Supposing there is a population of 1,250 in a fair area to allow for distributing pipes, in my opinion, the circumstances of the case warrant in additional pipes, and the cost of the mains in Yardley, and I consider it to be a very fair area. I have made out a scale for the supply of these two districts is 16 inches diameter, and it is calculated to meet the increase in consumption for very many years.

Cross-examined by Mr. Cleveland: I have not worked out the figure with regard to Sutton Coldfield, which is a fairly-populated district. I have not, Bromwich state that, assuming the obstruction of this differential rate, I have not done so. I have not worked out the question of charge per 1,000 feet in this district, and Yardley; but it will be about that. It must be very long time before the two districts will be supplied to the extent that the consumption might be increased; but I think it could be very rapidly increased. There is no other Gas Company in those districts which have gone through that place, because it is within the limits of our supply. To[illegible] of[illegible] Yardley, and I think it is a very fair area to supply. The entire extent of the[illegible] is a mile into Sutton Coldfield, but since May, 1875, they have been extended. The[illegible] supply was given, but not to the[illegible] to the south of the[illegible]. There are 67 yards of 3-in. main at 2s. 3d. per yard, 66 1-in. 1½-in. 253 yards of 4-in. main at 2s. 6d., 267 3s.-in. main at 2s. 9d., 1,584 4-in. main at 3s., 1,767 yards of 5-in. main at 3s. 3d., 2,240 9-in. main at 3s. 6d., 1,848 yards of 9-in. main at 3s. 9d. 1,257 yards of 12-in. main, 1,848 yards of 15-in. main, 1,848 yards of 18-in. main, 1,848 yards of 21-in. main, 1,848 yards of 24-in. main, 1,848 yards of 27-in. main, 1,848 yards of 30-in. main, 1,848 yards of 33-in. main, 1,848 yards of 36-in. main, 1,848 yards of 39-in. main, 1,848 yards of 42-in. main, 1,848 yards of 45-in. main, 1,848 yards of 48-in. main, 1,848 yards of 51-in. main, 1,848 yards of 54-in. main, 1,848 yards of 57-in. main, 1,848 yards of 60-in. main, 1,848 yards of 63-in. main, 1,848 yards of 66-in. 945-in. main, 1,848 yards of 948-in. main, 1,848 yards of 951-in. main, 1,848 yards of 954-in. main, 1,848 yards of 957-in. main, 1,848 yards of 960-in. main, 1,848 yards of 963-in. main, 1,848 yards of 966-in. main, 1,848 yards of 969-in. main, 1,848 yards of 972-in. main, 1,848 yards of 975-in. main, 1,848 yards of 978-in. main, 1,848 yards of 981-in. main, 1,848 yards of 984-in. main, 1,848 yards of 987-in. main, 1,848 yards of 990-in. main, 1,848 yards of 993-in. main, 1,848 yards of 996-in. main, 1,848 yards of 999-in. main, 1,848 yards of 1,002-in. main, 1,848 yards of 1,005-in. main, 1,848 yards of 1,008-in. main, 1,848 yards of 1,011-in. main, 1,848 yards of 1,014-in. main, 1,848 yards of 1,017-in. main, 1,848 yards of 1,020-in. main, 1,848 yards of 1,023-in. main, 1,848 yards of

other means of lighting or heating authorized by the said Acts or any of them.

The CHAIRMAN: The question is whether a certain number of ratepayers have any right to appear.

Mr. HERBAGE said that his friend Mr. Michael had gone into the merits of the case, and, therefore, he must beg to be entitled to be heard in reply. He contended that, *prima facie*, the Corporation represented the ratepayers.

The CHAIRMAN: If a certain number of ratepayers meet, and pay their own dissentient, are they justified in appearing to oppose the Bill?

Mr. HERBAGE thought that it should be shown who were the ratepayers, and that a certain number only were in the gas concerns of Dublin. This petition was signed by 25 persons.

The CHAIRMAN: Is it not proposed that they are a committee to represent the whole body of consumers?

Mr. MICHAEL: Look at paragraph 18 of the petition, which states that "on their own behalf, and on that of the general body of consumers of artificial light within the city of Dublin and the neighbourhood, your petitioners submit that the grant of such extended powers, and the establishment of such new monopoly, or quasi monopoly, with regard to the supply of artificial light, would be greatly to their injury, and against the interests of the citizens of Dublin and other residents within the gas limits of the Company."

The CHAIRMAN: Can it be shown that there has been any public meeting held on the subject?

Mr. HERBAGE said he could show that meetings were held, representing the consumers of gas.

The CHAIRMAN: Can you show that the petitioners are a committee representing a large body of ratepayers?

Mr. CLIFFORD: We are prepared to show that.

Mr. HERBAGE submitted that it would be a dangerous precedent to grant the petitioners *locus standi*.

The CHAIRMAN: Supposing they could say there was a meeting held on the 1st of March?

Mr. HERBAGE: If you think it necessary to show that public meetings of citizens were called, and that certain resolutions were come to sufficient to set aside the legislative sanction, I cannot object.

The CHAIRMAN: But what about 1875?

Mr. HERBAGE: In that year there was a large representative public meeting on the subject, and the resolution, it was stated, was adopted at a meeting of gas consumers.

The CHAIRMAN: Do you mean to say that a number of ratepayers are dissatisfied with the agreements between the Corporation and the Company. The question is, can you show that you represent a large number of ratepayers were dissatisfied and had a right to object?

Mr. MICHAEL: A committee was appointed to watch over the interests of the ratepayers. I can file further evidence to show the constitution of the Committee.

Mr. HERBAGE submitted that it was not a case for evidence. The Committee were in possession of all the facts.

The CHAIRMAN: Sir Arthur Guinness is not a petitioner.

Mr. MICHAEL: I thought it better that an independent witness should be called to speak as to the status of the petitioners' Committee.

After some further discussion, the room was cleared, and the Committee retired for a few minutes. Upon the re-admission of the public,

The CHAIRMAN said: The Committee have decided that the petitioners have an *locus standi*.

[The Bill, as unopposed, afterwards came before Earl Redesdale, and the preamble having been proved, it was reported to the House.]

95

Journ. of Gas Lighting, Vol. 3, 1878, p. 27.

GAS APPARATUS AT THE ROYAL AGRICULTURAL SOCIETY'S INTERNATIONAL EXHIBITION.

SECOND NOTICE.

Next to the gas-engines, in point of interest to those who advocate the extended use of gas, come the steam-boilers which are designed to use gas as fuel. There were several of these shown by different exhibitors, yet this branch of gas development was not so well represented as it might have been. Although the nature of things forbids the attainment of such a high duty from a given quantity of gas by this method as from an equal quantity consumed by a direct gas-engine, still there are simple but powerful reasons in favour of the latter being generally more easily gas-heated boiler. Chief among these is the fact that, compared with steam-engines, gas-motors are as things of yesterday, and a knowledge of their construction has not yet reached the great majority of engine-fitters and handy men throughout the country, most of whom are able to do small repairs to any ordinary steam-engine, and there is no doubt that the fear of having to send a machine in the maker in the case of a break-down, deters many otherwise willing purchasers in small or inaccessible towns. Here it is that a gas-heated boiler, which without sacrificing the simplicity of the steam-engine possesses the advantages of not requiring stoking, with regular steaming, cleanliness, and absence of smoke, would frequently find favour, despite its increased cost, which, after all, would still be covered by the saving in labour. It may, however, be said that many progress has not been made in this line. There is still too great adherence to the general idea of the forms associated with the use of solid fuel. It will be a considerable time before boiler-makers will be able to divest their minds of the memories of large fires and a heating agency of great bulk, and confine their designs strictly to the problem of making the most of a flame of comparatively small size, intensely hot, but deficient in radiating power, such as that of the Bunsen burner and its modifications.

Messrs. Blake and Co., of Manchester, had a 2-horse power gas-heated boiler, which was also capable of burning solid fuel; and the General Engine and Boiler Company, of 9, Union Court, Old Broad Street, E.C., had two engines, of 1-horse power and 3-horse power each, fitted with gas-heated boilers. Mr. R. S. Hindley, of Beeston, Derby, showed a very neat little 1-horse power engine and gas-boiler.

Messrs. Thomson, Sterne, and Co., Limited, of the Crown Iron Works, Glasgow, showed a gas-heated boiler of somewhat singular design. This was in connection with an implement which was styled a domestic machine for driving churns, &c. In this little machine, which was nothing more nor less than a miniature steam-engine of peculiar design, the steam was generated in a small gas-heated boiler, passed through a form of gas, and the water was pumped through this "boiler of forced circulation" by the cylinder, the necessary arrangements and appliances for maintaining this action being very curious and beautiful. The example shown was 4-horse power, and consumed one gallon of oil per hour, thus taking one-fifth of a gallon per horse power per hour. The machine altogether, appearing, as it did, refulgent with nickel plating, and with all its guards and rods and pumps going with easy and precision, was more like a specimen of elaborate clockwork than a real machine in the working world. It was a machine which few visitors to that part of the yard could fail to notice, for it arrested general attention in a rather original way, and probably most of the people who inspected it had discovered its wheelbarrow by *following their noses*.

96

Gas-stoves for cooking and heating were represented in only two stands, and of these the display made by Mr. T. G. Potter, of 17, Oxford Street, W., was confined to four examples of Williamson's manufactures which call for no special remark. Messrs. Billing and Co., of Smart's Buildings, Rosemary, W.C., and 90, Hatton Garden, E.C., showed a good collection of 72 stoves of various kinds, which well maintained the reputation of the firm for careful workmanship. There were no particular novelties among the exhibits, but it was satisfactory to see that the firm were alive to the desirability of giving the greatest possible amount of accommodation without unnecessary bulk, in stoves intended for small families where probably no servant is kept, and where the convenience of gas is so powerful a recommendation as any anticipated economy. It is among this class of consumers that gas-stoves ought to make great way; but there is danger lest buyers should be attracted by cheap articles, which might, by failure, cause disgust. Messrs. Sidney Leoni and Co., of 31, Strand, W.C., who were down in the catalogue for a great display, were, on the ground, conspicuous by their absence. It was unfortunate that none of the French manufacturers of gas-stoves were represented, as the comparison of their renowned goods with those of the best English makers would have been instructive.

Useful in hotels, &c., would be the gas calender of Messrs. Thomas and Taylor, of Stockport and Salford, by which one person can calender the largest table-cloth without assistance. It is probable that there would be found a considerable field for gas calenders for domestic purposes, if the matter were taken up and properly pushed by a few enterprising firms.

Although the list of gas-consuming apparatus was not particularly long, there were shown a great many implements and appliances of interest to manufacturers of gas. The stands of steam and general machinery, in action and otherwise, which could be said to appeal to gas engineers as much as to any other frequenters or users of power, were, as might have been expected, numerous and important. Boilers of every type, engines in endless variety, and pumps enough to be sensibly lowered the Thames, were to be seen ranged in lines that might have been measured by miles.

Messrs. Gwynne, of Hammersmith, had a fine show of their well-known centrifugal pumps, which were lasting examples of dirty water into an extemporized reservoir in a style which evidently aroused in the spectators a desire to see them employed in draining the Show Yard. The nicest character with this firm now fit to their centrifugal pumps, the object of which is to obviate the troublesome process of charging the pump, is a very neat arrangement, the value of which will doubtless be fully appreciated by any one who has ever sunk a draining well with the old pattern pumps. A portable centrifugal pumping-engine and boiler, with shelter and delivery pipes made to swivel to any angle required, was a conspicuous article in their stand.

Messrs. G. Waller and Co., of Holland Street, Southwark, had several of their compact and well-finished manufactures on view, ranging from engines and gas-motors through various descriptions of utility in water and sewage or drainage works, although they did not send such a collection of articles germane to gas-works as they might have done, if the general scope of the exhibition had been more favourable for their display.

Messrs. Tangye Brothers and Holman, of 35, Queen Victoria Street, E.C., had a very extensive stand, filled principally with examples of this firm's well-known types of steam-engines, then which none are stronger or steadier, and with their "Special" direct-acting pumps, description of which is superfluous. Quite a new departure for this firm are the centrifugal pumps of their manufacture which were exhibited. They had an arrangement whereby either the disc or spindle could be removed without disturbing the pipe-connections. Several hydraulic lifting-jacks, similar to those in the aid of which Cleopatra's Needle was raised, were also shown.

The Savile Street Foundry Company, of Sheffield, were well represented. We may mention particularly the new blower and gas exhauster made by this firm, as a promising apparatus deserving careful attention.

Messrs. Hayward Tyler and Co., of Whitecross Street, E.C., were well represented by a list of 55 entries. The curious hot-air engines, Hibbert's patent, which are manufactured by this firm, were shown in three examples. One in action was worked by gas, but it does not appear likely that such a method of working would be very economical. The "Universal" direct-acting steam-pumps, of which there was a good show, attracted considerable attention. There is no doubt that as this type of pump becomes generally known it will be preferred for most purposes to the more cumbrous barrel and crank pumps.

A great show was made by the Fulcometer Engineering Company, of 61 and 63, Queen Victoria Street, E.C., who showed 19 pulsometer steam-pumps, besides other articles. These machines may certainly claim to be the most direct-acting pumps in existence, and with fewest working parts, save only Giffard's and similar injectors. The valves are made in various patterns for special purposes. For excavators use, the pump has met with considerable favour, from its simplicity and freedom from liability to get out of order. The Hydrotreplex (boiler-feeder), which is a lineal descendant of the pulsometer, was also exhibited. It was claimed for this little apparatus that it could be regulated for continuous or intermittent feed, and required no attention. This firm also showed a rotary cleansing water filter, for cleansing large quantities of water for boilers, &c.

The "Comet" pump was exhibited by Messrs. Bartram and Powell, of 35, Queen Victoria Street, E.C., and is claimed to be very reliable especially for slow speeds. In appearance it is somewhat similar to Beale's exhauster, but in the present case the slide is fixed to the bottom, and the eccentric drum on the shaft moves around the inner surface of the case.

Messrs. Joseph Evans and Sons, of Culwell Foundry, Wolverhampton, showed a combined pump, termed the "Suitable," specially designed for pumping tar and other thick liquids, the valves being mechanically actuated. A particular feature in this was the reversing gear, by which a back current through the pump could be set up at any moment, with the view of clearing an obstruction from the valves or suction-pipe.

Messrs. Schiffer and Budenberg, of Manchester, had a modest stand of really valuable articles. Besides their well-known steam, vacuum, and hydrostatic gauges, and the strangely-shaped "Bose" governors, and numerous other engine and boiler mountings, they showed an ingenious invention—Doyle's patent swivel union for gas, water, or steam pipes. By means of a diagonal bolt and groove in the joint, the same fitting was adaptable either as a straight, elbow, or skew union at any angle; and by adhering to a uniform size of bolt and nut, one quarter is rendered available for all-sized unions. The chief drawback to these appliances would appear to consist in the bolt, which crosses the bore, and might prove an obstruction.

In various parts of the ground there were a number of appliances in connection with domestic water supply; but the important branch of waste-preventing apparatus was but scarcely represented. Messrs. Yeloe, Godfrey, and Co., of Broad Street, Bloomsbury, showed several varieties of their new "Hydrostatic" valves, and a water meter designed on the principle of the hydrostatic paradox. Messrs. A. Barr and Co., of Anderston, Glasgow, showed a compact and strongly-made water-pressure engine, in several sizes, which are better known and appreciated in Scotland than further south. Where water in bulk can be bought cheap, as in Glasgow, the simplicity of these machines would lead to their frequent use. With the pressure of 90 feet head, which was available for a yard, it was a pity that one of the engines was not shown in action.

Messrs. F. H. Atkins and Co., of 62, Fleet Street, E.C., the well-known makers of filters in infinite variety, exhibited a novel water softening and purifying apparatus, which was calculated to extend the benefit of Clark's process to small, or rather private establishments. It was ingeniously constructed to ensure a regular admixture of lime solution to the water-cistern, and the strainer could be readily cleansed of the precipitate, which, with the carbonic matters, has eliminated the noxious impurities which the water might previously have contained. A filter completed the outfit, and completed the process, and the purified water was wonderfully soft of hard water, but, for all that, a soft smooth water is a great luxury during it otherwise unattainable.

In conclusion, the exhibits of the so-called portable gas-making machines of Mr. R. L. Muller, of Birmingham, and the firm of Sugg, Pneumatic Lighting and Heating Company, of Newcastle Street, E.C., whilst quite a lighting medium by passing air over volatile hydrocarbons without much heat, and that of Mr. F. W. Clark, of Great Queen Street, W.C., who heats his material, were worthy of notice, as showing the popular appreciation of the convenience of gas lighting, and the consequent desire to obtain it even where coal gas is not obtainable. We may also mention the exhibit by Mr. J. C. H. Clare, of 39, Queen Victoria Street, E.C., of an assortment of "Victoria" leather belting. It was of English make, and certainly, if we might judge by appearances, was some of the best we have ever seen.

BRITISH ASSOCIATION OF GAS MANAGERS.

(Concluded from page 1214.)

Mr. L. Mabe (Lincoln) proposed the following paper, which was read by Mr. W. Carr (Belfast), Mr. C. Carpenter, Jun. (Southampton), and Mr. SOUTH (of the Kent Coal Exploration Co.) also joined in the discussion:—

HOT CLINKERS.

As the durability of gasholders differs so very much in various districts—lasting less in hot climates than others—and various opinions having been given to those appeared in print on the subject; and as it is an important and often very annoying subject for not only directors, shareholders, and managers, but also for the public who use gasholder manufacturers, it occurred to me, during the delivery of that excellent, instructive, and interesting lecture, at the evening sitting of the Institution of Gas Engineers, by Dr. Percy, Mr. C. Wilke, on "The Products of Combustion," and partially a solution of the hitherto apparent mystery, and I thought it would take place—that is to say, all chemical action whatever by lowering down to a sufficiently low extent the temperature of those products of combustion.

Another interesting subject on such occasion as this, and witnessing the experiment, my opinion was confirmed, that the question of the greater or less durability of gasholders in various climates was entirely a chemical question, as it evident, by the last paragraph, and the experiment, as well as the same may be, by the absence of sulphur and ammonia allowed to get into the gasholders, especially in hot climates; and not, as frequently supposed, by the mechanical action or swelling of the materials, that the iron was not, or should by no means, another cause, in transit, or carelessness in erection, seriously affecting or causing the decay of some of the greatest nuisance in the world.

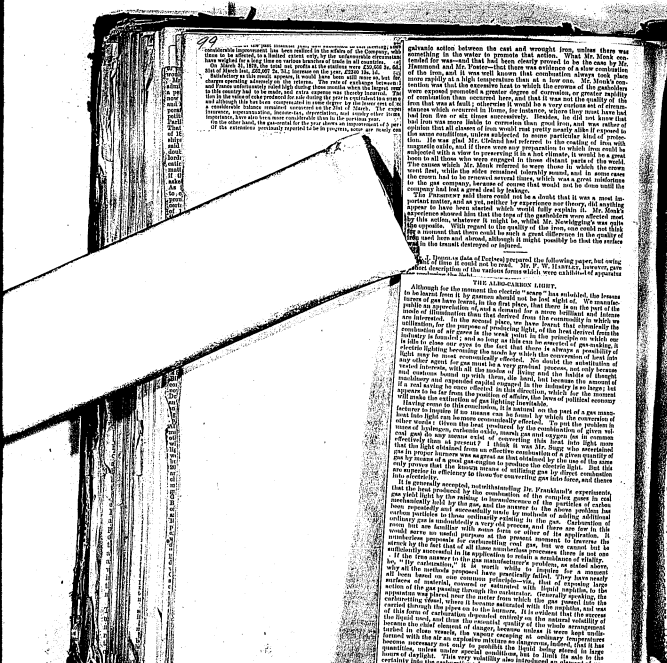
If I recollect rightly, the Messrs. Morrison, Bombay, and Calcutta Companies have had serious losses from the decay of their gasholders, consequent from the action taking place—as stated, in my humble opinion, by the sulphurous fumes and ammoniacal salts so commonly used in the United Kingdom, and which are conveyed frequently through the gas after such gas comes out, instead of a few hours, as at present, but after many days consumption, and, as I have stated, after the gas has been purified, which, I suppose, is the case, with ordinary management, that, with ordinary care, the gasholder, though getting leaky, would not require renewal for some years, is followed by the decay of the whole of the iron, and the gasholder is absolutely worthless, and requires more than a new purification, and, as I have stated, frequently upsetting the calculations of directors, and causing them to look upon the gasholder manager's reports as unreliable.

A very curious, in confirmation of what I have stated, that when in Bombay, I was informed by Mr. Hewett, the engineer of the work in hand was removing the iron and two top rows of the sides of an 80-feet gasholder, and the crown of another, which had been in use since lighted in 1854, and which, in the opinion of the engineer, was the fourth time new crowns had been put on, and the second time of renewing the sides, and which was required, and got so, also a new crown for a 50-feet holder erected in 1852, and which, I was informed, required renewal in 1862-4 or the first time, although a possible case of the erection of gasholders of similar capacity in England, of the best description, and which, I am sorry to say, is owing to politics, and the Italian Government into force a short time ago, and which works with 100-feet gasholders immediately erected. There the gasholders are to be of the size of 140 feet, or as I am informed, nearly so, and the difference between the contractors and the gasholders being sufficiently large and most elaborate, whereas the contract is very small indeed.

I now come to the question of the "residual" value of the iron of gasholders, as the seeming proof of this. These must expire at the end of the sun, and especially the crowns, and the present and older schemes of the gas-plays with the greatest effect for the longest time, require renewing from time to time, requiring, and as fast when it commences, that the ordinary Colonial lists and tenders are required by the press, and soon the crown is not safe to walk on, and the sides, and, in some cases, the floor of the tank, being entirely gone, and simply the foundation or cable steps left. Even inside, for, a portion of the framing sometimes remaining 10 years work. Further, be it the consideration of Companies in the process of electrical energy by means of the intense heat on the crowns, and the consequent destruction; if it is this must be the task?

We have a question, What is the remedy? Would steel plates, charcoal iron sheets, or the best galvanized iron be the means of preserving iron from corrosion, or even diminish it in the water in the tanks prevent oxidation; or, is it necessary to cover the iron in cement with bosses. And what is it, if any, that the engineer is to be allowed where the purity of the gas entering the gasholder is beyond question?

I now come to the question, in connection with this subject, that when at Aberdeen, at the works of Messrs. De Bruyn and Sons, a galvanized iron crown, 50 feet diameter, of Macquaire's gasholder first diameter, of 50, 14, and 20 gauge plates, belonging to position, the only one I have ever heard of. On inquiring as to reason for such construction, Mr. Howard, the maker, replied that in his long experience of 40 years as a gasholder manufacturer, it was the only galvanized iron one that he had met with, it was the opinion of the Engineer that it was very desirable and a matter of economy to have it galvanized; and he had received no complaint or information from him as to the results up to that time. Probably the Engineer considered it necessary, on account of the rapid corrosion of gasholders by the use of brackish water in the tanks, to consume there.



galvanic action between the cast and wrought iron, unless there was something in the water to promote that action. What Mr. Mark's opinion was—and that had been clearly proved to be the case by Hammond and Mr. Foster—that there was evidence of a slow combustion of the iron, and it was well known that combustion always took place more rapidly at a high temperature than at a low one. Mr. Mouk's conclusion was that the excessive heat to which the crowns of the gasholders were exposed, and which was greater than the iron could bear, produced a sort of combustion there occurred here, and that it was the quality of the iron that was at fault; silicerize it would be a very serious matter to the plates which occurred in Rome, for instance, where they must have used iron five or six times successively. Besides, he did not know that bad iron was more liable to corrosion than good iron, and was rather of opinion that all classes of iron would rest pretty nearly alike if exposed to the same circumstances, and subjected to the same particular kind of process. He was glad Mr. Clowes had referred to the coating of iron with magnetic oxide, and if there was a process by which the iron could be subjected with a view to preserving it for a hot climate, it would be a great boon to all those who were engaged in those distant parts of the world. The causes which Mr. Mouk referred to were those in which the crown went first, while the sides remained tolerably sound, and in some cases the crown had to be renewed several times, which was a most misfortune for the gas company, because of course that would not be done until the sides had become thin, and the bottom rotten.

The President said there could be a doubt that it was a most important matter, and as yet, neither by experiments nor theory, had they appear to have been started which would fully explain it. Mr. Hoyle's experience showed him that the tops of the gasholders were affected most by this action, whatever it might be, whilst Mr. Newington's was quite the opposite. With regard to the quality of the iron, one could not think but that bad iron had been could be used to a great difference in the character of the steel used here and abroad, although it might possibly be that the surface was in the tenants destroyed or injured.

Mr. T. Symes (a data of Dorking) prepared the following paper, but owing to the lateness of the hour it could not be read. Mr. F. W. Hyde, however, gave a short description of the various forms which were exhibited at the meeting.

THE ALBO-CARBON LIGHT.

Although for the moment the electric "arcs" has subsided, the issues to be heard from it by gaseous should not be lost sight of. We must not lurose of gas having in the first place, that there is at least a very large possible an approximation to it, and a demand for a more brilliant and intense needs of illumination than that which the ordinary flat flame burner can be interrupted. In the second place we have learnt that chemically the utilisation, for the purpose of producing light, of the heat that is now wasted in the combustion of our gases is the weak point in the principle on which our ordinary burner is founded; and as long as this can be done so easily and cheaply as it is the case, there is no hope to the fact that there is always a possibility of electric lighting beating the mode by which the conversion of coal into gas by any other agent for gas must be a very gradual process, not only because vested interests, with all the undue influence they exert over the public mind, will make the existing gas lighting fashionable, but because the amount of machinery and expended capital engaged in it, is not because the amount of it a real saving of expense effected in this direction, would be for the present to be far from the position of affairs, the best method for the present

101

carburation on the above basis cost 1s.6d. per 1000 cubic feet with an illuminating value of 28,000 candles, it would revolutionize the gas manufacture in every a district, town, and introduce it, with all its civilizing advantages, into many places where it is now unknown.

Discussion.

Mr. G. B. Isaacs (Gosport) said that last year Mr. Bourbouze (President of the Portsmouth Literary and Philosophical Society, and Electrodectory address was on the subject of artificial lighting. Among other things shown on that occasion was the albo-carbon light. He had seen it exhibited in the Westminster Aquarium, and considered it gave a very good light. The only objection to it was that there was a slight effluvium from the burning material.

Mr. W. Cross (Bristol) said he had had one or two of the lights in exhibition at the gas apparatus exhibition at Halifax. They were known rather as a curiosity than otherwise, because he did not think it would answer his purpose much to introduce the albo-carbon lights, seeing that it was his special business to increase the quantity of gas rather than thought gas was sufficiently good for all ordinary purposes, and people did not get light enough, he would rather encourage them to use a little more gas. It was continually struck with the smokelessness of the gases, and this small light was a great deal smokeless than many of the lights they were examining, which he supposed to the result of imperfect combustion. The albo-carbon is was a beautiful improvement. The effect produced with the small burners used was simply marvellous, but it ought to be pointed that those burners were not at all well adapted for light-giving purposes. Ordinarily speaking, they were about the worst class the company could use for common coal gas, and therefore the contrast shown between the albo-carbon and common gas was very great; but if one of those burners with the unpleasant burning in it was connected with a good flat-flame burner he thought the light would be found to be pretty useful. His own impression was that a light was better for the consumers to use a 5-foot flame than have small burners and be troubled to fill the albo-carbon burners, and should do it wherever it required attention. He should like to know whether it would be cheaper to use the albo-carbon illuminating by the use of the albo-carbon light, or to use the additional quantity of gas (take, for example, London gas, and, if so, how much more gas would be required to produce the same amount of light as that of the apparatus used for albo-carbon. It was important that they should be supplied with some particulars as to the quantity of coal, light for light, of that supplied by the albo-carbon gas and by ordinary coal gas, otherwise they might be admiring a beautiful effect without knowing the cost of it. If the cost for a given amount of light by albo-carbon was less than that produced by coal gas, the Albo-carbon Light Company had a very valuable property on hand, but the cost must be considerably less than gas, in order to enable it to compete with it, and to undergo the trouble of fixing up the apparatus and attending to it. He thought it was very likely to be a little more rain, but if it were cheaper to consume the extra amount for naphthalene—which was a product of coal tar—and the increased quantity of tar produced, which would result from the increased use of this naphthalene, would naturally tend to raise the price, and thus make the gas more expensive compared with gas consumed in the ordinary way.

Mr. S. Aisbitt, who had been exhibiting the light, said it had been found at the Westminster Aquarium that 240 burners, fitted with the apparatus, did the work of 300 supplied with ordinary coal gas, and consumed 5,000 cubic feet of gas per hour, whereas 6,000 feet were consumed by the ordinary burners. Generally speaking, after the cost of the naphthaline used was allowed for, the consumption of gas showed a result that of the gas ordinarily sold for. For example, if 6,000 feet paid £300 a year for gas, he could, if using the albo-carbon apparatus, consume 5,000 feet, pay £250 for gas and naphthaline, and adding £50 for the extra purifying material, the expense would come out to about one-half the previous amount. The light from the burners they was exhibited in burning under the apparatus was of a beautiful penetrating material had the peculiar property of steadying the gas-flame. It was proposed that they could use, as an ordinary gas-burner, the flame from a No. 1 Argand burner; they must employ 5 flat-flame burners to produce the same light as that of a single Argand, supposing the latter to consume 5 cubic feet of gas per hour. The flame of a single Argand burner was equal to that of 20 candles, calculating for burning sulphur 16 candle gas, was about 20 candles, calculating for burning sulphur 16 candle gas, was about per hour. This was the new burner which was probably used more frequently than any other by gas consumers, and which was the best to be taken as the standard of comparison, instead of the Sugg burner. The best burner for albo-carbon, instead of the Sugg burner. The best burner for albo-carbon, instead of the Sugg burner, was the burner which was found to be the lighting power of such a burner, the between 10 and 20°, or 20° to the naphthalising process was the difference flame as much light as the ordinary gas, which was naphthalised gas gave 21 cent. It was also found that the increase of light was an increase of 107 per cent. when the flame was 1 inches, and when it was only obtained by three inches high, if the pressure was 1 inches, there was an increase of 107 per cent. when the same burner non-carbureted; but if the pressure was in excess of 1 inches, there would be as much as ten feet of flame 10 inches were used. The greater the pressure the more naphthalin-flame could be conveyed through the flame, and therefore the higher the illuminating power obtained.

Mr. Dunn wished to explain that his remarks did not apply to Mr. Bray's burners in general, but simply to the size of the burners used on the present occasion.

[16270.]—I, LIKE many others, have found that any gas bills have been increasing in amount of late years, and this has caused me to look about for something wrong somewhere, as in my office and warehouse I have, wherever I could, substituted petroleum oil lamps for gas. When you have a large number of lights burning, the saving is great, as I at others instead of gas-lights, so that now I can say to yourself that it is blazing" hence I think the great outcry against the gas companies; but those who wish to fix the blame on the companies must remember that as a certain quantity of their profits includes the gas consumers, and I think gas consumers should think twice before practically adopting that a kind of conspiracy has been entered into by the gas companies to increase the price, instead of as opinion of the gas consumers. Let my say fact first out if it is not to consumers who are, after all, really the guilty or faulty parties. I remember thinking, after carefully reading all the correspondence that has appeared in your columns lately on this vexed subject, that the difficulty has to be met and contended against in the *entire pipe after* the gas leaves the meter, for years past great complaints were made against the inferior quality of the gas supplied, or want of sufficient pressure of gas. The companies appear to have met the complaint of the consumers by putting down larger mains, and thereby giving the extra pressure that was demanded of them; but the consumer in most cases, I expect, has done nothing with regard to regulating the supply to his burners, but has left the matter entirely to others. I feel, then, perhaps that in this case we are getting a larger amount of gas forced through the meter, and causing flaring and setting and a great waste of gas? I propose to put a regulator on to the outlet pipe in my warehouse, and have just recommended to try Bowditch's patent mercurial gas regulator, Mitcham, I understand, has been put up by the Mitcham Board of Works in the series in Tooley-street, and I shall be glad to hear if any of your readers have tried this or other regulators, and with what results.

W. Shevelinhaven Jones.

GAS-METERS.

[15571.]—SIR,—I HAVE just examined the inside of our gas-meter yet, notwithstanding I had some notion of how it was done. The drum, the greater and description by J. H. Warren, latter 1871, p. 105-6, I find the partition-plate, *a* in Fig. 1, is not fixed, but therefore, would be kindly explain it. In Way the axis of drum Fig. 1 supplies the gas, and passes it into four chambers, as fixed in Fig. 2 is shown as a simple spindle? also, how it could be seen as there represented when the partition-plate is fixed, and also in gas-light communication with said axis? 2. Is the "dip" of the partitions as set at one-fifth of the internal diameter of drum parallel to it, and if so, why? 3. It does not seem to me that the "dip" of the ends or side of meter can in anywise be evidential, as I have asserted in Fig. 2, the bench marked S ought evidently to be parallel to the axis of the meter, but as shown, it would have considerably fit the seats water less W, and if the meter was filled to the seats water bottom of the meter, as represented, it is not easy to see how the gas could dislodge the water in the space, without taking the whole of the water-revolving meter. 6. How is the space made to fill with water? Is it done by water without leakage (space) if the meter be caused a little on one side, would not gas escape at the water-line? 7. What is the water-level space, as shown in Fig. 2, also the rectangular piece marked A in Fig. 2? 8. How is it regulated that each chamber is "certain" to be "full" of gas, at a uniform pressure at each delivery? 9. It appears to me that the meter would not work much easier when all the lights were burning, than when only one was burning, because there would be less back pressure, one light will pass through a burner when lighting, as well as 100 lights and the tap left open, but the meter-index will not register (*total, my*) all, one and that with all the burners lit up, and it is possible for the drum to minutes under any circumstances, without perfectly filling the chambers with uniform pressure? There is probably a somewhat prevalent opinion that gas bills are much heavier than they ought to be, but I would ask that, as far as my experience goes, few people that

fill the meter from the street main, consequently the meter is probably never quite at rest, as there is the main leakage and the loss in the meter itself, through faulty fittings and incompetent fitters. It would be well to have a test-meter between the main and the meter, to ascertain the exact amount of leakage, and if the fittings are extinguished, and the meter is at rest, then the fault lies elsewhere, and I fancy that it would tell a tale in most cases.

A., Liverpool.

[16005.]—SIR,—In a letter p. 465, I asked a "Consumer" how he knew that he was paying for more gas than he used? I have since received a letter, which, I have no reason to suppose, in some obscure reticulations, remarks which set closely resemble those of your correspondent, that I could almost think he is the writer. I would suggest now, that a "Gas Consumer" should produce his "index card," stating the exact amounts of gas consumed during the last year, and the amount of gas he has to complain for consumed during the previous periods. Failing the production of evidence which a meter, who makes grave charges should only be too ready to supply, your reviewer will be able to form their own opinions. I commend to the attention of a "Gas Consumer" the remarks of Mr. Glover, of Manchester, and Mr. Liverpool, in the last quarterly, that will at least be useful to the consumer, and, failing other aid, it is not impossible that it may be his fittings that are at fault." For myself I am wondering whose pamphlets instance it is to be at the weeks to attempt to defend the consumers. I don't see who, otherwise it would be to the manager, and a director I am sure they're not, and the shareholders I don't suppose they are not sufficiently sober and methodical to be entering the last from the coals before selling them? I know mines are not lated or long this summer as they generally do. It has been previously pointed out in the columns of gas companies are public property, and are annually published, and I should think that the "Gas Consumer" alluded to, if he

IMPROVED PUBLIC LIGHTING OF GAS IN PARIS.—The Place du Châtelet d'Orléans is now lighted with the improved gas burner and burners similar to those employed by the Paris Gas Company for the lighting of the Rue du Quatre Septembre. There are 72 burners in the Place, and the gas consumption of this former being 60 cubic feet, that of the latter 30 cubic feet per hour. The amount of light produced by each is equal to 75 candles and 82 candles respectively, and the effect produced is very creditably beautiful. The area now selected for the Company's experiments is the most favourable illumination in competition with the electric light is of greater extent than the thoroughfare in which their operations were first conducted, and consequently the effect of the gas lights is much less intense. Nevertheless the Company have achieved an undoubted success, which certainly justifies the hope that at the Halles Centrales—the only remaining locality allotted to the Company by the Municipality for conducting their experiments—the improved lighting by means of gas will prove also an experience. The original intention of the Municipality was to divide the lighting of the Place du Châtelet d'Eau by placing upon it 30 electric lights of 2000 candles each, or 60,000 candles in all, and furnished the light of about 2000 candles. The Paris Gas Company therefore proposed to light the area with their new burners, which, with a consumption of 30 cubic feet per hour, produced a light equal to 82 candles, at the cost of 9c. 6f. 12c. per hour. To produce an equal illumination by electricity would, it is calculated, cost 38c. an hour.

THE ACTS OF PARLIAMENT which regulate testing for illuminating power in London, state in express terms that the light given by the gas is to be that of so many sperm candles of sixty to the pound, and remember well when Mr. Forster's Committee sat in 1872 the introduction of the mode of testing was noticed, and they refused to make any change either in the substance or wording of the acts. It happened in the year 1876, Pole, one of the gas referees, was engaged to watch the proceedings of the before the Committee, and when the clause in question was arrived at, he went to the chairman and suggested a change in the wording of the act, in lieu of "the light of 16 candles," he proposed that it should be "a light equivalent to that of 16 candles," so as to allow, if desired, the use of some other spermaceti than the candles, as hitherto. At that time a lamp, Mr. Reader or some other, was what was contemplated in lieu of candles; but of course, had the terms of the act been so changed, it would have allowed of Mr. Harcourt's new process being adopted, or any other. But the fact is that the alteration proposed by Mr. Pole was decisively rejected. It was opposed by Mr. Cripps, on the part of the Corporation of London, and no repeal was at once rejected by Mr. Forster and the Committee. This is a fact worth remembering.—*Gas Trade Circular and Review.*

PETERBOROUGH GAS COMPANY.—With reference to one of the paragraphs in our "Trade Notes from Scotland," in the account of Alex. Mc. Alexander, Chairman of the Directors of the Company for the past year, writes under date of the 10th inst.: "In your Notes from Scotland you refer to our annual meeting, and you say 'that the affairs of the Company are in a more prosperous condition than at any former period.' That is very true, but I should like, however, your correspondent makes a mistake when he credits it to the Manager—Mr. Thomas Nicolson—by whose faithful services, for the past twenty-one years, the energetic Collector and Secretary, and a thoroughly good men for his Assistant-Overseer, not nothing to do with the management of the works, which are under the immediate care of Mr. David Stevens, as Manager, with a Works Committee of three Directors, to whom special thanks were accorded. To Mr. Nicolson, however, is due the accomplishment of the most tangible was immediately noted of the year's results, in consideration of their services in the Company's interests. I should not have referred to this matter, but I observed not long since an interview with the Manager's friend or relation on his pre-retiral, and also to short next year, and, thereby a small works. It may be of our balance sheet for, in forwarding a wholesome rivalry." From the abstract of accounts for the year ending 31st January, for the year ending the 31st of May last, 13 realising 2956 lin. yds. mains, 1 of gas were sold at 6s. 8d. per 1000, produce and sundry receipts of 110 1780 yds. 4d. made a total charge of £7790 Against this there was a discharge of £1209 2s. 6d. for coals and £2301 1s. 3d. for purifying material, wages, &c.; and £200 for dividends. The capital of the Company is £20000.

DUNDEE GAS COMMISSIONERS.—At the meeting of the Dundee Gas Commissioners, held Thursday, Mr. Russell, in moving the adoption of the Treasurer's report, and the reduction of the price of gas from 3s. 2d. to 3s. per 1000 cubic feet, made a few remarks on the prosperity of the the town first had an interest in them, was £8593; in 1850, when they passed into the entire control of the Commissioners, the revenue from this source was £15,661. In 1861 the price was 4s. per 1000 feet, in 1870 it was 3s. 2d. From 1845 to 1875 the works were managed by a Joint Board of the Town's Trust and the Shareholders, and in that period the works yielded surpluses to the extent of over £20,000. The sum, £10,000 was transferred to the extension of the works; £10,000 was divided in the shareholders' stock; and the balance was handed over to the Trust in the shape of a loan. Since 1859 they had surpluses to the extent of £16,000 and £7000 has been placed to the sinking-fund. At present they had £7000 less debt to the Commissioners than in 1875, with appliances for making quite in a position to reduce the charge for gas to 3s. per 1000, and they might expect a surplus for the year as large as £4000, even at this rate. —Sir Alexander Grant, M.P., moved that £7000 carried to the sinking-fund. Bailie Hallow seconded the adoption of the minutes, and the recommendation to reduce the price of gas, both of which were agreed to. It was afterwards resolved to set aside £1000 of the gas profits for street improvements.

SALTCOATS GAS COMPANY.—From a statement of the affairs of this Company, presented to the Shareholders at their meeting on the 6th inst., it appears that the consumption of gas during the year ending the 30th of April last was exactly 4,190,000 cubic feet, which, at 4s. per 1000 feet, realised £8380 which, with residual products sold for £107 12s. 10d. The expenditure included £2000 for coals, the quantity of which was equal to 1s. 7½d. per 1000 feet of gas used; the total ordinary expenditure being £747 16s., equal to 3s. 6½d. per 1000. The "Abstract of Accounts and Product of Gas," which is appended, shows that during the year 4251 tons of coal and shale were used, estimated to produce 4,359,655 feet of gas, 4,190,000 feet, actually made, as indicated by the station-meter, was 4,359,655 feet, leaving a loss over 4037 feet per ton. The gas used by consumers amounted to 3,980,500 feet, as shown by 21 street-lamps, 12,500 feet; and used at works, 40,000 feet; thus the unaccounted-for gas was 692,000 feet, or 19·04 per cent. of the make.

EXPLOSION OF GAS IN THE METROPOLIS.—On Friday evening last, an explosion of gas occurred at the New Cross Station of the London, Brighton and South Coast Railway, resulting in considerable damage to one of the waiting-rooms, and injury to five persons, who were slightly burned about the hands and face.—On Saturday morning, about eleven o'clock, an explosion of gas took place in the gas-meter and paint store-room at Somerset House, by which a number of gas-fitters were at work with a naked candle in the room, which is said to have caused the amount of the building. They detached a pipe from the meter without first turning off the gas at the main, and the gas pouring out, became ignited. The window was blown out, and the gas, which was blazing fiercely, set fire to the contents of the room, and created great alarm. Several fire-hose belonging to the Strand Union were brought into use, and two or three engines of the Fire-Brigade were also soon on the spot, one of them commenced playing upon the room. In less than an hour from its outbreak the fire was completely extinguished, leaving less confined to the place where it originated.

ATHENS GAS-WORKS.—We hear that Mr. Charles H. Hutchinson, son of Mr. John Hutchinson, of Barnsley, has retained his appointment as Engineer to the Athens Gas Company, and will shortly return to England.

PEMBROKE GAS COMPANY.—At the half-yearly meeting of this Company, held on Monday, the 16th inst.—Mr. J. H. South in the chair—the ordinary dividends of 3l per cent. on the A stock, and 7 per cent. on the B stock were declared.

makes a profit. All things considered, the Corporation may engage in the supply as a matter of fact, they have not encouragement, and this is antagonism to the interests of the Gas Companies.

It was very well and fairly put before the Committee of the House of Lords, when it was said that the object of the Bill promoted by the Corporation was simply to cheapen the undertaking of the Liverpool United Gas Company. We question whether, in their hearts, the Town Council of Liverpool have the smallest intention to seriously experiment. They have five years before them, but at the present time only one invention offers itself for public and partially internal utility. That is the Jablochkoff system, which Mr. Deacon saw in operation in the Avenue de l'Opéra, at Paris, and did not report on in very favourable terms. This system is still on trial on the Victoria Embankment, and the results of the extended experiment we shall learn in about six or seven months time. Beyond this, two or three other schemes are offered to the Corporation for experimentation. There is, for example, the Lontin light, which, we are bound to say, answers remarkably well in single instances, but has not succeeded so far as to induce Mr. Hollingshead, of the Gaiety Theatre, in the Strand, to push it into public notice. Then there is the Rapieff system, which commands attention in some interiors, and promises to be effective. Lastly, we have the Werdermann light, which offers the advantage of a more minute subdivision of an electric current, so that smaller lights may be available for internal illumination without much loss of power for the supply of larger lights exteriorly. We need scarcely mention Mr. Edison's invention, for it seems to exist only on paper—at all events, while inventors come from all parts of the world with their electric lights, Mr. Edison stays at home with his. So far, then, the Corporation of Liverpool have a choice of several systems with which they may set to work at once. There is the Picton Reading Room, about the lighting of which they are so anxious; there is the St. George's Hall, with the steps up to the roller, and the large space in front of the building, which are particularly still we are told, delays. If the Corporation are anxious to assist in developing the [illegible] they might begin the work [illegible] Society associated with the Legislature, [illegible] antagonism to the Gas Company in Parliament, [illegible] not see they have gained much. The privilege [illegible] a profit can hardly be considered as worth [illegible] Nevertheless this would appear to be all that the [illegible] have received for their money. The rather wide [illegible] powers they have obtained for [illegible] we do not suppose [illegible] much drawn upon, though it may be that at the end [illegible] years a quantity of old pipes will be found in the [illegible] market.

[illegible] question whether gas loses in illuminating power by [illegible] through long lengths of mains, is likely presently [illegible] a good deal of attention. It is proposed to abolish [illegible] thousand yards limit, at which distance all Gas Acts now [illegible] the places where examinations shall be made. This limit, [illegible] believe, first settled—we write from memory—upon [illegible] the result of experiments made by the late Dr. Letheby, on [illegible] the Great Central Company, as it travels from [illegible] King station, on Moor Common, to the terminus [illegible] Street, City. Within these limits, far exceeding [illegible] mile, no appreciable loss of power was [illegible] these experiments was, namely, we do not remember that any have been carried [illegible] having a special reference to the alleged loss of power, [illegible] certain observations [illegible] shown that little or no deterioration of [illegible] takes place even when long lengths of mains are [illegible] stressed. The gas of the late Birmingham and Staffordshire [illegible] Company was tested at stations several miles apart, and [illegible] little or no loss of power was observed. So, too, in the [illegible] of the Chartered Company's gas, which was tested by [illegible] Independent Examiners at Beckton within the thousand yards [illegible] and at Cannon Street, City, six or seven miles distant [illegible] the works. Here, again, the reports of the two Examiners showed great uniformity. While, then, we strongly object to any alteration of the law which affects the limit, and think that the Companies ought to oppose the Bill to be brought in on each occasion to extend the distance, which, for all that we know, might prove prejudicial to their interests, the matter may be found of little importance.

History repeats itself at the police courts and in the newspapers. A man who gets into houses under the pretence of being sent to examine the gas-meter, is constantly figuring. We notice a recent case for the sake of a suggestion made by a newspaper correspondent—namely, that the servants of the Companies should be provided with some token of identity,

Gas Lighting Experiments.

Colonel Haywood, C.B., the engineer to the City Commissioners of Sewers, London, has reported to them the results of an experiment now being made in a portion of Queen Victoria Street, between Mansion House Station and the Poultry, with new gas burners, by the Gas Light and Coke Company, at their own expense.

The experiments commenced on the 6th March. The Gas Company mixed with Sugg's London Argand "Governor" burners with glass chimneys. The first three sets of one consuming 22 cubic feet of gas per hour, the other 20 cubic feet. The gas is consumed in the smaller burners in two concentric coronas or rings of flame, and in the larger burners in three rings. The burners are so arranged as to be self-lighting when the gas is fully turned on. They are in lanterns of an improved description, the smaller in lanterns octagonal in plan, and the larger in twelve-sided lanterns. Both lanterns are larger than those ordinarily used, and have the upper parts glazed with a new kind of white glass, which partly reflects and partly transmits the light. The lower portions are glazed with ordinary clear glass. Proper means are provided for ventilation, and preventing down-draughts. There are 36 of the smaller and 6 of the larger lamps, and they supersede 55 ordinary lamps. The length of the street lighted is 333 yards. The burners consuming 22 feet of gas per hour have an estimated illuminating power of 80 candles, and thus 36 lamps are equal to 2880 candles. The 20-feet burners have a power of 70 candles, and 6 lamps are thus equal to 1260 candles. The ordinary lamps formerly superseded are equal to 720 candles, or 15 times less than the experimental lamps. The cost of the 55 ordinary lamps superseded is £1 7s. 6d. each per annum, or £393 2s. 6d. in all. The cost of the smaller experimental lamps is £1 17s. each per year, and of the larger £11 5s. 6d., or £777 2s. 6d. in all. The new system, therefore, is nearly three times more costly than the old. The general result, therefore, is that the new system gives nearly 4½ times as much light as that in general use, and costs about three times as much. It should be added that the experiment is being conducted at the sole cost of the company.—*London Paper.*

It is thought that the heavy reductions in the price of gas made recently by the New York City gas companies will tend to foster the introduction of gas engines for light work into hundreds of shops and stores in this city. Thousands of these engines are in regular use for such purposes in England and European cities generally, but the extraordinary rates demanded by the gas companies in American cities have heretofore been a great hindrance in this country, a state of things not entirely profitable to the positive [illegible] ity of the gas company managers.

Gas Lighting Experiments.

Colonel Haywood, C.B., the engineer to the City Commissioners of Sewers, London, has reported to them the results of an experiment now being made in a portion of Queen Victoria Street, between Mansion House Station and the Poultry, with new gas burners, by the Gas Light and Coke Company, at their own expense.

The experiments commenced on the 6th March. The Gas Company mixed with Sugg's London Argand "Governor" burners with glass chimneys. The first three sets of one consuming 22 cubic feet of gas per hour, the other 20 cubic feet. The gas is consumed in the smaller burners in two concentric coronas or rings of flame, and in the larger burners in three rings. The burners are so arranged as to be self-lighting when the gas is fully turned on. They are in lanterns of an improved description, the smaller in lanterns octagonal in plan, and the larger in twelve-sided lanterns. Both lanterns are larger than those ordinarily used, and have the upper parts glazed with a new kind of white glass, which partly reflects and partly transmits the light. The lower portions are glazed with ordinary clear glass.

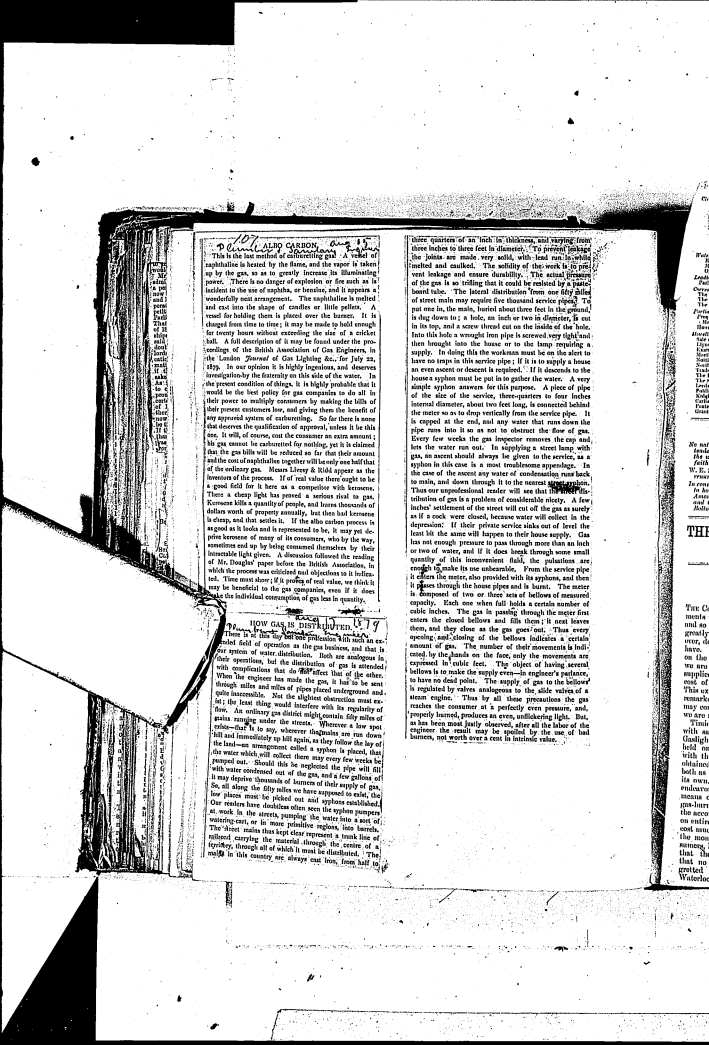
Proper means are provided for ventilation and preventing down-draughts. There are 36 of the smaller and 6 of the larger lamps, and they supersede 55 ordinary lamps. The length of the street lighted is 333 yards. The burners consuming 22 feet of gas per hour have an estimated illuminating power of 80 candles, and thus 36 lamps are equal to 2,880 candles. The 20 feet burners have a power of 70 candles, and five lamps are thus equal to 1260 candles. The ordinary lamps formerly superseded are equal to 720 candles, or 15 times less than the experimental lamps. The cost of the 55 ordinary lamps superseded is £1 7s. 6d. each per annum, or £393 2s. 6d. in all. The cost of the smaller experimental lamps is £1 17s. each per year, and of the larger £11 5s. 6d., or £777 2s. 6d. in all. The new system, therefore, is nearly three times more costly than the old. The general result, therefore, is that the new system gives nearly 4½ times as much light as that in general use, and costs about three times as much. It should be added that the experiment is being conducted at the sole cost of the company.—*London Paper.*

In all cases of the smaller experimental lamps is £19 1s. each per year, and of the larger £11 5s. 6d., or £777 2s. 6d. in all. The new system, therefore, is nearly three times more costly than the old. The general result, therefore, is that the new system gives nearly 4½ times as much light as that in general use and costs about three times as much. It should be added that the experiment is being conducted at the sole cost of the company.

THE JOURNAL OF GAS LIGHTING,
WATER SUPPLY, & SANITARY IMPROVEMENT.
TUESDAY, JULY 1, 1879.

Circuit of the Gas Companies.

Our readers will [illegible] read from our Liverpool Correspondence that the Lighting Bill [illegible] Committee of the House of Lords yesterday week, so [illegible] was then mentioned, and it may now [illegible] part of the law of the land. Under [illegible] Liverpool Corporation have power [illegible] It empowers them to make experiments [illegible] which may extend over five years, [illegible] obtain any profit by a supply of [illegible] which may be open to them. Thus the Corporation may illuminate any public streets or areas and interiors, property belonging to themselves, at a cost price which can be easily estimated. But the Bill gives further power to the Corporation to supply places of public resort, such as theatres, music halls, and railway stations, and these must be supplied without profit. The pretence for acquiring powers of light these latter was, that the expense of the light could not be ascertained unless some of it was sold, although without profit. Now that the Corporation have these powers, we shall be curious to see how and when they will be exercised. The excuse for granting powers of this kind to Corporate Authorities rather than to Gas Companies is, that the former are likely to do their utmost to promote the success of the new light, while the latter, it is alleged, would endeavour, or at least speak, to smother an invention which professed to rival the light they already purvey. The absurdity of this supposition is palpable. If Gas Companies went in for the supply of electric light, they would do it [illegible] more, and with a vigour



ALBO CARBON, June 1
This is the last method of illuminating gas! A vessel of naphthaline is heated by the flame, and the vapour is taken up by the gas, so as to greatly increase its illuminating power. There is no danger of explosion or fire such as is incident to the use of sophine, or benzine, and it appears a wonderfully neat arrangement. The naphthaline is melted and cast into the shape of candles or little pellets. A vessel for holding them is placed over the burner. It is charged from time to time; it may be made to hold enough for twenty hours without exceeding the size of a cricket ball. A full description of it may be found under the proceedings of the British Association of Gas Engineers, in the London Journal of Gas Lighting &c., for July 1st, 1859. In our opinion it is highly ingenious, and deserves investigation by the fraternity on this side of the water. In the present condition of things, it is highly probable that it would be the best policy for gas companies to do all in their power to multiply consumers by making the bills of their present customers low, and giving them the benefit of any approved system of economizing. So far there is some that deserves the qualification of approval, unless it be this one. It will, of course, cost the consumer an extra amount; his gas cannot be carburetted for nothing, yet it is claimed that the gas bills will be reduced so far that their amount and the cost of naphthaline together will be only one half that of the ordinary gas. Means Livesy & Ridd appear as the inventors of the process. If of real value there ought to be a good field for it here as elsewhere with increasing fuel. There a cheap light has proved a serious rival to gas. Kerosene bills a quantity of people, and burns thousands of dollars worth of property annually, but then bad business is cheap, and that settles it. If the albo carbon process is argued as it looks and is represented to be, it may yet do. prive kerosene of many of its consumers, who by the way, sometimes end up by being consumed themselves by their detestable light given. A discussion followed the reading of Mr. Douglas' paper before the British Association, in which the process was criticised and objections to it indicated. Time must show; if it proves of real value, we think may be beneficial to the gas companies, even if it does the individual consumption of gas less in quantity.
HOW GAS IS DISTRIBUTED. 3 7
There is at first a bad confusion, with such an extent of field of operation as the gas business, and that is our system of water distribution. Before the beginning of their operations, but the distribution of gas is attended with complications that do not affect that of the other. When the engineer has made the gas, it has to be conducted through miles and miles of pipes placed underground and quite inaccessible. But the slightest obstruction must exist; the least thing would interfere with its regularity of flow. In ordinary city district might contain fifty miles of mains running under the streets. Wherever a low spot exists—that is to say, wherever diagonists are run down hill and through every up hill again, as they follow the lay of the land—an arrangement called a syphon is placed, that the water which will collect there may every few weeks be pumped out. Should this be neglected the pipe will fill with water condensed out of the gas, and a few gallons of it may deprive thousands of burners of their supply of gas. So, all along the fifty miles we have supposed to exist, the low places must be picked out and syphons established. Our readers have doubtless often seen the syphon pumpers at work in the streets, pumping the water into a sort of watering cart, or in more primitive regions, into barrels. The direct mains then kept clear represent a trunk line of pipe, three quarters of an inch in thickness, and varying from three inches to three feet in diameter. To prevent leakage the joints are made very solid, with lead run in while melted and caulked. The solidity of the work is to prevent leakage and insure durability. The actual pressure of the gas is so trifling that it could be resisted by a piece of board tube. The latest distribution from one fifty gallon of street main may require five thousand service pipes? To put one in, the main, buried about three feet in the ground, is dug down to; a hole, an inch or two in diameter, is cut in its top, and a screw thread cut on the inside of the hole. Into this hole a wrought iron pipe is screwed very tight and then brought into the house or to the lamp requiring a supply. In doing this the workmen must be on the alert to have no traps in this service pipe; if it is to supply a house an even ascent or descent is required. If it descends to the house a syphon must be put in to gather the water. A very simple syphon answers for this purpose. A piece of pipe of the size of the service, three-quarters to four inches internal diameter, about two feet long, is connected behind the meter so as to drop vertically from the service pipe. It is capped at the end, and any water that runs down the pipe runs into it so as not to obstruct the flow of gas. Every few weeks the gas inspector removes the cap and lets the water run out. In supplying a street lamp with gas, an ascent should always be given to the service, as a syphon in this case is a most troublesome appendage. In the case of the ascent any water of condensation runs back to main, and down through it to the nearest syphon. Thus our unprofessional reader will see that the difficulties of gas in a problem of considerable nicety. A few inches' settlement of the street will cut off the gas as surely as if a rock were closed, because water will collect in the depression! If their private service sinks out of level the least bit the same will happen to their house supply. Gas has not enough pressure to pass through more than an inch or two of water, and if it does break through some small quantity of this inconvenient fluid, the pulsations are enough to render its use unbearable. From the service pipe it enters the meter, also provided with its syphons, and then it passes through the house pipes and is burnt. The meter is composed of two or three sets of bellows of measured capacity. Each one when full holds a certain number of cubic inches. The gas in passing through the meter first enters the closed bellows and fills them; it next leaves them, and they close as the gas goes out. Thus every opening and closing of the bellows indicates a certain amount of gas. The number of their movements is indicated by the hands on the face, only the movements are expressed in cubic feet. The object of having several bellows is to make the supply even—in engineer's parlance, to have no dead point. The supply of gas to the bellows is regulated by valves analogous to the slide valves of a steam engine. Thus by all these precautions the gas reaches the consumer at a perfectly even pressure, and, properly burned, produces an even, unflickering light. But, as has been most justly observed, after all the labor of the engineer the result may be spoiled by the use of bad burners, not worth over a cent in intrinsic value.

W. E. S.—If it be an ordinary allotment of shares, a letter or form of renunciation will be quite sufficient.

In consequence of pressure on our space to-day, we are reluctantly obliged to hold over till next week much interesting matter already in type, including a report of the meeting of the Surrey St. Saviour's, Lambeth, and Kingston Gas Companies, the Colne Valley Water Company, the Holton Company, &c., &c.

THE JOURNAL OF GAS LIGHTING,
WATER SUPPLY, & SANITARY IMPROVEMENT.
TUESDAY, AUGUST 9, 1859.

Circular to Gas Companies.

THE Corporation of Liverpool have commenced their experiments with the electric light, at the Picton Reading-Room, and so far, according to newspaper account, the results show greatly in favour of electricity over gas. The report, however, does not give us all the particulars we should be glad to have. The Gas Companies of Liverpool are, it is said, in favour of the scheme; but it was said to be expensive. Electricity, we are told, gave an admirable light; whether equal to that supplied by gas, it is not said; but it is reported that the cost of the former was only one-third that of the latter. This experiment is only a small matter; but it deserves to be very much spoken. There is, of course, a prospect that electricity may come into some sort of use as an internal illuminant, but we are not at all afraid of competition with it.

Timid gas shareholders, if there are any such, may peruse with satisfaction the able address of the Governor of the Gaslight and Coke Company at the half-yearly meeting, held on Friday last. This Company have experimented with the electric light, and, so far as the results they have obtained have been concerned, it was proved conclusively that, both as regards economy and illumination, gas can well hold its own. The Company have gone a step further, and have endeavoured to persuade the Local Authorities to adopt improved means of lighting while thoroughfares by the use of large gas-burners. These experiments, as our readers will see by the accounts which we publish elsewhere, have been carried on entirely at the expense of the Company. They have not cost much, it is true, and the carping critics who object that the money eventually comes out of the pockets of the consumers, have but a small grievance. The answer is it is that the public had the benefit of the experiment and that no one missed any complaint. It is much to be regretted that the trial of the improved gas lighting in Waterloo Place was stopped so soon. The motives which actuated the Vestry of St. James's, Westminster, in putting so sudden an end to the experiment, can only be guessed at. They, no doubt, surmised that the public who use that immense gas consumption would presently demand a continuation of the light, the charge for which would have to be defrayed from the parish rates. Some would, no doubt, found an argument on this in favour of shewing the whole gas supply under some municipal body, who would be able to charge the inhabitants of Hampstead the same amount for public lights as they charged those in the neighbourhood of Piccadilly. But the city has not yet arrived for this, and, probably, never will arrive. Local bodies must continue to discharge their own liabilities, and we may say in a few words that the Chartered Company acted perhaps somewhat Quixotically when they attempted to persuade the Vestry of St. James's to adopt an improved mode of public illumination.

We must turn for a few moments to the accounts of the Company, which will be found in detail in another place. The Governor referred with satisfaction to the circumstance that the gross rental during the past half year had been higher than in any similar period. To receive more than a million sterling in six months for the supply of gas, is a fact unprecedented in the history of gas supply, and it is natural that special reference should be made to the fact. The undertaking must of necessity go on increasing in size and importance, and the revenue which now excites something like wonder will presently appear to be but a small affair. Although this large amount has been obtained for gas, it must not be supposed that everything has gone well with the Company. Residuals, and especially coke, have not produced the amounts which might have been expected. Coke is, unfortunately, a drug at Beckton, and it is, we fear, likely to remain so for some long time to come. It may be broken, and its sale undoubtedly increased by this means; but marketing costs money, and the question leaves a rosiitious, conjunctively worthless. Beyond all doubt it would be greatly to the advantage of the Company if they would engage in the sale of heating apparatus for the economic consumption of coke. Cheap as the fuel is, it is only the very poorest classes who are likely to have to its ingenuities. It would be to the interest of all Companies to promote its use among middle-class consumers, who would pay a better price and use much more. It is absurd, however, to criticise the actions of Directors in such matters. They are doing their utmost to get rid of the vast accumulations of coke they have on hand, and we can only wish them success in their efforts.

We must also refer to tar, on which there has also been considerable loss. That the working up of this residual will eventually prove highly profitable to the Company, we have no doubt whatever; but at present it must be admitted that the state of the market is against a profitable exploitation. The aniline business is still in its infancy, and cannot yet command a ready sale at remunerative rates. What are called the disinfecting materials of coal tar, when obtained from coal tar, want a sharp outbreak of cholera to stimulate their sale; but the water supply of the Metropolis is so excellent, that we do not expect to have another epidemic of cholera. The manufacture of sulphate of ammonia, it seems, has been carried on with much success; but the substance agricultural, we believe, is not now in a position to purchase expensive manures. The South American markets are largely drawn on for price of our manufactured manures; but, to say the truth, we have not carefully watched the state of the markets.

As regards the appropriation of the large balance of £101,921, which remains in the hands of the Company after the payment of a ten-and-half per cent. dividend, it may be safely left to the discretion of the Directors. We are strongly of opinion that their best policy will be to increase as they can their reserve-fund. The halcyon times through which the Company are now passing may not, and probably will not last for ever. Coke, as was very properly pointed out by one of the speakers at the meeting, may become an increasing difficulty, and the future profits of the Company may, in consequence, become further abridged. As this contingency cannot be accurately calculated, all doubts as to the success of the undertaking may be set at rest. Difficulties in the management will, of course, arise; but, happily, the Chartered Company have among their Directors and Managers a class of gentlemen fully equal to grapple with them.

As we reported last week, the Gas Committee of the Corporation of Leeds resolved to recommend the Council to reduce the price of gas from 3s. 6d. to 3s. 2d. per thousand feet, and their recommendation was agreed to at a meeting of the Town Council held last Wednesday. A little opposition was made in Committee, a member wishing that, in place of reducing the price of the gas, money should be expended in

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, AUGUST 12, 1879.

Circular to Gas Companies.

We have no wish to suppress one atom of information which relates to the extension of the use of the electric light. The Metropolitan Board of Works, having resolved to give the light a more extended trial on the Thames Embankment and Waterloo Bridge, but having failed to obtain the sanction of the Vestry of St. Martin's-in-the-Fields to use the light in Northumberland Avenue, have cast about for some other spot in which to expend their surplus power. Under the inspiration of their Engineer and Chemist, they have determined to illuminate their Board-room by electricity, and also to place some large light over the entry in Spring Gardens. The hall is to be lighted by four lamps placed upon standards. The light over the doorway in Spring Gardens will have a manifest advantage, for a strong light has been wanted there for years. The narrow issue out of St. James's Park decidedly needs illumination, and the Metropolitan Board will be doing good work if they can effectually light up this thoroughfare. With regard to the internal illumination, we shall, of course, watch the results with much interest. It can hardly be considered a conclusive experiment, as the Board only sit for a few hours at a time; so that, as far as the lighting up of interiors is concerned, but a limited conclusion can be drawn. However, it will doubtless answer, and much will, of course, be made of the satisfactory result.

A larger experiment in electric lighting is about to be made by the Corporation of Blackpool, who, in the course of September next, intend to convert night into day on their long promenade, by the use of six naked lights, having the illuminating power of about 6000 candles, and fixed at a height of fifty feet above the pavement. This is, in some respects, a novel experiment; but it is one which should be made. Blackpool will not be converted into a summer residence all the year round, however well the *electric light may succeed. Lancashire people go to bed early, and any amount of illumination on the promenade will only induce a few to remain thereon. Hardly a word need be said about the extension of the light on board ironclads, and for the illumination of harbours. A more extended application of the light is being made in this direction, which will probably be followed up by others. In this application we see the most legitimate use of the electric light, and shall be happy to congratulate the Admiralty and all concerned on its successful employment.* In all this there is nothing to alarm gas proprietors or shareholders. We watch the developments of the electric light with perfect equanimity, certain that there is not in its use anything inimical to the interests of gas proprietors.

We believe we are right in asserting that the amalgamation between the South Metropolitan and Surrey Consumers Gas Companies will be sanctioned this week. Difficulties arose, but have now, we believe, been settled, and we understand that the Board of Trade will, in the course of a few days—subject to the approval of Her Majesty in Council—sanction the arrangements which has been come to between the Companies with some alterations of no great importance which have been made since we published the scheme.

It is now fully understood that the Phœnix Company do not propose, for the present, to enter into the arrangement intending to go to Parliament next year for, among other things, power to amalgamate with any Company whom they can persuade to unite with them. It is difficult to say in what direction they can be looking for allies. So far as can be seen, the South Metropolitan and the Surrey Consumers Companies are now closed against them. The London Company would appear to have nothing to say to any combination. In hardly any case could they fall in with the Phœnix, unless their district were divided, and the best part of it went to the Chartered across the water. It is very much to be regretted that a southern combination has not been effected; but the spirit of union which will, we hope, be sanctioned in the course of the present week, must tell greatly to the advantage of the consumers within the Surrey Company's limits. It is something to have an immediate reduction of sevenpence per thousand feet, with a prospective diminution of twopence per thousand feet more within a short period. We shall not stop here to inquire whence the profits are to come which in time will justify this reduction, and maintain the dividends at the rates proposed. It is quite clear that they cannot be derived at present from the working of the Surrey Consumers Company, and hence some uproar on the part of consumers in the district of the South Metropolitan, who imagine that the price of gas within their limits must be kept up to provide a dividend for the Surrey Consumers Company. There is perhaps a substratum of truth in this supposition, but it must be remembered that in practical life we have all to make sacrifices, sometimes large and sometimes small. The consumers in one district may not get all the advantage they might hope to derive from the independent existence of the South Metropolitan Company, but they have at the same time the satisfaction of knowing that in the course of a year or two, after aiding their neighbours to obtain the benefits of cheaper gas, they will themselves participate in advantages which could only be derived from amalgamation. It is in the highest degree essential that the two Companies to which we now allude should unite. The one, as we have said before, has exactly what the other requires, and their combination can only tend to enhance the benefits to the Shareholders and Consumers of each.

The report of the Directors of The Gaslight and Coke Company, and the accounts for the past half year, have been issued in anticipation of the half-yearly meeting to be held next Friday. It is unnecessary to say that the working results have been eminently satisfactory. From the sale of gas the Company received no less than £1,024,796, against which may be placed a cost for coals of £474,224. Meter-rents produced £18,116, and residuals £255,945, &c. The balance of revenue account shows a profit of £389,005, which, after providing for all preferential charges, leaves a balance applicable to dividend on ordinary shares of £327,216. The amount required for the payment of the dividend for the previous half year was £285,607, which leaves £101,612 to be appropriated to the reserve and other funds, and to be carried forward. This result is certainly not quite so good as that obtained in the previous half year, but the difference is small.

We have spoken of the dividends; those for the past half year amounted to 10½ per cent. on the ordinary stock, and

AMALGAMATION OF GAS COMPANIES.—On Friday last week, a deputation from the Vestry of Lambeth had an interview with Mr. Talbot, M.P., at the Board of Trade, with reference to the scheme now before the Board for the amalgamation of the South Metropolitan Gaslight and Coke Company and the Surrey Consumers Gas Company. The chief objection of the Vestry to the amalgamation scheme is that the effect of it will be to reduce the price of gas in the Surrey Consumers Company's district, and deprive the Vestry and the consumers of gas in the South Metropolitan district of the advantages they now derive from the favourable position of the South Metropolitan Gas Company. Mr. Talbot said the representations of the deputation would receive his most careful consideration.

[From London "Journal of Gas Lighting."]

The Proposed Substitute for Candles in Testings for Illuminating Power.

"Mr. A. Vernon Harcourt has written to the Board of Trade a letter which has the appearances of being a private communication, but which has been made a public document by being printed and circulated by the Board. We scarcely understand the position of his colleagues in regard to this matter. There are three Referees, whose salaries are paid by the gas companies; two of these gentlemen, the Acts of Parliament say, shall form a quorum, and concur in any recommendation and instruction. In the document above referred to, however, which we are bound to regard as of some importance, the names of Mr. Harcourt's colleagues do not appear. We are obliged, then, to regard it as a private communication. Mr. Harcourt is very much dissatisfied with the candle test, and therefore is anxious to substitute another which he considers more reliable and trustworthy. "I desire," he says, "to obtain the sanction of The Board of Trade to the introduction at the testing-places" established for testing gas supplied by the Metropolitan gas companies "of a more trustworthy standard." We may stop here for a moment to express a strong opinion that the Board of Trade have no power to change the standard of comparison. The Acts of Parliament say that the gas supplied shall have an illuminating power of *sixteen candles*. The Referees have the power to prescribe the apparatus to be used in ascertaining the illuminating value, and at that point their obligation ends. Candles are the universal standard, which can only be changed by some general enactment. We are far from saying that the use of candles gives entirely satisfactory results; but as no approach to scientific precision is possible, even with Mr. Harcourt's pentane test, we may be excused for expressing our adhesion to the old standard. And on this point we may call Mr. Harcourt himself to witness. He admits that taking the mean of three testings during the day tends to neutralize the variations of the candles; and, further, he says that, according to his experience, "it does not often happen that any one of a set of three testings varies by more than half a candle from the mean of the three. This is the case even if a different pair of candles is used for each testing, when the candles are from the same packet, and the mode of operating is kept rigorously uniform." Further than this, he admits, "that when candle testings are made with great uniformity, fairly concordant results may be obtained." Beyond this, in an appendix, he shows that when tests are made alternately with pentane and candles, the variations in the latter are really but small.

It may be asked, can we be more certain of the invariability of the pentane test, any more than that of candles? We may take it that it would be a difficult matter to answer this question. Pentane, as prepared by Mr. Harcourt himself, is a body of definite composition and great volatility; but who is to guarantee that all poured into the holder is volatilized and diffused through the bulk of air contained therein? We admit that the presumption is, of course, in favor of the perfect diffusion of the whole of the pentane vapor in the air. Still, we do not see how this is to be guaranteed; and when a second portion of pentane is poured into the holder, we deem it possible that it may meet with some residual unvolatilized pentane, and so the light of the flame may be a little enhanced. We do not put this as an objection to the pentane test; all we would say is, that the objections which appertain to candles will apply with equal force to the hydrocarbon test, which is really a candle test in disguise. Doubtless, as stated by Mr. Harcourt, the testing of gas by candles is affected by causes, the influence of which the actual Application of the method of average does not tend to eliminate. Different operators, we know, have different modes of proceeding. Some, as Mr. Harcourt says, turn down the tips of the candles; others trim the wicks. In this latter case, we hope they leave them burning for some considerable time before they begin testing, otherwise great differences are sure to be observed. Uniformity of usage with candles cannot be too rigidly enforced on gas testers; and if that be followed, as Mr. Harcourt says, "fairly concordant" results may be obtained.

It only remains to be noticed that the writer of this letter does not ask to have the system adopted on his own responsibility. He wishes to have it examined into and reported upon by a body of experienced gas examiners, who will inform the Board of Trade of the results of their examination and inquiry. Such a Committee, we believe, has been appointed, and we shall presently know the results they have arrived at.

The following is the letter by Mr. A. G. Vernon Harcourt, one of the Metropolitan Gas Referees, to the Assistant Secretary of the Board of Trade—

Sir:—I desire to call the attention of the Board of Trade to the untrustworthiness of the standard which is at present in use for estimating the illuminating power of coal gas.

I desire to obtain the sanction of the Board of Trade to the introduction at the testing places established for testing gas supplied by the Gaslight and Coke Company, the South Metropolitan Gas Company, and the Commercial Gas Company, of a more trustworthy standard.

Under the Acts of the above-named companies, the Gas Referees are charged with the duty of prescribing the materials and apparatus to be used within the testing-places for testing the illuminating power of gas. Soon after my appointment, in 1872, as one of the Gas Referees, in the course of experiments upon the effect of heating gas, with a view to its purification from sulphur, the inaccuracy of the usual photometric process was brought under my notice. In 1871 I began a series of experiments with the aim of devising a more trustworthy process, which I have continued with occasional intermission till the present time.

In the course of my experiments I have had occasion to make a large number of testings with candles of the kind ordinarily employed, and also with candles differing in diameter and in the structure or preparation of their wick, but coming within the definition of "sperm candles of six to the pound, consuming 120 grains of sperm per hour."

For some account of the results of these experiments, I may be permitted to refer to a paper "On a New Unit of Light," read before the Chemical and Physical Sections of the British Association, at its meeting in Plymouth in 1877, a copy of which accompanies this letter.

The existing system of photometric attempts to neutralize the variations in the amount of light emitted by standard candles by using two candles simultaneously, and by extending each testing over a period of ten minutes. The further provision that three testings shall be made daily, and that the mean result of the three shall be taken to represent the illuminating power for the day, though intended to provide for fluctuations in the quality of the gas supplied at different hours, really serves also to neutralize the variations of the standard candles.

This method of obtaining a fairly accurate result by taking the mean of a number of experimental results varying considerably from each other is rightly used, and leads to correct conclusions, when the experimental errors are likely to be evenly distributed, and when the whole series of observations is not liable to be affected by a common cause.

Thus, if a single candle were employed to yield a standard light, and if the correspondence between the light and that of a gas-flame were observed during one or two minutes, the variations in the results obtained by the same operator using the same candle in the same photometer would be very great. In the actual mode of working, the variations are not very great. According to my experience, it does not often happen that any one of a set of three testings varies by more than half a candle from the mean of the three. This is the case, even if a different pair of candles is used for each testing, when the candles are from the same packet, and the mode of operating is kept rigorously uniform.

In Appendix I., I have put together the results of a large number of candle-testings made in my laboratory with the view of obtaining a receipt for preparing a gas from hydrogen and pentane, which should burn, when consumed by a standard burner, exactly the illuminating power of 16 candles.*

* Important as are the appendices which accompany this letter, space will not admit of the[illegible]g given in the *Journal*; they occupy 10 pages of print of foolscap, and consist largely of tabular matter.

Such a gas might be used as a photometric standard in the manner which described and showed in a lecture before the Society of Arts on the 31st March, 1876.

Three testings were made of each sample of gas, stored in a small g holder, in quick succession, one after the other, so that the light given the gas did not vary, and the variation between the three results is d solely to errors of observation, which are inconsiderable, and to differen in the illuminating power of three different pairs of candles treated simil in every respect. The numbers have been corrected, as usual, on the assumption that the light given by similar sperm candles varies directly the weight of spermaceti consumed; and where the consumption of gas in any degree greater or less than 5 cubic feet an hour, a proportional rection has been introduced.

The conclusion which may be drawn from this large number of obse tions is, I think, that when candle testings are made with great unifor fairly concordant results may be obtained. It is, no doubt, owing t fact that concordance is attainable under these conditions that an ar of confidence is bestowed upon candle testings to which they are not entitled. In fact, the greater pains an operator takes to obtain concd results by working in a perfectly systematic and uniform manner, the significant and trustworthy do his mean results become.

The result of testing by candles of any sample of gas depends upon conditions beyond those named in the Companies Acts of Parliament the notification of the Gas Referees, and is effected by causes the infl of which the actual application of the method of averages does not te eliminate.

I will here point out a few of these, in addition to those mentioned accompanying paper.

1. Since the prescription of the Gas Referees of the apparatus to b in the Metropolitan testing places, which included a balance external photometer for weighing the candles used in testing, a new form of t has been substituted by Mr. Keates, chemist to the Metropolitan Ra Works, by which the candles are weighed *in situ* within the photo The plan of weighing the candles *in situ*, or of observing, without r or extinguishing the candles, the time required for the consump 10 grains of spermaceti, is both less troublesome and more accurat introduction is therefore a boon to the Gas Examiners; but I belie under a plan of lighted candles from a balance to the photometer out filling the cups of the candles with melted grease, and thus id the light of the candles, probably by diminishing temporarily the le wick within the flame.

2. Some operators make a point of trimming the wicks of their others of leaving them alone. I have known a difference of 2 ci be made in the illuminating power attributed to a sample of gas, by bending down slightly the wicks of the candles between a first and testing. A similar difference may be produced by cutting off the t wick.

3. The greater or less movement of the air around the candles in photometer, and the greater or less movement of the candles to an a box photometer, according to the habits of the operator, affect cons to the development of the light of a candle, and this, I believe, is on why open photometers sometimes give results less favorable to the box photometers.

4. The seals in which a candle has been extinguished, and which are left in the tubes, have been found to affect the light of the candle for 30 minutes and upwards, and to produce a difference of 2 candles in the result of a testing, or set of testings. Perfect stillness is ind to the accurate testing of gas by candles, and this, I believe, is on

le of much service in a few years hence." Has he given the slightest consideration to the result which would ensue supposing his prognostication to be fulfilled? Why, in fact, computation there is expended on gas undertakings in the United Kingdom alone no less a sum than £50,000,000, representing an investment of capital which is constantly earning the shares or stock to that amount are held principally by the middle classes of the community, and are a measure of the thrift of the people, which we, as a nation, have good reason to be proud. A large portion of the investment is in the hands of, or in trust for spinsters, widows, and others dependent on fixed revenue, whose whole or chief means of subsistence is derived from the interest they thus receive. The result of gas-works becoming "useless in a few years hence" would be to plunge vast numbers of the most deserving of the population in penury and distress, and this surely, even if the interests of science demanded it, would be a matter for deep consideration.

But there might be some show of justification for even such a calamity as this, if it could be proved that gas directors and the officials of our companies, as a whole, are the grasping and unscrupulous knaves they are sometimes represented to be. Take the Metropolis as an example, the Gas Companies of which the writer of the article holds up to scorn and contempt. "The Metropolis," he says, "is placed in a miserable position as regards a supply of gas, and before long public indignation may rise to such a height as to render it necessary to secure the administration of London out of private hands." I deny the preposterous allegation, and challenge the writer to make good his assertion. The gas supplied in London is of the highest illuminating quality, and of a most generous character. In this respect, as well known to some of the readers of the civilized world. The purity clause in the London gas Acts is a model of its kind. In existence; in no provincial or foreign town is anything like the same surveillance exercised. Does the writer of the article refer to the "fog nuisance" of the winter? Then he is surely unaware that the public lighting is managed and controlled by the Corporation and the Vestries, and all that the Gas Companies are required to do is to furnish the necessary quantity of gas of a given illuminating power, whilst the size and number of lights in the streets are matters entirely beyond what they have no voice, and are not allowed to interfere. In all vast industrial enterprises there will arise occasional causes of distrust and disagreement, and gas undertakings will be found, in the hands of corporations, companies, they are not excelled in their management by any other industrial undertakings. Of the London and Westminster Gas Companies, after all, are the representative purveyors of the gas to the Metropolis? I can say from personal knowledge that I have less of trouble in dealing with them than with any other, for ability and integrity, are as characteristic of them as of the Bank of England.

But what has all this to do with the electric light? Surely we can be gas shareholders and gas-employés, and even gas directors, without being influenced in the progress of science. The electric light will eventually supersede gas light in the theatres of the prophetic faculty, a mere matter of opinion. I am of opinion that it never will, for many reasons of a practical character. Lighting, and I have elsewhere given substantial reasons for my belief. The electric light has its uses, but it is not in the very remotest degree a rival to gas lighting. The writer of the article quotes the illuminating of Regent Street, Sunday as a successful application of electric lighting. He could not have selected a worse example, for after dodges and contrivances, and was almost useless on every road by both the electric and the gas light at midnight. Again, the writer of the article in the most inconsistent manner, says that it is quite beside the question to discuss the "cost of the largest gas lighting compared with electricity." The truth is that of all the gas companies in England, during the year, not one of them has proved greater foes to gas than the electric light, although it would, in my opinion, have been altogether to the interest of science if they had not. Improved burners, restricted supply, but it is safe to predict they will never be the source of remarkable economy of light. Private enterprise alone can be trusted to entirely for the cheap and abundant blessing of gas light.

I am, Sir, your obedient servant,
JAMES NEWMARCH.
5, Norfolk Street, Manchester, Aug. 16, 1879.

Improved System of Street Lighting by Gas.

Coal Trade Journal 28/11/79

Mr. B. Hill, civil engineer to the Bristol, England, corporation, has invented a greatly improved system of street lighting by gas. Dealing with the present burner, which consumes five cubic feet of gas per hour, and is in general use, he divides the light into two jets, each consuming two-and-a-half feet of gas per hour, but leaves the total consumption unchanged. Between these two jets, placed in each street lamp, he suspends a double convex lens, forming a powerful reflector, and the result is found to be an increase of lighting power to the amount of fifty per cent. Ordinary bats wings burners are used, and the only care required to insure a perfect light is a due adjustment of the suspended lens, so as to get the right focus and the full reflection of the light. When this is secured the jets, even at a distance, are very brilliant and have the appearance of globes of light. They illumine the foot path between each lamp with much of the effect of the electric light. At 150 yards the light, backed by the reflector, is very powerful. As the plan consumes no more gas than ordinary and the reflectors are of simple construction and of trivial expense, the corporation of Bristol is about to put the new system into universal use in the public streets.

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, SEPTEMBER 30, 1879.

Circular to Gas Companies.

THE results of the past half year's working of the Metropolitan Gas Companies, as shown in the accounts which are issued in anticipation of the half-yearly meetings of Shareholders, exhibit a continuous prosperity. Without referring at present to the operations of those Companies who are under the sliding scale, we may mention that two of those who were working under the Act of 1860 are, as may be supposed, able to pay full dividends, and carry forward a considerable balance. The London Company, for example, after bringing down the price of gas to 3s. 3d. per thousand feet, find themselves for the past half year with the balance of net revenue amounting to £30,880. After providing, out of this sum, for all preference charges, there remains to pay the dividends on ordinary capital a balance of £22,468. Now, as only £19,370 are required to meet the dividend on ordinary stock, it follows that there is left a balance of £3098 to be carried forward or placed to the reserve-fund. We note again with satisfaction that the details of the working accounts are remarkably good. The yield of gas per ton of coal was excellent, and the unaccounted-for gas is a relatively small amount. All concerned with the Company may be congratulated on the satisfactory condition of affairs, which does them much credit, and which will be duly capitalized upon to-morrow week, when the half-yearly meeting of Shareholders will take place. Notwithstanding the reduction in price, the rental continues to increase in amount, and, happily, the London Company had a good half year for the sale of residuals.

The Phœnix Company also had a successful half year's working. The balance of revenue for the past six months amounted to £53,116; and, after payment of full dividends on all classes of ordinary and guaranteed stocks, there is left a sum of £1716 to be carried forward. The continually increasing business of this Company necessitated their making provision for future needs, and to provide for them the Directors have in hand considerable additions to their coal stores, and a further extension of their carbonizing apparatus. By these means we may anticipate that the coming winter will be safely tided over, and probably, if matters go on quietly, there will be sufficient power to provide gas in abundance for the whole of the Company's limits for some years to come. During the past half year, 68,860 tons of common coal and 3,000 tons of cannel were carbonized and used in the Company's works, and the average yield of gas was over 10,000 feet per ton. Of this the greater part was sold, the unaccounted-for gas being relatively small. We are happy to say that in the report of the Directors no complaint is made of the want of sale of residuals. Coke, in fact, produced £32,982, which leaves a fair relation to the cost of coal; and the other residuals fetched good prices; so that the Company may well be congratulated on the results of their half year's business.

The accounts and report of the Directors of the Alliance and Dublin Consumers Gas Company have been issued in anticipation of the meeting to-day. The balance of profit for the past half year amounted to £52,427, which leaves the Directors the power to pay 10 per cent. dividend, and carry forward the sum of £2297, which will make their unappropriated balance £25,022. It is against the payment of full dividends and these appropriations that some Irish journalists protest. They suggest that the Shareholders should content themselves with a 9 per cent. dividend, and that any excess of profit necessary to pay the 10 per cent. rate should go in reduction of the price of gas. These good-natured gentlemen appear to forget that for several years the Shareholders received very small dividends, and for two years none at all. The large reserve-fund, we may take it, is as much a protection to Consumers as to Shareholders. It is because the Company are in possession of such a good reserve that they are enabled to reduce the price of gas they did at the beginning of this year, and, at the same time, protect the interest of the Shareholders. Up to this time, at all events, no proposition has been made for the payment of back dividends, so on that score the citizens of Dublin have nothing to complain of. As a matter of course, the Company still continues to be managed by the Corporation, whose modes of attack vary. At the present moment the contest is that—the reserve is the same is too high, while men of experience think it too low. To the Corporation the matter cannot be of much moment, while to the Company it would be a matter of serious importance. In any case, the Directors are endeavouring to obviate all accusers of complicity by reopening the present feeling-mains with others of larger capacity. As our readers know, a Bill promoted by the Company received the Royal Assent in the past session, which, among other things, enables them to manufacture and supply apparatus for the consumption of gas for other than lighting purposes, such as cooking and heating, and also for gas-engines for the production of motive power. Great preparations are being made for entering upon this business as speedily as possible. There can be no doubt that the business once begun will be extremely profitable to the Company. The apparatus will not perhaps bear any very great profit, but what we look forward to is a large additional demand for gas in consequence of its use. It is, we believe, the universal experience, that the consumption of gas is greatly increased wherever such appliances are adopted, and we hope that other Companies who obtained similar powers last session will exert themselves to bring gas-stoves and other apparatus more into use as quickly as possible.

The little Brixton Water Works Company had a pleasant meeting on the 24th inst. The business of the Company continues to increase, and would increase much faster if the Company could reduce the price of gas; but the difficulty and expense of getting coal to their works acts as an effectual barrier to any reduction, as all events at present. There seems to be a prospect that presently a new railway will carry coals to within an easy distance of the works, when cheap carriage may allow of some diminution of price. The districts of the Company rapidly improves, and nothing but

Gas Undertakings and the Electric Light.

We extract the following letter from the Manchester *Evening News*:

Sir,—I regret that I should have occasion to differ with many of the remarks contained in a leading article of the *Evening News*, treating of gas companies and the electric light. The tendency of such statements, if left unchallenged, is bad, and especially so in the present instance, for under a show of encouraging and assisting the progress of scientific discovery and improvement, the claims of justice and truth are entirely ignored. The writer expressed the belief that "gas undertakings are unlikely to be of much service a few years hence." How he gives the slightest consideration to the result which would ensue supposing his prognostication to be fulfilled? At the lowest computation there is expended on gas undertakings in the United Kingdom alone no less a sum than sixty millions pounds, representing an investment of at least one hundred and ten million pounds sterling; the shares or stock to that amount are held principally by the middle classes of the community, and are a measure of the thrift and self-denial of which we as a nation are justly proud. A large proportion of the investment is in the hands of, or in trust for, minors, widows, infants, and aged persons, whose whole or chief means of subsistence is derived from the interest they receive. The result of gas works becoming useless in a few years hence would be to plunge vast numbers of the most deserving of the population in penury and distress, and this surely, even if the interests of science demand it, would be a matter of deep consideration. But there might be some show of justification for even such a calamity as this, if it could be proved that gas directors and officials of gas companies as a whole are the grasping and unscrupulous knaves they are sometimes represented to be. Take the metropolis as an example, the gas companies of which the writer of the article holds up to scorn and contempt. "The metropolis," he says, "is placed in a miserable position as regards a supply of gas, and before long public indignation may rise to such a height as to render it necessary to take the illumination of London out of private hands." I deny the preposterous charge, and challenge the writer to make good his assertion. The gas supply of London is of the most ample and generous character. In this respect, as is well known, it is one of the wonders of the civilized world. The gas referees of the metropolis, Professor Tyndall, Dr. Pole, and Mr. Vernon Harcourt, who are appointed by the Board of Trade, are men in the foremost rank of science, and they certify week by week, through their examiners, that the illuminating power, purity, and pressure more than conform to the acts of Parliament by which they are regulated. The purity clauses in the London Gas Acts are the most stringent in existence; in no provincial or foreign town is anything like the same surveillance exercised. Does the writer of the article refer to the illumination of the streets? Then he is surely unaware that the public lighting is managed and controlled by the corporation and the vestries, and all that the companies are required and permitted to do is to furnish the necessary quantity of gas of a given illuminating power, whilst the size and number of lights in the streets are matters over which they have no voice, and are not allowed to interfere. In all vast industrial enterprises there will arise occasional causes of distrust and disagreement, but taking gas undertakings all round, whether in the hands of corporations or companies, they are not excelled in their management by any other industry in existence. Of Co London Gas Engineers (and they, after all, are the responsible purveyors of the gas of the metropolis) I can say from personal knowledge, and without fear of contradiction, that they are men who, for ability and integrity, are an honor to their profession. But what has all this to do with the electric light? Surely we can be shareholders and gas employees, and even gas directors, without being inimical to the progress of *science*. That the electric light will eventually supersede gaslight is, in the absence of the prophetic faculty, a mere matter of opinion. I am of opinion that it never will, either for general or domestic lighting, and have elsewhere given substantial reasons for my belief. The electric light has its uses, but they are in no way antagonistic to those of gas light. The writer of the article quotes the illuminating of Billingsgate Market as a successful application of electric lighting. He could not have selected a worse example, for after repeated trials the light there was condemned on every hand, both by dealers and customers, and was almost angrily hustled out of the place and the familiar gaslight reinstated. Again, the writer is quite beside the mark in his statement "that one of the largest gaslight and coke companies in London has obtained powers to illuminate the metropolis by electricity." The truth is, that of all the gas companies in Parliament during the year, not one of them has powers granted for supplying the electric light, although it would, in my opinion, have been altogether in the interest of science if they had. The Liverpool Corporation obtained powers to experiment upon and use the light under certain restrictions, but it is safe to predict they will never take advantage of the powers granted to them. Private enterprise alone can be trusted to undertake work of this kind, and we have private enterprise to thank entirely for the cheap and abundant blessing of gas light.

THOMAS NEWMARCH.

Pres. Manchester Ins. Inst. of Gas Engineers.

5, Norfolk street, Man., Aug. 18th, 1879.

The *Journal of Gas Lighting* comments as follows on the article to

In the Manchester *Evening News* of Monday, the 18th inst., an article appeared which displayed, if anything, rather more than the usual amount of ignorance of facts observable when writers in the general public press treat of special subjects—such as gas supply. For instance, the writer of the article referred to says: "One of the largest gaslight and coke companies in London has obtained powers to illuminate the metropolis by means of electricity," which is not a fact. He then goes on to remark: "Nothing much has been done as yet; but it is a significant sign of the times that such should be the case." A quotation follows from a London daily newspaper report of the speech of the Governor of The Gas Light and Coke Company at the half-yearly meeting of shareholders held on the previous Friday, when, referring to the improved system of street lighting carried out at the expense of the Company, he said: "It is now proved that if the public like to pay for it, we can give them a better light than the electric light will be, and at a very much reduced price." On this the writer remarks: "The views expressed by the Hon. Richard Howe Browne strongly suggest the idea that he is not entirely unacquainted with the adage, 'There's nothing like leather!' It would be difficult for the chairman of a gas company which, in bad times, pays 10½ per cent. to say anything through the medium of the electric light. And yet the efforts made and the powers acquired by the Company are calculated to excite doubts, if not of the sincerity of the belief expressed, at least as to the wisdom of the conclusions upon which it is based. It is absurd to suppose that the question can be shelved, or that scientific research should fail to discover means whereby electricity may be turned to further account in the interest of mankind. The world continues to move, whatever prejudice and self-interest may assert to the contrary."

It would be difficult to find more misstatements and misrepresentations in any column of type than appear in the article in question, and it must be viewed as a lamentable circumstance that the leading columns of a newspaper having the wide circulation of the Manchester *Evening News* should be open to writers displaying so much ignorance of the subject of which they treat.

Mr. Newbigging, however, in a letter which appeared in the *Evening News* the next day, ably replied to the article; and it would be well if gas engineers and others throughout the country, following his example, would make a point of writing and setting the true facts before the public, when remarks calculated to convey so erroneous an impression as the ones we have referred to are published in local newspapers.

[From the "English Mechanic."]

The Light and Energy of Electricity and Gas.

By J. T. Sprague.

Some very remarkable statements were made before the Committee of Parliament on Lighting by Electricity. These statements are embodied in the report, and having gone the rounds of the press without examination or comment, they will, no doubt, be adopted as settled facts. It is therefore very desirable that they should be examined, and that an understanding should be arrived at as to how far they are reliable, and in what sense they are true. We will therefore commence with the remarks of Sir William Thomson.

1746. We are anxious to obtain your opinion upon various points connected with electric lighting; perhaps you will let me go to the root of the matter, and ask you to tell us the energy which is used and exhibited in light in the production of the electric arc?—The energy which is actually used in the electric arc is about 1-horse power per 2,000-candle power. Of even more than 2,000-candle power, according to the dimensions and other circumstances of the electric arc.

1747. That is to say, 1-horse *power*, if fully employed, produces 2,000 candles or more?—Yes; 1-horse power actually in the electric arc; 1-horse power spent in stirring the luminiferous ether between the carbon points and on the surfaces of the carbon.

1748. Have you at all calculated the energy appearing as light in the case of the combustion of gas?—One-horse power of energy is the equivalent of gas produces about 12-candle power.

1749. And 1-horse power converted into electric light produces 2,000 candles?—Yes.

1750. As these are rather startling figures perhaps you will explain to the committee how you arrive at such results?—Sir William's *reply* is [illegible]

119

Regenerative System for Gas Light.

1879

Mr. F. Siemens, of Dresden, Germany, like his brother, a prominent electrician and inventor, has published in the *Verhandl. z. Bef. d. Gewerb.*, a valuable application of his regenerative system for gas-light. Starting from the fact that the intensity of the light is increased by an increase in the temperature of combustion, he designed a number of different styles of lamps in which the air for the combustion of gas is heated by the waste gases, the supply of air being regulated by the currents produced by the difference of the temperature of the air, the gas and the products of combustion. The lamp consists of three iron tubes of suitable diameters, placed one within the other, the upper portion of the lamp being enclosed in a spherical globe. The entire space inclosed by the different tubes is filled with wire netting, constituting what Mr. Siemens calls regenerators, and which serve for absorbing the heat of the products of combustion and for giving it off to the gas and the air for burning the latter. The central tube is used for conveying the gas, which enters it from below. The air is admitted from below into the annular space between the central and second tube, while the hot products of combustion descend through the annular space between the second and the third tube. By this means the heat absorbed by the wire netting in the outer tube will be conducted and reflected to the two inner ones, and serve to heat air and gas and increase the intensity of the flame. The products of combustion rise upward within the space inclosed by the glass globe, and then descend along its sides, until they reach the annular space of the regenerator, without impeding the flow of air or gas. Mr. Siemens has constructed the lamp in such a manner that the regenerator, having a disc shape, serves as a reflector at the same time. While the construction of these lamps is not such as to make the system readily applicable to single burner lights, it is destined to enlarge or maintain within certain limits the ground which gas has been rapidly losing in its competition with the electric light for the illumination of large spaces.—*Iron Age.*

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, OCTOBER 14, 1879.

Circular to Gas Companies.

WE were wrong last week, in speaking of the electric light as "a half-forgotten wonder;" for, before the ink was dry, an experiment was made with the Lontin system at the Aldersgate Street station of the Metropolitan Railway. This large cavernous building, it must be confessed, is very difficult to effectively illuminate. It could be brilliantly lighted by gas, if the Railway Company would go to the expense of a sufficient quantity, with suitable burners; but they have preferred not to make an experiment with the electric light. The lamps employed are eight in number, which are supplied with electricity by a Gramme machine, driven by a 25-horse power engine nominal, the distributor making 410 revolutions per minute, and the exciter half that number. As a matter of fact, the engine was only working on the Saturday evening, up to 14-horse power, which was sufficient to produce in each of the eight lamps a light said to be equal to 200 candles—more or less. With the Lontin system it is alleged that the carbons, of which we gave a description when the light was first introduced outside the Gaiety Theatre in the Strand, with a Serrin regulator, will burn at the rate of three inches per hour. The cost of the carbons, and the coal necessary to drive the machinery, is reckoned at less than threepence per hour. It is not to be expected, therefore, that gas can compete at this rate; but the figures we quote require substantiation. It may turn out that, after all, good gas light might at a little cost to wear is involved in the production of the electric light, furnish an illumination quite equal to that which is now said to flood the Aldersgate Street station. There is a talk that a large amount of undeveloped power lies dormant in the machinery, and this it has been proposed to utilize in lighting up the Metropolitan Meat Market. The machine now actuating the eight lights at the Aldersgate Street station is reported as capable of maintaining sixteen lights, which will have the same illuminating power as those at present in use—600 candles. About this we shall say nothing; but we turn with interest and curiosity to the experiments recently made by Professor Crookes, F.R.S., who is credited with having succeeded in obtaining, without the use of carbons, lights of small illuminating power, ex uno. Each one of these lights, it is said, will have the luminosity of three candles. Thirty of the lamps, it is thought, might be maintained with an expenditure of 1-horse power, at a cost of 1*d.* per hour, a penny per hour. Here, it must be confessed, we have the germ, at all events, of domestic illumination by means of electricity. Mr. Crookes is not the man to rest on his oars, but has a long and weary task before him ere he makes the electric light applicable to household service.

Further experiments in electric lighting have also been made by the Metropolitan Board of Works. We announced, some time ago, that a trial was to be made with the Jablochkoff system on Waterloo Bridge. Last Friday evening it duly came off. Ten lights were placed on circuit to illuminate the bridge—five on the western and four on the eastern side of the bridge, and one on the refuge at the Strand end. In addition to these, and in order to test the power of the machinery, five more lights were fitted up in the engine-shed at Charing Cross; thus making, with those already on the Embankment, six, five lights being maintained by a 20-horse power engine nominal. The five lights which were in the engine-room at Spring Gardens, and the entrance to the hall. Since the commencement of the experiment last December, up to the 9th inst., the length of cable laid down was 17 miles 361 yards. When the Board's offices in Spring Gardens are illuminated, the total length will be about 18¼ miles. Mons. Berly, the Ingineer to the Société Générale d'Electricité, intends shortly to experiment with electric candles of larger dimensions, giving lights equal to from 2000 to 6000 sperm candles, thus intimating to show that the Jablochkoff system can furnish a highly concentrated light if required.

But what of all this? Is the stronghold of gas lighting in the least interfered with when we have reports such as that presented at the half-yearly meeting of the London Gaslight Company, held last Wednesday? The report of the Directors, to which we referred a fortnight ago, contains facts which are all that could be desired. They show that gas is now so largely used for purposes other than illumination, that it is quite clear electricity cannot in any way affect the amount of its consumption. The question of the Company's amalgamation stands over for the present; but it cannot be long before a decision one way or the other will be arrived at. The London Company are solicited on two sides, and, if we understand matters rightly, are offered pretty much the same terms on both. It little affects the gas-consuming public in the Company's district whether or not they enter into a combination with the northern alliance, or whether it would be better to promote a complete southern alliance. To our mind, as we have repeatedly said, the London Company should be split into two parts, divided by the Thames. The Company's district this side of the river would be fully maintained as at present. On the opposite side, where, however, the Company are now doing a good business, a large district still remains to be, and will eventually be built over, and this, when accomplished, will add largely to the profits of the Company. The Governor, in his speech, a report of which will be found in another column, sends mention of the large increase in the consumption of gas during the past half year, it having been eighteen per cent. over that of the corresponding half of the previous year. This is a remarkable fact, and shows how little, after all, the electric light at present affects the use of gas. With results such as we have stated, the Company can afford to look upon the electric light with perfect equanimity. We report above two new experiments with the light, but they scarcely touch what we have all along called the stronghold of gas lighting. It must be confessed there is, in the discovery by Mr. Crookes, an approach, though only a very small one, towards domestic lighting; but the effect of this has to be verified by experience, and then we shall have to look seriously to the results of the new mode of illumination. It will not, however, affect us in the least degree. Supposing Mr. Crookes's discovery to be worked out to a success, so far as to supply a number of consumers of gas with those small lights, what would be gained? Obviously nothing at all. How many engines are to be employed, and where are they to be placed to supply light to the streets? A gas-pipe would furnish all that is required, and more than is offered by electricity, at much less cost, and engine power, with exciters and distributors, would be entirely dispensed with.

Parliamentary Intelligence.

HOUSE OF LORDS.

MONDAY, MAY 4.

Saint Leonard Local Board Bill—On the Order for Committee informed to-day that the respective petitioners against the Standing Orders are applicable to the Southampton Corporation Water Bill.

The Birmingham Corporation Water Bill, with amendments—Petitions against the Birmingham Corporation Water Bill referred to the Committee on the Bill.

Petitions against the Birmingham Corporation Water Bill presented.

Petition against allocation of Charges in Birmingham Corporation Water Bill presented from the Corporation of Wigan.

TUESDAY, MAY 5.

The Westgate and Birchington Water Bill was reported without amendment.

THURSDAY, MAY 7.

The Llandudno Improvement Bill was considered and agreed to.

Great Ormes Head Tramways Bill, as amended, was considered—Petitioner against the Bill withdrawn.

Petitions against the Cefn Mawr Estate; Scotfield Water, from London, Tilbury, and Southend Railway Company.

FRIDAY, MAY 8.

Manchester Corporation Water Bill,—reported specially from the Select Committee, with amendments.

Dudley and Stour Gas Bill,—Queen's consent signified, and Bill ordered to be reported from Select Committee, as amended.

Reported from the Select Committee, with amendments,

Glasgow Corporation Water Bill,—reported from the Select Committee, with amendments.

Dudley Sewage Bill,—reported without amendment.

Portsmouth Corporation Water Bill, Bromley Gas Bill,—read a second time, and committed.

Wenlock and Birmingham Water Bill,—read the third time, and passed.

HOUSE OF COMMONS.

MONDAY, MAY 4.

Colchester Water Bill.—The Examiner's report—"That the Standing Orders have not been complied with in the case of the petition for additional powers to the Colchester Water Bill," was referred to the Select Committee on Standing Orders.

Tay and Forth Navigation Bill.—The Examiners Report that the Standing Orders applicable to this Bill have been complied with.

The Torquay Bay Water Bill was read a second time, and committed.

London Sewage.—A petition from Plumstead, for leave to bring in a London Sewage Bill, was presented.

Resolutions to withdraw their petitions against the following Bills were communicated to the table by their petitioners:—Bill 7; Leicester Gas, from the Corporation of that town; Bill 8; Leicester Gas, from the Leicester and North-Western Railway Company; Bill 9; Preston Corporation, from the Midland Railway Company; and Wombwell Local Board, from the Midland Railway Company, Incorporated, and Wombwell Local Board, from the Wombwell Local Board; West Kent Main Sewerage, from the Dartford Rural Sanitary Authority.

TUESDAY, MAY 5.

Llandudno Improvement Bill,—read the third time and passed, with amendments.

Houghton-le-Spring District Gas Bill,—as amended, considered; to be read the third time.

Bills read a second time, and committed.—Blackpool Extension and Improvement, Leicester Corporation, Newcastle-upon-Tyne and Gateshead Gas.

Resolutions to withdraw their petitions against the following Bills were communicated to the table:—Bill 10; Leicester Gas, from the Leicester and North-Western Railway Company; Bill 11; Preston Corporation, from the Preston Improvement Commissioners; Bill 12; Wombwell Local Board, from the Wombwell Local Board.

Petitions against the following Bills were referred to a Select Committee:—Bill 13; Wombwell Local Board, from Elsecar, Wentworth, and Hoyland Gas Company.

Petition against Bill 14; Walton-le-Dale Local Board, from the Corporation of Preston, except as against clause 6.

Petitions against the following Bills were referred to the Examiner:—Bill 15; Taylor's Gas, Alliance and Dublin Consumers Gas, and Lots-worth Gas, from the Portsmouth Corporation Water Bill, Mr. H. Jenkins, and Mr. Hawksley to meet on Tuesday, May 12.

WEDNESDAY, MAY 6.

Resolutions to withdraw their petitions against the following Bills were presented:—West Kent Main Sewerage, from the Rural Sanitary Authority of Dartford; Local Board, from Elsecar, Wentworth, and Hoyland Gas Company.

Preston Gas Bill.—The Issue stated of the following petitioners against the Bill was disallowed:—Of Walton-le-Dale Local Board; Of Corporation of Preston, except as against clause 6.

THURSDAY, MAY 8.

Gas and Water Provisional Orders Confirmation Bill,—read a second time, and committed.

Resolutions to withdraw their petitions against the Nottingham Corporation Bill were presented from—By Thomas Allwood Mann, Of Thomas Lowe and others.

FRIDAY, MAY 9.

Colchester Water Bill.—The Standing Orders Committee reported "That in the case of the Colchester Water Bill, petitions for additional powers to the Bill, the Orders ought to be dispensed with, and that the petitioners be permitted to prosecute their additional powers, if the Committee on the Bill think fit."

Hoyland Gas Bill.—Bill read the third time, and passed.

Houghton-le-Spring District Gas Bill.—read the third time, and passed.

Wenlock and Wellington Water Bill.—as amended, considered; to be read the third time.

Tay and Forth Navigation Bill.—The Examiners reported that the Standing Orders had been complied with in the case of the petition for additional powers to the Bill.

Standing Orders Committee.—Sir Edward Colebrooke discharged from the Committee, and Mr. Arthur Peel appointed in his room.

Bills read a second time, and committed.—Aire and Calder Navigation, Dearne and Dove Canal, Warrington Corporation, Wearside District, Tay Association, Hereford Gas, Warrington Corporation, Wearside and Hebburn District Water.

Petition was presented from Henry Rose Dixon himself and the Rev. Edward Penrose Hethersall, Jun. Rector of Rumbold Light and Water Bill.

Mr. Newdegate presented a petition against the Bill, praying that the Bill may not be passed until the Report of the Select Committee on the Law of Property and Conveyance of the Ecclesiastical Commissioners, and a resolution for abolishing their public patronage have been considered.

A petition for and against the Bill was presented from the Rev. Thomas Carr and others.

Newcastle-upon-Tyne.

LONDON GASLIGHT COMPANY BILL.

On the motion of Mr. CHARLES FORSTER, the order that this Bill be committed was read and discharged, and the Bill withdrawn.

THE METROPOLITAN AS REGARDS ILLUMINATION BY ELECTRICITY.

(Continued from page 1.)

A Select Committee, consisting of Mr. Tollemache, Mr. Hardcastle, Sir Thomas Bateson, Mr. Adam, Mr. Alderman Sir Robert Carden, Mr. Ayrton, Mr. Hanbury, Mr. Mayhew, Lord Elcho, Mr. Arthur Peel, Mr. Torrens, Mr. Tollemache, Mr. Spencer Walpole, and Mr. Whitbread, was appointed by the CHAIRMAN.

Mr. Colonel Wilkins, Clerk, attended.

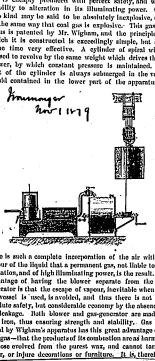
I am a Civil and Consulting Engineer, a Member of the Society of Telegraph Engineers, and of the Physical Society of London. I was the first to receive the Gramme machine in England. It was brought over in 1873 by Mr. Werdermann, the machine that was used in the shock brought in 1851 I designed the machine that was used in the shock brought in 1851 I designed the machine that was used in the shock brought in the Houses of Commons. The special difficulty in connection with that was getting the light to bring a signal light to show that the shock was sufficient to do the work. I designed the light that was used to Members outside the House. I designed the lamps which were used in the Committee of Works made in the Houses was very and the Prince Consort's Committee of Works made in the Houses was very and the Prince Consort's Committee of Works made in the Houses was very and the Prince Consort's

...ation in favour of the electric luminary, no further addition to the working staff is necessary.

"By Lord Lovaine:—It appears desirable, for a complete coast light and fog signal establishment, that the highest possible intensity of the light be available for covering the sea between the two-mile zones of the light be geographical light range (which range is typical of the "visible" horizon) and the distance at which the atmosphere ceases to be penetrable. From experiments made with the electric light, and with the Fresnel lenses in use, relative to the penetrative power of the light in thick weather, it is ascertained that the electric light, as at present applied, would be visible at the full French lighthouse authorities and the Trinity House, at the same distance such as double lights, I conclude that the strongest light which can be made by the electric light, with all the accessories and appliances, is important, and all experiments at the fog signal sound range of maximum intensity, would be visible at the full geographical range of maximum intensity, would be visible at about 2 miles. Further, in thick weather, when the visible range, the electric light would be visible at about 60 miles, the range of 70 miles. Although the results would be visible at its full intensity during long intervals of the atmosphere, it is believed by increased light appear double when compared with the power expended on the transmission of the double light, with 6° of artificial divergence in the vertical plane, being equal to the light delivered at equal to 9°3. The results seem to be confined to the vertical plane, the results seem to approximate, as the diaphragm is made more complete, effect noted as "double" may nearly to an equal to the double divergence, to the old light, the "double" may nearly to an equal to the double divergence, to the old light, the "double" may nearly to an equal to the double divergence, to the old light, the

WIGHAM'S PATENT ATMOSPHERIC GAS-MACHINE.

THE merits of air gas for illuminating purposes are well known. Gas of this kind is, indeed, no novelty—it is nearly as old as the century in which we are living. We show, however, a diagram of a new apparatus by which carbonetted air is cheaply produced with perfect safety, and without liability to alteration in its illuminating power. Gas of this kind may be said to be absolutely inexplosive, except in the same way that coal gas is explosive. This gas apparatus is patented by Mr. Wigham, and the principle upon which it is constructed is exceedingly simple, but at the same time very effective. A cylinder of spirit wires is caused to revolve by the same weight which drives the air-blower, by which constant pressure is maintained. One part of the cylinder is always submerged in the volatile liquid contained in the lower part of the apparatus, and



there is such a complete incorporation of the air with the vapour of the liquid that a permanent gas, not liable to condensation, and of high illuminating power, is the result. The advantages of having the blower separate from the gas-generator is that the escape of vapour, inevitable when but one vessel is used, is avoided, and thus there is not only absolute safety, but considerable economy by the absence of this leakage. Both blower and gas-generator are made of cast iron, thus ensuring strength and stability. Gas produced by Wigham's apparatus has this great advantage over coal gas—that the production of its combustion area harmless as those evolved from the purest wax, and cannot tarnish silver, or injure decorations or furniture. It is, therefore, peculiarly suited for the illumination of private residences. J. Wimshurst & Co., of 19 Great George Street, Westminster, are the sole manufacturers of the Wigham apparatus.

such distinct, and having values to regulate the coal and cash for gas, for which purpose our engineers have furnished us with some excellent valves. Many attempts have been made to do away with or supersede the hydraulic main, and to employ clever and ingenious contrivances instead, either partially or wholly self-acting or otherwise—for either. Mainly as to have made meeting the seal from the dip pipes.

Many of these have failed from the advisability of forsaking old tools; but none so reliable, which, when properly working are old friend the hydraulic, which, when properly working are old friend the hydraulic, and it seems to me that [illegible] is, after all, the nearest line to one to given, when we do just reason for its retention. Its risk, expense, and trouble connected with the risk, expense, and trouble connected with the dip pipes. In hydraulic mains we have various plans for regulating the seal of dip pipes, and four of the best known of these are, I may mention among them Wilson's patent, with his contracted and movable tar chamber, its division between each dip pipe, and its most ingenious but very complicated self-acting "anti-dip reliever."

GAS CONDENSERS.

And now, passing on to the condensing apparatus, which in the early days of gas making, and even at present, was a very simple yet effective affair, the gas, passing through a series of perpendicular pipes, was cooled, and dropped the cooler matter on it reached the next stage; and I may say when this condenser is constructed so that the gas can be changed so as to leave the entrance and exit from either end, a great amount of cleaning is thereby saved, as the gas when at a certain temperature will keep the pipes clean. Now we have the condenser in many forms, horizontal or vertical. The vertical is not also a very efficient plan, in the wall condenser, which, in many instances, is carried all round the walls of the works, thus saving space, which in most works is not overplentiful. We have also the perpendicular pipe condenser, with the internal air pipe, which gives a large cooling surface to this class of gas. The box condenser, with its contents consisting a current of air through them, the gas to be cooled passing in both in the form of a screw, so that the figures formed by the gas and air currents are like with the current of gas through the sandwich of the cell, and in many cases a flow of liquor is kept up—generally water, these pipes, in some cases with the flow of gas, and in others against it. This seems to be a desideratum of condensation—either to let in the air or water with the gas, or the gas with some cases underground, with a view to carry the condensed liquors as far as possible with the flow of gas, and thereby to let in its purification, by taking from the gas further impurities. One gas engineer has applied the principle of the screw condenser to the ordinary condenser. It does its work most effectively. We have, however, four valves of a small size to the gas leaves the hydraulic main, especially from its liquor, or they will, and the flow of gas is perfect, giving and the tar and liquor at the risk of improved cleaning the gas, and thus be a fair field for the Jeffrey & Young process, in converting the crude liquor into rich vapor to be picked up, and excited the gas for light, which I should have been sent out of it. And while here we are leaving we have at the same time made progress.

WASHERS AND SCRUBBERS.

And now we have washers and scrubbers, such as there were in the early days of gas lighting. These two processes are very alike, and of the present day are combined and included in the best of works. The old form of washer, which can remember was a vessel with a mixed chamber and one, having its cover studded with rows of small inch, through which the gas passed, washing the water, and forcing it forward to the mixed chamber, [illegible] and passing through a succession of cells and flows. The scrubber was a washer, pure and simple, which I thought had long since had its day, but as it undoubtedly took precedence of the washer, I again revived, and being added to a "patent scrubber" of the early days, consisting of wooden frames filled with boards, bricks, coke, and wooden shelves were used, but only to a small extent. We now have many forms of apparatus for washing the gas—the gigantic lower scrubbers, filled with thousands of feet of coke, with the liquor constantly flowing over for distributing the liquor over the wide-extending material, [illegible] and displacing large surface for the easy passage of their means of gas. Other scrubbers, I might mention, Bills which are on which form we see, if we can get it to do it work [illegible] by dividing gas into minute streams, and [illegible] the particles of it may come in contact with the scrubbing material, thus washing it of its impurities, and in a certain form, will become a most unmodified liquor. Already we have taken strides in this direction, and have a patent scrubbing machine, guaranteed to work with a pressure of 1 inch, and consists of small discs, with arrangements of perforated iron plates, either washed by a shower of liquor or dipping on a shaft, and which will be so simply constructed that every gas engineer will be able to work out any increase of his present capacity.

GAS PURIFICATION.

Then we come to purifiers, when we get rid of the bulk of our impurities—subjoined liquors, and [illegible] and [illegible] with the gas, which, when [illegible] to small degree, [illegible] no doubt, by the necessity to the [illegible] the removal of the ammoniacal compounds, more especially to our lower manufacture, we have had to devote our attention to the [illegible] and improvements following in quick succession, and [illegible] have proved [illegible] to [illegible], and it is here, however, that we have [illegible] in the matter of purifiers we have another question. [illegible] purifiers by their [illegible] changes in their [illegible], so as to utilize the purifying material, also position and [illegible] may be effected. The first arrangement of purifiers we have in use is that by placing a quantity of lime in two with [illegible] the gas in such a manner as to [illegible] thoroughly, we have had a [illegible] enough, but gave us the idea for our first purifier, the first one ever, which is the most effectual one, however, for the removal of the carbonic acid and sulphuretted hydrogen, but [illegible] the ammoniacal compounds, and the moist gases required to [illegible] the [illegible] considerable, that now this form of purifier is of rare occurrence. Then we come to the dry lime process, which is now generally used, and the purifiers for same, and [illegible] for lifting and [illegible] which otherwise would be a work of no small difficulty, and valves with which we can control the gas and arrest its progress [illegible] and [illegible] alone we have many beautiful [illegible] valves, [illegible] purifier, as far as apparatus is concerned, we may [illegible] that we have [illegible] remember when purifiers were used without valves and covered continuously—the first, always first, and the last always last—consequently [illegible] the [illegible] was stopped when they were being cleaned and filled with fresh lime. When we look back and see the former means of changing the passage of the gas to and from the various purifiers, and [illegible] of from those vessels by means of the series of side valves attached to the pipes—a costly, intricate, and dangerous plan—and the now simple method by means of the hydraulic valve first, of the many forms of fixed valves now in use, we cannot help noticing progress great indeed.

[illegible] the years oxide of iron has become very generally adopted for the purification of gas, even more so in England than in this country, but that [illegible] to that of [illegible] for effectiveness, or I question if in many cases it is on the score of economy. In [illegible] we have various [illegible] where the color from spent lime is found so objectionable, as to [illegible] the manufacturer to adopt oxide of iron, as here the carbonic acid where the oxide is used, and this lime, when spent, has very little smell, if any. Another great advantage in the use of oxide is that it can be used over and over again, until the sulphur forms nearly 50 per cent. of the mass, and then it can be treated by the chemist, who extracts the sulphur for commercial use. Patents have been secured, and in some works adopted, whereby the oxide is revivified without removal from the purifiers. Where this is done a great saving is effected, otherwise the labor account incurred in working for extinction is considerable. We are promised yet another advance in the purification system, and that in the revivifying of the oxide, and I may say that a gentleman who has either seen the process or practically tried it, [illegible] for satisfactorily [illegible] the [illegible] is now in several works, giving promise of success, and I may say that [illegible] to-day from seeing [illegible] a gentleman who has either seen the process or practically tried it, [illegible] for satisfactorily [illegible] the [illegible] is now in several works, giving promise of success, and I not stop here, for it has been sold by chemists and eminent engineers, and [illegible] to [illegible] the [illegible] can be conducted in closed vessels, and already we have made, in the old of progress, but profit.

SUBSTANCES FOR REMOVING IMPURITIES.

We have the exhauster and governor, neither of which was in use in the early days. Both are now indispensable in every well-arranged work, and I feel that the latter should be found wanting, unless, as in some cases, the use of different governors for different [illegible] for satisfactorily [illegible] the [illegible] and very clever and serviceable forms of apparatus for controlling the pressure of gas, and [illegible] the [illegible] have drawn from the field of labor, yet the governor, in its various forms, has done much to [illegible] the [illegible] in reducing the pressure to an even standard, and equalize the same at other times, thereby enhancing the value of the gas to the consumer, and [illegible] more and more to the testimony and wisdom is now to consume gas at very [illegible] pressure can only be regarded as [illegible] large mains and services, accompanied with a like increase on internal fittings of all kinds.

GASHOLDERS.

And, gentlemen, when we come to the gasholder we can certainly make progress, for the gasholder is at other times of the present day, and those in the early days, when the holder was considered a [illegible] and [illegible] the [illegible] among buildings for fear of accident, we, and even the outsiders, [illegible] to the advance we have made. And again, looking at the enormous holders now in use, capable of storing not thousands, but millions—and one holder which is being constructed capable of containing over 3,000,000 feet—this, gentlemen, is a great stride indeed, and shows the confidence of the manufacturer, to which it appears they is no limit, either in point of [illegible] or size.

It has been asked, and made a subject for a prize paper, "Is the gasholder a necessity?" and what has been the [illegible] elicited for them?" An attempt was made on paper to show how this could be done by the building of such large holders as are noted, shows that we are far from the realization of such a [illegible].

MAINS AND SERVICE PIPES.

Should the day come when we are called upon to supply 10 candle gas instead of 16 candle, as we do at present, we shall [illegible] be required in our plant, with larger mains and services. The [illegible] should induce us, as I already [illegible] to [illegible] the use of small services and [illegible], and, if possible, to [illegible] the [illegible] of [illegible] pipes, and [illegible] the [illegible] of [illegible] pipes, knowing that, to secure a good supply and proper consumption, we have [illegible] to do this cannot be large, or the pressure with our many improved burners too light. I myself do not think that, as far as [illegible] is concerned, it is [illegible] to [illegible] in illuminating power will be necessary, or be desired, but [illegible] increase in general use we need to have [illegible] than gas, and from this fact we would gather that our [illegible] of [illegible] gas engineering is to devise and adopt any and means that will enrich our present gas from our present make, and [illegible] any that our consumers use the same as at present [illegible] for its proper combustion, so as to get [illegible] of a given quantity of gas, and [illegible] of light [illegible] [illegible] any improvements in the various appliances, so that the [illegible] be [illegible] and [illegible] and [illegible] light secured from the [illegible] And I would [illegible] that at present they have anything [illegible] [illegible] [illegible]

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, NOVEMBER 18, 1879.

Circular to Gas Companies.

We may commence the "Circular" to-day by correcting a statement made last week, when referring to the extraordinary meeting of the United Gaslight Company, recently held. We stated that the Companies Clauses Act, 1863, only allows four per cent. interest to be paid on debentures, overlooking the fact that the Amendment Act of 1869 removes this restriction, and enacts that—"Part III. of the Companies Clauses Act, 1863, shall be read and have effect as if the following words, that is to say, 'not exceeding the rate mentioned in the Special Act, and if no rate is prescribed then not exceeding the rate of four pounds per centum per annum,' had not been inserted in section 22 of that Act; and any Special Act of a Company passed before the passing of this Act prescribing any rate, shall be read and have effect as if no rate had been prescribed therein." *The rate of interest, therefore, is at the discretion of the Directors, unless a rate be prescribed in the Special Act.*

The daily papers of last Saturday contained the usual "Notice of parliamentary notices of measures to be submitted in next session of Parliament." The Bills [illegible] *that put forward by the Corporation of the City of London.* The co-operation of the Metropolitan Board was invited, but that body, at their meeting last Friday, *declined to join in the enterprise*, and we now do not know what will become of this projected Bill, the object of which is to alter and amend certain clauses in the Acts of The Gaslight and Coke, The Commercial, and the South Metropolitan Gas Companies. The alterations proposed to be made mainly relate to the fullness and pressure that may be incurred for defects in illuminating power, purity, and pressure; but there is, at the same time, notice given of an intention, if possible, to alter the illuminating power, of course in an upward direction. We do not think we need say more on this matter, for since the Metropolitan Board, who are alone concerned with the Commercial and South Metropolitan Companies, decline to join in promoting the Bill, it will probably be dropped. The Corporation of the City of London are interested in The Gaslight and Coke Company only, and they have accordingly, on their own account, given notice of a Bill to alter and amend certain clauses in the Company's Acts relating to testing and testing stations, and to make further and more effectual provision as to testing the purity, pressure, and illuminating power of the gas supplied within the City, also as to the position and number of the testing-places. It is, of course, desired to alter the present mode of measuring deficiencies and penalties, and to impose new ones. The notice also proposes to give further powers to the Gas Referees.

It has been known for some time that the Phœnix Company have it in their minds to erect extensive works not exactly in rivalry of those at Beckton, but still on a large scale, nearly opposite that station, on the Kentish side of the river. They gave notice of a Bill to acquire for the further purpose eighty-six acres of land on which to erect manufacturing and storage works, and for the conversion of residual products. The Bill will further be to empower the Company to raise additional capital. The Company will necessarily go in for the Beckton trade, and, we presume, nothing else. It is further desired to manufacture and supply apparatus for the use of gas for other than illuminating purposes, and to supply ordinary gas-fittings. Other powers of amalgamation with all Companies within the Metropolitan district are also desired. This is significant, and makes us hope that before many years are over a general amalgamation may take place.

Seeing that there is, as our readers have already been informed, a scheme before the Board of Trade for the amalgamation of the Phœnix with the South Metropolitan Company, and in the event of its being confirmed, this measure will be proceeded with by the United Company.

Perhaps, under the circumstances, it was necessary for the South Metropolitan Company to give a "Circular" to the above. Accordingly, we find this Company announcing their intention of applying the same bonds as will be scheduled by the Phœnix Company, and for the same purposes. New capital will be asked for in the Bill, and this is to be raised by the creation of new stock, and by borrowing on mortgages or bonds. As a matter of course, the standard illuminating power of the gas to be supplied by the United Company will be brought up to that of the South Metropolitan Company; but it is only fair to say that the Phœnix Company, though legally bound to supply only twelve-candle gas, have for years past supplied gas equal, or nearly equal in power and purity to that furnished by the South Metropolitan Company.

We look for the happiest results from the combination of the Southern Companies which is foreshadowed in these notices, and in the scheme now before the Board of Trade. As consumers in the Phœnix district must in any case be considerably benefited, and have reason to be more than well satisfied, enjoy a long course of prosperity.

The London Gas Company give notice of a Bill very similar to that which they promoted but withdrew last session, to give them power to supply gas-fittings, gas-stoves, and other appliances for lighting, warming, ventilating, cooking, and purposes in lighting, and for other purposes. We hope the Company will succeed in obtaining the powers they desire, which cannot but be equally beneficial to them and to their consumers.

From the abstracts, in another column, of the Gas Acts passed last session to confer further powers upon Companies already incorporated, it will be seen that gas legislation, as we have already said, has taken an almost surprised turn. The peculiar features of the Alliance and Dublin Companies' Act is the power to supply in bulk different qualities of gas for any purpose. We can hardly guess what the Company intend to do. To supply gas of different qualities for special purposes would involve [illegible] establishment of plant, and we do not know that the Co-

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, DECEMBER 7, 1869.

Circular to Gas Companies.

THE Corporation of the City of London are just now much exercised as to the question of the alleged abnormal consumption of gas, and require to know why the gas bills of the Corporation should be so much higher than they were for corresponding periods of previous years. It is a fact belief in the minds of some members of the Court of Common Council, that the Gas Companies have in their power to force gas through pipes and meters, and thereby exaggerate the registration. Mr. G. C. Haweis curiously enough, brought been for the past year under the consideration of the Corporation of Dublin. Our neighbours at Guildhall may pick up the question exactly where it was left in Dublin. They have two officers who can set them perfectly straight on the matter. For example, they have the very able Chief Gas Examiner, Mr. C. Heisch, F.C.S., the gentleman who was consulted by the Corporation of Dublin, and who is as practically versed in chemistry as in physics; and they also have Mr. Sylvern, perhaps the most experienced man in the Metropolis for the examination of meters. The first-named gentleman's difficulty is to get enough, rather than too much pressure; and that it is only when pressure is very excessive that there is any need to prevent it, and then it can always be controlled by means of the finger-tap or a governor—an instrument, which should be placed in every establishment where the consumption of gas is large. Thus, if consumers will only take a very small amount of trouble, and go to a little expense, they may easily save themselves from over-pressure. Besides, it surely ought by this time to be a well-known fact, that what we had occasion a few weeks back to call an overdriven meter, always registers slow, to the advantage of the consumer and the disadvantage of the Company.

We are not surprised that a delusion on the point we have just mentioned should prevail in the gas consumer's mind—that if extra pressure be put behind the instrument, the gas must necessarily go faster; but this does not apply to gasmeters, in which the alternations of water-level form such an important item in the measurement. For example, the difference in registration of a meter with a pressure of five-tenths of an inch or three inches is exceedingly small, but that different results to cause the meter to go slow—that is, to register against the Company, and to the advantage of the consumer. All this will be made perfectly clear to the Court of Common Council of the City of London by their officers, and in the long run the gas-consuming public will be gratified by the reports of these gentlemen.

A year ago, as we have said before, a question of precisely a similar character was brought under the notice of the Gas Committee of the Corporation of Dublin, and a report has been furnished by the experts and officers employed. The secret of the increased gas consumption is to be found, it is said, in increased pressure; but if that be the case, it is really the consumer's own fault, in not regulating it. The Corporation of Dublin have consulted a large number of gas authorities in all of the principal cities and boroughs of the Kingdom, and these gentlemen substantially agree as to the cause of the apparent abnormal increase in the consumption of gas. The simple explanation is that the days have been short and dark, and consequently more light has been required. The Dublin Corporation do not seem to be satisfied with the information they have received from the experts—they have so far consulted, and secondly they desire one further reference—that a person well skilled in the matter should be consulted, not simply for the satisfaction of the citizens of Dublin, but for guiding the Corporation in regard to their future dealings with the various companies, when the "skilled" person has made his report, we shall no doubt learn much as to the so-called vagaries of meter registration, and the causes of excessive consumption. When the Gas Committee of the Corporation of the City of London, last year on this subject, first came over the present session, we shall also, no doubt, find that the conclusions they have come to will substantially the same as those at which the Dublin Corporation have arrived—viz., that if the consumers would only take the trouble to regulate the flames by means of the finger-screw, and at the same time use proper regulating appliances, there would be no cry of increased gas bills.

We have now before us all the parliamentary notices of the Bills to be brought forward in the coming session. It will be seen, as we go along, that some are duplicate measures. But as the numbers now stand, there are only in all twenty-nine applications for authority to incorporate Companies without statutory powers. We never remember, in any session of late years, so small a number of notices for special Acts of Incorporation; nor, we observe, the paucity of the number of Bills made up by applications for Provisional Orders. It may be a very general impression is abroad that the next will be but a short session, and that it would be a waste of money to promote measures which would never be considered; but there are some who cannot wait. Incorporated Companies are often in urgent need of further powers and additional capital: this we have fifteen Companies in this category. We have previously noted the numerous proposals by three of the large Metropolitan Companies, and the most important remaining are the Liverpool United Gas Company, who, as we read the notice, do not in this case seek power to raise additional capital, but only go in for increased borrowing powers. The British Gaslight Company, London, have given notice of a Bill to raise more money for their Stratford-shire Potteries station. The Malvern Gas Company give notice of a very comprehensive measure, which is to grant them power to enlarge their works, extend their limits, supply gas in bulk, and manufacture and sell gas-stoves and lighting engines, &c. The Wandsworth and Putney Gas Company, give notice of a Bill to sanction further loans for amalgamation purposes, and to raise additional capital. That well-managed undertaking, the Reading Gas Company, now require to increase their borrowing powers. The Company give notice of a Bill to enable them to acquire land upon which to extend their works, and for that purpose to raise further money. Reading is one of the most progressive of inland capitals, but little depends on manufactures.

TUESDAY, DECEMBER 14, 1869.

Circular to Gas Companies.

ONE is a very general impression among tourists who never get beyond the leading boroughtowns, that Paris is a illantly lighted city, and so, it must be confessed, certain tions of it are. The Boulevards, the Rue de la Paix, and public places in general, are much more brilliantly illuminated than anything we have to show in London. The ce de la Concorde shames our Trafalgar Square, while the anse d'Enfumement, even with the electric light, pales ore disgraced to the Champs Elysées. And yet it is not mere gas is better in Paris than in London. As a ter of fact, it is much poorer; but then it is dressed to ge competition. The Municipality employ its wealth, ority, and consequently low prices; and the Municipality ing these powers, you may actually have a visible illumination of the public establishments open much later than we are.

TO CORRESPONDENTS.

P. ST. JOHN PATENT GAS PURIFIER.—*Some of the earlier copies of last week's* JOURNAL *were printed before it was noticed that the numbers on page 836 had been inadvertently duplicated. The mistake would not cause any confusion, the lettering being the same in both pages, but it is to be regretted, and that Fig. 3 was the duplicate, and Fig. 4 the plan of the apparatus.*

No notice can be taken of anonymous communications. Whatever is to be inserted, must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of good faith.

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, DECEMBER 16, 1869.

Circular to Gas Companies.

THE Corporation of the City of London are just now much exercised as to the question of the alleged abnormal consumption of gas, and require to know why the gas bills of the Corporation should be so much higher than they were for corresponding periods of previous years. It is a fact belief in the minds of some members of the Court of Common Council, that the Gas Companies have in their power to force gas through pipes and meters, and thereby exaggerate the registration. Mr. G. C. Haweis curiously enough, brought been for the past year under the consideration of the Corporation of Dublin. Our neighbours at Guildhall may pick up the question exactly where it was left in Dublin. They have two officers who can set them perfectly straight on the matter. For example, they have the very able Chief Gas Examiner, Mr. C. Heisch, F.C.S., the gentleman who was consulted by the Corporation of Dublin, and who is as practically versed in chemistry as in physics; and they also have Mr. Sylvern, perhaps the most experienced man in the Metropolis for the examination of meters. The first-named gentleman's difficulty is to get enough, rather than too much pressure; and that it is only when pressure is very excessive that there is any need to prevent it, and then it can always be controlled by means of the finger-tap or a governor—an instrument, which should be placed in every establishment where the consumption of gas is large. Thus, if consumers will only take a very small amount of trouble, and go to a little expense,

HELD AT PHILADELPHIA, PA., OCTOBER 15, 1870.

[Continued from page 204.]

Mr. Nettleton—I am not aware that there are any other committees to report. I have a communication to the President of the Association which I think if proper to read. It is from the Philadelphia Gas Trust, and is as follows:

Gentlemen:—We cordially extend to the American Gas Light Association an invitation to visit all the gas works in Philadelphia under the control of the Board of Trustees.

Very respectfully,

THOS. ROBIN, Registrar.

Mr. Cartwright—I move that the invitation be accepted at the convenience of the members, and that the thanks of the Association be tendered to the Secretary of the Franklin Institute for the invitation.

Carried.

Mr. Helme—It might be proper to say at this point that the Secretary of the Franklin Institute, before we convened here to-day, requested that I should extend to the members of the American Gas Light Association an invitation to attend their monthly meeting, which takes place in this room this evening, at 8 o'clock.

Mr. C. A. White—I move that the invitation be accepted at the convenience of the members, and that the thanks of the Association be tendered to the Secretary of the Franklin Institute for the invitation.

Carried.

Mr. Helme—I think the members will find the meeting here to be very interesting. The general order of business is first gone through with, and then various subjects, of a scientific nature and otherwise, are brought up, discussed, explained, and illustrated. I would state that at this time a year ago we were all interested and excited upon the subject of the electric light. We did not know exactly where we stood. Up to that time large gas meters had not been experimented with to any great extent. We all knowthat some experiments have been made in this direction upon the outskirts of the Atlantic, and some of the large burners that were used themselves found their way to this country, and I desire to say, for the information of the Association that there is a large Wigham burner which is operated on Westminster Bridge in competition with the electric light, and which was decided to be preferable to the electric light. It is put up at Cherry street, in this city, and will be burned this evening and next week for the gratification of such members of the Association as wish to let it. It is a 28-jet burner. That gives us the very highest light of 12 cubic feet per hour, and a power of 420 candles, camel gas. It is a thing to see, and in our tests we have only been able to pass about 25 ft., and it seems to give a candle power of about 250 or 275 candles. It is to be burned to-morrow evening and every succeeding evening until 12 o'clock, at the point I have named, and if any one wishes to go and see how a of these burners operates, he will have an opportunity to do so.

The President—Doubtless every member of the Association will accept that invitation. It is very desirable to learn all we can about the new

Mr. Helme—It merely serves to give us an idea of what may be accomplished in that direction. It is a large light, and certainly very much preferable to the electric light.

Mr. Neal—I move that we proceed to the election of officers.

REPORT OF COMMITTEE ON NOMINATION OF OFFICERS.

Mr. Wood—On behalf of the Committee on the Nomination of Officers, I beg leave to submit the following report:

The Committee recommend for President of the Association, W. H. Price, of Ohio.

For Vice-Presidents, Geo. A. Hickenbower, Ohio; John P. Harbison, Connecticut; Geo. A. Mellhenny, D. C.

For Secretary and Treasurer, Wm. H. White, New York.

For Finance Committee, John S. Chambers, N. J.; Theobald Forstall, N. J.; S. Slater, R. I.

For Executive Committee, Henry Cartwright, Pa.; F. C. Sherman, Conn.; C. Wood, N. Y.; Geo. S. Hookey, Ga.; James M. Starr, Ind.; P. T. Ill.

Respectfully submitted,

A. C. WOOD,
GEO. DUNBIT,
P. T. BURNS,
THEOBALD FORSTALL,
W. A. STEARNS,
Committee.

Mr. C. A. White—I move that the Secretary be authorized to cast the ballot of the Association for the gentlemen named by the Committee as officers for the ensuing year.

There being no objection, the Secretary was then proceeded to cast the ballot for the Association for the gentlemen named as officers for the ensuing year.

Major Prosser was appointed teller.

Mr. Wood—I trust that it is understood by the Association that General Boone and Mr. Nettleton both peremptorily decline re-election.

Major Prosser—Mr. President, the teller appointed to receive and count the votes of the Association for officers for the ensuing year, begs leave to report that he has examined the ballots, and has found the gentlemen whose names were presented by the Nominating Committee to be unanimously elected.

The President—I have been in very great doubt whether I ought to thank you for this election. I certainly do thank you, gentlemen of the Association, most heartily and sincerely for this evidence of your good will and esteem; but I feel very greatly inclined to go again into the ranks. I have reached an age when I have got beyond the petty ambition to occupy a conspicuous position. I would rather have had the opportunity to be at liberty to make motions and talk a little, than to be tied up as I am in this place. It may be, however, for the good of the Association that I am tied up in this way. I might talk too much, and make too many motions. Since, however, you have chosen me to occupy this position, I will endeavor to perform its duties to the best of my ability, and I desire once more to return my thanks for this expression of your preference. [Applause.]

PAPERS.

The President—The next thing in the order of business is the reading of papers.

Mr. C. A. White—As there are but a few minutes before the hour fixed for adjournment, I think it would be proper to take up the reading of papers at this time. If a paper is read now, and we take a recess until 2 o'clock, many things which might present themselves to our minds as the paper was being read, will have been forgotten during the intermission. It therefore seems to me to be proper to defer the reading of the papers until we assemble this afternoon. I think we had now better adjourn until 2 o'clock, unless there is something which requires our special attention.

Capt. White—Before that motion is put, I desire to say that I think the Association has overlooked one very important matter. The President and Secretary of this Association, who have served so so faithfully and acceptably for the past four or five years, now, of their own free will, retire from office. It seems to me, sir, that we should express our manners if we allow those gentlemen to step down from the positions which they have filled from year to year to our home and abode, without expressing to them our sincere and hearty thanks for the manner in which they have administered the duties, oftentimes onerous, of their several offices. I therefore move you, sir, that the thanks of this Association be tendered to the retiring officers—to our honored President, Gen. Charles Boome, and to our able and efficient Secretary, Mr. Charles Nettleton. [Applause.]

The President—I am sure that every member of the Association will respond most heartily to the motion that has just been made, and I am very glad that Capt. White has had the thoughtfulness to bring it to our attention. We certainly ought not to adjourn without expressing our high appreciation of the services rendered by the gentlemen who retire from office to-day. I am sure we will all of us gladly bear testimony to the high esteem with which we regard the honored gentleman who has filled the office of President, as well as to the efficient, zealous, and satisfactory manner in which the duties of Secretary and Treasurer have been discharged by the gentleman who now voluntarily retires from the office. I think that to him, perhaps, more than to any other man, is due in a large measure the success which has followed the organization of this Association. We have sometimes discussed our Secretary pretty freely—not in the way of criticism, but in the way of commanding upon the amount of compensation to which he was entitled for his services. A question has from time to time been raised in regard to the amount of his labors, but for my own part I do not think that the Association has ever really appreciated the amount of labor performed by our Secretary, and the obligations we are under to him for the very excellent position which we, as an association, occupy to-day. And while we all recognize and appreciate to the fullest extent the distinguished services which our President has rendered, I think we must all admit that to Mr. Nettleton, more than to any other man, is due the success which has attended our labors thus far. [Applause.] I am glad, gentlemen, that this expression of my sentiments meets with your approval. For my own part, I have never felt that the services of the Secretary have been very highly paid for; but in that I have had the misfortune to differ with

Proceedings of the Seventh Annual Meeting of the American Gas Light Association.

HELD AT PHILADELPHIA, PA., OCTOBER 16, 1879.

[Continued from page 276.]

SECOND DAY—AFTERNOON SESSION.

Mr. Wood (Syracuse)—I have had a little experience in the use of gas stoves, but I do not believe that the gas stove interests can be handled by individuals, but must be handled by gas companies. We arranged for the use of gas stoves, and give them to our consumers at cost price in our own men. We took particular pains, in the first place, to let the people in Syracuse know we had gas stoves by calling their attention to the fact. I invited a party of gentlemen to my office, and I brought a caterer there and had them a good, square meal. The scheme operated very successfully. We gave them a meal in courses—giving them broiled sand, broiled oysters, broiled steak, roast quarter of lamb, etc. We made gravy, and heated paper and washed the dishes four times. We set the table that number of times. As for the economy of them, I agree fully with the figures that Mr. Goodwin has given. I never tried any experiment to know what the cost would be in using coal and giving such a supper. The cost was $1.50 with gas at $2.50 per thousand. The fish and the meats were cooked extraordinarily well, and everybody was pleased with them. Among the party present that night I took particular pains that there should be the editor of our daily paper, as well as a Sunday morning paper. They gave us a very fine notice indeed and had notice in each paper. Contemporaneously with that I prepared an advertisement on the subject and put it in all the papers at once. I also printed it on the back of our gas bills, and sent them to our consumers, so that the people of Syracuse knew that we had gas stoves to sell.

I do not think there has been anything brought into our community that has attracted so much attention. The people are ready for it. I could not go into the street, and meet friends on business or socially, or even go to church on Sunday, without being asked about that gas stove; and even the minister, after hearing him preach a sermon, asked me about it. There is no trouble in introducing the stove to your consumers, and no trouble in selling the stoves if you bring them properly before the attention of the people. I have placed three stoves in the best houses in Syracuse, where they have large ranges of the most approved patterns, and the occupants of such houses have told me that they considered them the best article of furniture that was in use in the house, and the most convenient. Many of those people are using them through the winter.

As to the cost of running these stoves, I have not heard the first complaint from any one. We have prevented several bills, but no complaint has been brought to my attention in a single instance. I do not quite agree with Mr. Hinsley about the profits that gas companies are going to make by putting up these stoves. I think it costs just as much for his plant, and for every item which goes to make up the cost of making gas for cooking purposes as for lighting purposes. I think we include all the elements of cost in the manufacture of gas in making it for cooking purposes the same as we do in making it for lighting purposes. I do not know that I have anything more to say upon this subject. There is no trouble in introducing these stoves in my judgment, if you only let people know that you have got them. If you can once introduce them, of course it will make a very great increase in your consumption of gas. The first stoves we got some time in May or June.

The Secretary—How much has your consumption increased?

Mr. Wood—We cannot tell. Since the oil excitement has come on, some of our consumers have left us and bought oil stoves, and have been burning oil. But they have been coming back; the oil don't suit them very well. The consumption of gas in these stoves for that reason has been somewhat intermittent, and I am not able to tell what our consumption has been during the whole season.

Mr. Neal—I am informed by the Committee on Arrangements that the use of this hall has been given *free* to the *Association*. I would therefore offer a resolution that the Secretary be directed to express our appreciation of the kindness and generosity of the officers of the Franklin Institute in giving us the use of this hall *free of charge*, and that a vote of thanks be tendered to the officers of *the Institute for their courtesy*.

Carried.

Mr. Neal—I would like to state, on behalf of the Executive Committee, that since the recess of the Association I have received some application for membership. As I understand it, the business will be finished and the Association will adjourn at 7 o'clock to-day. It is therefore too late for the Executive Committee to take the proper action upon these requests for admission. I am sorry that they were not sent in before. I trust these applications will not fail to the ground, but that they will be presented at our next meeting. I merely state this in order that the gentlemen whose names have been proposed will understand it.

Major Dresser—On behalf of the Association, I wish to offer the following resolution:

Resolved, That this Association tender to the local committees its thanks for the most admirable manner in which every arrangement for the comfort of the members and the success of this meeting has been made by them.

Carried.

Mr. Starr—I understand that the results of the interesting experiments made by Mr. Goodwin are to be published in a separate pamphlet. I think it would now be a good time for the members to come forward and give their orders for these pamphlets, which are to be given to the people of the community in which they live. I would ask Major Dresser to set me down for 100. I want to distribute them among our people, and if this information is put in tubular form it will save a great deal of trouble.

Major Dresser—It will save a great deal of expense in the printing of these pamphlets if the members will indicate the number they want.

Mr. Starr—If we go in proportion to the size of the town, I suppose Chicago will want 100,000.

Major Dresser—I am not able to state just what the cost will be, but it will be trifling; and, of course, the greater the number of copies ordered, the less the cost.

Mr. Starr—I suppose the statements of Mr. Goodwin will be published in the GAS LIGHT JOURNAL, and Major Dresser will then know about what the cost will be, and he can make a statement in the columns of the JOURNAL so as to what it will be; and members can then send their orders to him by mail for the number of copies they desire.

Major Dresser—I think that will be the proper course to pursue.

Mr. Mellhenny—I desire to offer a resolution that the thanks of the Association be tendered to our worthy President for the very faithful and efficient manner in which he has performed the arduous duties of his office during this session. All in favor, please say "aye."

Carried.

Mr. Price—It is very well known that our friend Mr. Allen is here, and would like to make some remarks in regard to his particular system of making water gas, I suppose, or, at any rate, upon the subject of water gas. It is now somewhat late, and I suppose the members of the Association are a little weary; but I will put the question whether they will wait and listen to Mr. Allen or not.

Mr. Allen—I do not intend to occupy the attention of the Association more than 15 minutes.

The President—I think the gentlemen had better wait and listen to what Mr. Allen has to say.

Mr. Allen—Mr. President and gentlemen of the Association: The manufacture of gas is a science of no mean order, and it seems to me that the scientific principles upon which it is based should be discussed more fully than I have yet heard them.

I have heard a great deal said, and have seen a great deal written, with regard to the formation of naphthalin, which has been called the curse of gas making for many years. I believe I have never heard the question asked, Can a good illuminating gas be made without the formation of a particle of naphthaline? I have heard the subject discussed in regard to the removal of ammonia. I believe, under the process that has been in operation for 75 years, there has never been a gas works that has made gas without making ammonia. The question has not been asked, to my knowledge, "Can gas be made without the production of ammonia? So with sulphuretted hydrogen and impurities that are formed under the process ordinarily used.

Now there are certain chemical results produced in the manufacture of gas which depend entirely upon the temperatures used. There are two forces that a gas manufacturer employs—expansion and contraction, heat and cold. Without heat there is no light. The impurities in gas are nearly all made at low temperatures. Good gas—perfectly formed chemical gas—is made at a high temperature. Coal tar and oil are distilled, commencing from 212° and running up to 1000°. In the ordinary process you make about 12 gallons of tar per ton of coal.

Now, when your heats are down, ammonia is formed by one equivalent of nitrogen and three of hydrogen uniting over red heats. If you pursue a different course and have your heats are never lowered to red heats, you will have no ammonia.

Naphthaline is formed by a sudden change of temperatures. It is a crystallization of the elements subjected to heat. If by a given process you volatilize all the chemical proportions of the elements of gas, you will have no naphthaline. It is well known that in the production of illuminating gas there are about 100 simple gases that are combined together and form a compound which there are 40 hydrocarbons. You have in the ordinary coal gas

the force of men employed by the Providence Gas Co., who have charge of the gas-cocks and burners.

Alderman Smith moved the passage of the resolution, and asked for a call of the Board; but as screen prepared to act upon so im was withdrawn. It was th dent of Lights and the pres printed. Subsequently th copies of the documents fo rescinded the portion of th

[From the St. Louis *Gas-Light Journal*.]

The City of St. Louis vs. The St. Louis Gas Co.

Text of the Supreme Court Opinion in Full.

On the 23d ult., the Supreme Court of Missouri overruled a motion for a rehearing of this case on behalf of the city and affirmed the former decision. The St. Louis Gas Company will probably take possession of their property at once. What will be the final arrangement as to the affairs, etc., of the company is not yet fully known. The continuation of the decision in full, is this important case, is unavoidably crowded over till the next issue.—Ed.

Electric Light in Liverpool.

The Library Committee of the Liverpool Town Council seem to be very well satisfied with the result of their experiment in lighting up the Picture Reading Room by Electricity. It is admitted, however, that the effect is not all that could be desired. The lights will flicker, sputter, and hiss, and at the present moment there does not appear to be any effectual way of curing these eccentricities. We may mention here, in connection with Liverpool, that the electric light has been introduced on board ship, for the illumination of the saloons of large sea-going steamers. The *Mendora*, which from Glasgow to Liverpool with the light in operation, and it is entered in a donkey-engine will drive a Gramme machine, and we can see no obstacle they can only find a properly-constructed lamp that will give a steady light, and make no splutterings. Although we years ago pointed out that gas in the electric light a successful rival there, and have no wish to detract from its reported success.—*Journal of Gas-Lighting.*

Edison's Light in New York.

THE REPRESENTATIVES OF THE GAS COMPANIES DO NOT FEAR ELECTRIC LIGHT COMPETITION.

Chief Engineer C. V. Smith of the Manhattan Gas Light Company said yesterday:—"So far as I know, there is nothing in the recent developments regarding the electric light to cause the holders of gas stocks to lie awake nights. I am not speaking of the promises and alleged prospects of the electric light, but of what has actually been accomplished. * * * There is plenty of talk, promise, and prediction; but we have yet to see any one furnish a light as good and as cheap as gas. There has been no fright among the large holders of gas stocks—not even a flutter. There may have been some fright among a few small holders, but I am sure that if the fact of the recent sale of gas stocks had been known, there would have been a stampede of electric light competition. The more intelligent holders of stock keep pace with all the news as to the electric light, so far as they can, and are not in the least alarmed. So far as I know, the holders generally at the time, be any cause for it to fear. These investigations were not trivial nor superficial, but were as thorough as they could then be made. We expect to supply a large part of the people of New York with gas for a long time to come; and if anybody has any gas stock to sell at a sacrifice, there are plenty to buy it who think it a safe investment."

Charles Hoey, Secretary and Treasurer of the New York Mutual Gas Light Company said: "We have no confidence in the electric light yet. There is not enough of it used to amount to any competition with gas, and no facts are furnished on which to base a comparison of the cost of the two lights. It is nothing new to hear of plans of furnishing cheap light. Every month some inventor discovers a new method of burning gas more cheaply, gets a patent, and that is the last of it. You turn our gas in the gas office, although you have an electric light frequently on the outside of the building. Now, we are not going to get frightened until you have the electric light inside, and find that it is cheaper or better than gas. All the places where gas light is used. At present we are not alarmed about the prospective competition of electricity."

O. F. Zollikoffer, Secretary of the Metropolitan Gas Light Company said: "So far from becoming alarmed at the recent promises of the electric light, we are confidently expecting a gradual increase in the consumption of gas. The price of gas has been nothing to the composition of the different gas companies with each other that we are satisfied of its ability to compete with fuel for cooking and heating purposes. All the gas companies now make a reduction in price where large quantities of gas are used. There is a sliding scale of prices, so that when one consumes 100,000 cubic feet a month, the price is reduced one half, or to seventy-five cents per 1,000 feet. This, of course, tends to encourage the consumption of gas. We have been at much pains to inform our customers how they can use gas economically for cooking. The electric light man does not even think of that yet. We have a room with about twenty-five different patterns of gas stoves for cooking and heating purposes, where we show them in practical operation. It will be a good many years before the electric light can do anything like that. The use of gas for cooking purposes has probably been more developed in England than here, but our American manufacturers have produced some great improvements in gas stoves. We have a big gas stove in which you can roast two turkeys, bake six loaves of bread, and boil four pots all at once for seven cents an hour. I guess the electric light won't do that for some time. Our directors ordered a thorough investigation of the electric light last autumn. They employed chemists and practical men, and examined all the patents, and they could find no cause for alarm in the progress then made. There has been nothing since done that warrants a change of opinion, nor do I see anything in the course of the stock market to show any loss of confidence in gas stocks. Possibly the electric light may be practical for large spaces, for signal lights, &c., but for the purposes now requiring gas, you may say we are not think there is any immediate prospect of its being used. Our stockholders are not frightened. We expect to sell more gas instead of less."

At the Municipal Gas Light Company's office, the Secretary, P. Allen, said: "We can't tell what the electric light may come to, because the projectors of it do not make known sufficient facts on which to base the price of their light and cost. At present, taking all the scientific figures I can get, I do not see how they can make their light cheaper than ours. Certainly the price of gas has not been reduced on account of the electric light. We have heard many promises from Edison, but do not know what he can do yet. When we know that, we shall be able to say how it will affect the price and consumption of gas. But there are many practical details yet to be worked out. Even the electricians are divided in opinion about what he has done. When the experts disagree, how can we be expected to come to any conclusion? Possibly the electric light may succeed next year, and possibly its success may be fifty years off; at present we are not alarmed. When Edison shows us a cheaper and better light that can be used as generally as gas, it will be time enough to get frightened. The electric light is very pretty, but that is a long way from practical use in the lighting of dwellings, &c."

Representatives of several companies were asked whether there was any prospect of a consolidation, whether there was any talk of it, and they said but none were found who would say that they had heard of such a project.—*New York Sun*, Dec. 27.

Competition and its Results.

As a matter of interest at the present time, in connection with the proposed consolidation of the Brooklyn companies, we give the following, which appeared in the Brooklyn Eagle, in January, 1870.

It is good evidence, and shows exactly the usual promises made to get a good hold.

The consolidation, if carried out, only gives about a million and a quarter to the heirs, assigns, successors, etc., of the Mutual company then born.—Ed.

BROOKLYN, January 15, 1870.

To the Honorable, the Common Council of the City of Brooklyn:

Gentlemen—I have the honor to inform your Honorable Body that the undersigned represents a company composed of the citizens of the city of Brooklyn, which has been organized under the general laws of the State of New York, passed February 16th, 1849, and intended for the purpose of manufacturing illuminating gas in the city of Brooklyn, said company to be known and designated as the Mutual Gas Light Company of the city of Brooklyn, state of New York, and its premises thereof, I respectfully make application to your Honorable Body for permission to open the streets or avenues of said city for the purpose of laying gas mains and conduits in order to enable our company to accomplish the objects of its organization. Should your Honorable Body grant us this privilege we will furnish gas to the people of the city of Brooklyn of an illuminating power equal to twenty (20) candle light, at a reduction on their bills of at least twenty (20) per cent less than the present proposed reduced rates of our city gas companies.

We will furnish and set the meters, lay the service pipe, and connect them with the pipes in the buildings free of all cost to the consumers. We also claim that our fellow citizens should have the right and benefit of practical competition as the only means of obtaining better and cheaper gas. We also respectfully represent that the removal of upward of three thousand (3000) gas meters from the houses of gas consumers in this city within the four months last past indicates a degree of necessity for cheaper and better light by the people that cannot be wisely disregarded by your Honorable Body, and to that end we will give such security and assurances as your Honorable Body may suggest as a guarantee of our good faith, as well as our ability to maintain a company that will successfully compete with the present opposition for the privilege of supplying a cheap and superior quality of gas to the people of Brooklyn.

The Mutual Gas Light Company of the City of Brooklyn, by

[Signed] WARD B. MEEKER,
President.

[OFFICIAL NOTICE.]

The Third Quarterly Meeting of the Central New York Gas Engineers' Association will be held in parlor "A," Bresler's Hotel, Rochester, New York, on Thursday, November 25th, 1875, at 11 o'clock, A.M.

The importance of these meetings cannot be too highly estimated, and the results emanating from the papers read, and the discussions upon them by the members, has already proved a profitable source of information to the companies who have been represented.

These meetings are especially beneficial to the smaller companies—they necessarily are compelled to use every means to reduce the cost of manufacture, as they have the benefit of the experience and manner of working of all other companies.

The expenses attendant upon the meetings are very light, and cannot be set up as a bar to the admission of any company.

It is earnestly hoped that every company, not already represented in the Association, will forward the name of some representative, preferably the superintendent, to the Secretary, at an early date; and that their representative be present at the opening of the Convention.

A paper will be presented by Mr. A. D. Perry, of Rochester, on the proper and legitimate means to be used in the extension of our business. Other papers will be read, and matters of importance to every gas company will come before the meeting.

The headquarters of the Association will be at the ... [illegible] ... special rates have been obtained for the benefit of ... [illegible]

... Secretary.

Gas Stocks.

NEW YORK, Friday Evening, April 23, 1875.

The market is dull, prices remaining the same as last week, with the exception of Manhattan, New York City, which has declined from 165 to 160 bid; Brooklyn from 140 to 138, and Metropolitan from 91 to 89. Mutual has advanced from 97 to 99 bid.

Sensible Action of a Foreign Gas Company.—The London *Gas Circular* and *Review* of April 10th, 1875, contains the following plan, adopted by one of the English gas companies, looking to the increased use of gas for domestic purposes, a plan which would return to every gas company in the country benefit in cost should they adopt something similar to it, and educate the people to the admirable advantages which gas possesses for this and many other purposes:

"At Coventry the gas company has taken up the matter of cooking by gas, and has set to work with a will under the guidance of Mr. Hinton, who has formerly in the city and they have ordered this week a number of gas cookers of a large number of shapes being exhibited, and as an inducement, to commence to adopt the principle, they have reduced the price of gas for cooking to 2s. 6d. per thousand feet. The gas company throughout the country are showing a manner of enterprise that few have done the last few years."

Silica's Electric Light.—An important specification, relating to the electric light, has been published. It is dated March 30, Ethan Silica, of England, in America, and has been registered in the London Patent Office on the 17th ult. The specification is a long one, and is illustrated by a number of drawings which accompany it, as given in the description of the famous patentee's Park. The features of the invention are the regulation of the current and thermo-electric regulation of the intensity of the current.

Provision is made for preventing the cut or strife of the rays or other media, through which the electric current passes, from melting, and so destroying the apparatus, the electric current being automatically cut off when the fused silica rods, temperatures are reached, and increased in non-conductivity a melting contact, such as a fusible metal plug, which is fused by the heat of the rays, regulates, cutting in resistance or connection, the passage of the electric current through the incandescent rods. The specification also describes the application of a simple automatic thermal regulator. Under this invention the supply of the electric current will be precisely regulated to the degree of intensity of illumination required for the purpose of any article.

Natural Gas at Rochester, N.Y.—Mr. Bateson, of Rochester, one of drilling contract gas well near that of the Traveler Company. Until Every lessee also thinks of leasing his property for the purpose of boring for gas, and the result is to encourage the prospect of a new source of revenue to build market Rochester if the citizens will take $10,000 worth of stock.

Lighting the Parks of New York.—Councilor Kelly, Commissioners Watrous and Lane met on the 20th inst., and opened bids for the several contracts of the Park Department. The bids for lighting the various city parks were as follows: Manhattan Co., $14,000; Harlem Company, $13,000; Metropolitan Gas Company, $13,000; Harlem Company, $11,340; New York Mutual, $11,000.

The three Gas-light Company of Boston is to provide a total of gaslights upon 122 lampposts the common, the

ABERDEEN CORPORATION GAS SUPPLY.

A statement in our "Trade Notes Items" last week, on Wednesday, the 29th ult., the Gas Committee presented to the Town Council of Aberdeen an abstract of the accounts, for the year ending Sept. 30, in connection with the gas-works. From these it appears that the quantity of gas manufactured was 1,782,236 ft., made up as follows:—

Expenditure to Sept. 30, 1878	£156,313 16 6d	
Ditto during the year	6,000 0 0	
	£162,313 16 6	
Less dispreciation and contingent fund . .	4,775 16 6	
	£157,538 0 0	
Less amount of sinking-fund applied in paying off borrowed money	7,900 0 0	
	£149,638 0 0	

Of this amount, £111,352 13s. 11d. is represented by the gas annuities; £20,000 being borrowed on mortgage, and the balance, £18,285 15s. 1d., carried to account. The profit and loss account, which is as follows, shows a balance of £2,902 19s. 2d. carried to net revenue account to meet annuities, interest, &c.:—

Dr.—*Profit and Loss Account for the Year from Oct. 1, 1878, to Sept. 30, 1879.*

To Manufacture of Gas—		
Purifying materials	£19,661 12 2	
Salary of superintendent	131 5 3	
Salaries of engineers and foremen . . .	315 0 0	
Stokers and gasmen	1,172 4 7	
Maintenance of works and plant, including repewal of meters, apparatus, utensils, and tools	806 2 3	
Materials	£1813 16 6	
Wages	352 7	
	1,166 17 7	
Distribution of Gas—		
Wages of Meter Inspectors	£352,337 7 0	
Rentals, repairing, and collecting Meters .	£203 15 0	
Materials	£216 2 1	
Wages	276 12 2	
	492 14 3	
Repairs, maintenance, and renewal of mains and services, and laying, testing, and interchanging Meters	423 1 11	
Materials	£315 0 9	
Wages	290 3 8	
	605 4 5	
Rents, rates, and taxes—		
Gas-works, counting-house, and house .	£1,004 0 7	
Meters, showrooms, and house	247 11 5	
	1,251 12 0	
Management—		
Salaries	£1,743 11 8	
Collecting, carrying, printing, and advertising	1,743 11 8	
Bookkeeping	115 12 4	
	181 17 10	
Discount on gas and bad debts	297 10 2	
Bad debts	919 10 6	
	£431 1 10	
	£3,212 10	
Amount transferred to depreciation, including £500 on new plant	3,644 11 8	
Interest on gas annuities	5,570 11 7	
Interest on loans—		
£7,229 10 1		
Less £4,326 16 1		
	2,902 19 0	
Balance carried to net revenue account to meet annuities, interest, &c.	£18,285 15 2	
	£49,863 15 2	

Cr.—*Profit and Loss Account.*

Tar and ammoniacal liquor	£787 13 10	
	£791 15 10	
Transfer fees	4,221 12 8	
	4,013 8	
	£49,863 15 2	

PRICE OF GAS AT ST. JOHN, N. B.—Mr. Robert Hale and Mr. John

[illegible] are concluded their visit (on behalf of the St. John Gas Light Company) to the different gas works in the United States and the Upper Provinces, to see if any improvements could be made here in the manufacture of gas. They visited Portland, Me., Baltimore, Montreal, Toronto and Kingston. Out, but found no improvement that could be utilized here. In several places gas is manufactured from oil instead of coal as is done here, and can be furnished at a lower rate but that mode could not be carried out here as cheaply on account of the high duty.

COAL GAS *vs.* WATER GAS.

The standing Committee of the Society of Gas Lighting on this vicinity has lately been at work upon a pamphlet setting forth of an interesting pamphlet by Eugene Th. Peel, C.E., engineer of the Newark Gas Light Company, on "The Waste of Energy in the Production of Water Gas." In it Mr. Vanderpool, whose reputation is certainly second to no man in the profession, appears as the advocate of the coal gas process. So pronounced, indeed, is his position that one can almost suspect a *double entendre* in the words, as if he laughed that investors and engineers wasted their energy if they undertook the production of Water Gas.

He commences by giving an account of the old attempts at this manufacture. Then, taking an average analysis of anthracite, he calculates the amount of air which would have to be used to generate the steam required for the production of 1,000 cubic feet of a mixture of hydrogen and carbonic oxide. Next, he considers the amount of heat required to heat the carbon and keep it at a temperature which will dissociate water. He then allows a certain waste, due to the heat carried off by the gas, which, he says, leaves the generator at a temperature of 2,192° F., a statement which we do not at all assent to. It is declared, as the reader may have observed, from the idea that the water is dissociated, but it is a case of decomposition, or of dissociation, and we may suppose its temperature is not far lower. He finds that, theoretically, 28.31 lbs. of anthracite are required for the production of a thousand feet. We give the above as an illustration of the careful manner in which Mr. Vanderpool has worked up the subject. We condense his remarks, giving the final comparison he makes between coal and water gas.

The cost of 1,742 cubic feet of Scotch water gas is:—

1. Anthracite, 75 lbs. = 15.1 cents; 2. Naphtha, 5 gal. = 25 cents; 3. Coke, for vaporizing, etc., 4 cents; 4. Labor, 8 cents; 5. Lime, 1.5 cents; 6. Waste, 2 cents; total, 55.6 cents. Cost per thousand cubic feet, 48.6 cents.

The cost of 11,200 cubic feet of 16-candle coal gas is:—

1. Coal, $5.50; 2. Labor, $1.12; 3. Purifiers, 56 cents; 4. Wash, 5 cents; total, $7.23. Less residuals:—1. Coke, $2.52; 2. Tar, 25 cents; 3. Ammoniacal Liquor, 10 cents; total residual, $2.87. Net cost of above amount of coal gas, $4.01. Cost per thousand cubic feet, 35.8 cents.

Our criticism on the above would be that the residuals of the coal gas are entirely too high. He allows a sale of 31½ bushels to the ton, which is almost beyond theory, although Mr. Vanderpool supports it as a result which ought to be reached. Also, the case seems drawn against the water gas process. It would be presumptive to go further in criticism than this without going over the whole question as carefully as he has done, and the above review gives only a slight idea of the treatment the subject receives at his hands. The ratio of practice to theory of waste of heat and many other items enter into the calculation and make it a good example of the class of papers that should be read before our gas societies. It would be interesting to know whether the Society by publishing this interesting and able paper would wish itself to be considered as an advocate of coal gas and a condemner of water gas—the one defect of the treatment of the subject, to our mind.

The following is the list of members of the Society:—

Honorary Members—C. F. Chandler, M.D., Ph.D., LL.D.; Prof. Henry Morton, Ph.D.; Wm. King, C.E. (of Liverpool.) *Members*—James H. Armitage, C.E.; Frederick S. Benson, C.E.; Wm. Coombe; Geo W. Drenner, C.E.; George W. Edge, C.E.; William Farmer; Chas. C. Morton; Albert M. Smith; C. Vanderpool; Smith, C.E.; Joseph Russell Thomas; Eugene Vanderpool, C.E. *Non-Resident Members*—Oliver E. Cushing, C.E.; Theobald Forstall; Charles D. Lamson; Francis C. Sherman; S. G. Silsbee; Frederick A. Sabbaton.

METROPOLIS (GASHOLDERS).

Provisions Amending the Enactments to Amend the Penalty Clauses of the Chartered Gas Companies Acts, 1857 and 1859.—At the meeting of the Special Purposes and Sanitary Committee, summoned by the Board to consider the necessary notices of the Indemnities to apply to Parliament, either independently or in conjunction with the Corporation, for an amendment of the penalty clauses of the Gas Light and Coke Company Acts? His worke from which the gas is manufactured according to the make at its works; but in consequence of the manipulations which had taken place with regard to the purification of the gas, and the materials employed, the standard at which the Company were manufacturing. The alteration proposed was, in the case of Parliamentary authority being obtained, a certain stated fine should be inflicted, was known to the progress of the Bill, and that the Company would be prepared to go to Parliament in the next session, rather than submit to the probability of a dissolution; and the motion, especially considering it was carried by 17 votes to 12. The Corporation have, however, given notice of a Bill to effect the proposed alterations.

The following is the Whitmore's report on the Illuminating power, pressure, and quality of the gas as required by The Gaslight and Coke Company in the parish of Marylebone during October:—

Averages.	Illuminating Power in Sperm candles.		Mean Pressure.		Mean Quantity of Gas per Hour consumed by each Burner.	Gas Consumed per Cent.
	Minimum allowed by Act.	Highest.	Lowest.	Highest.	Lowest.	
Common gas . . .	12·41	17·12	12·10	2·06	2·00	Nothing.
Coked gas . . .	12·41	13·70	12·10	2·06	2·00	Nothing.

Mean of daily readings of barometer . . . . . 29·95

Mean of daily readings of thermometer . . . . . 52·75

* Each observation consisted in the readings of the photometer, at intervals of one minute.

This mean illuminating power of the common gas during the month of October was equal to 16·61 sperm candles; it was equal to 16·61 candles in 1877 October, and to 16·64 candles in 1876 October. The mean light of the coked gas was equal to 13·61 candles; it ranged between 13·70 and 13·52 candles. There was thus a fall below the legal standard. The consumption of gas per burner found in 100 cubic feet of both gases was very low, and of common gas little more than 2 cubic feet per hour. The pressures of the gas, and on occasion was unfavourable hydrogens detected by the ordinary tests.

The Gas Supply of Halstead.—In our issue of the 2nd inst., among the notices of Bills to be proceeded in next session of Parliament was one by the Proprietor of the Halstead Gas-Works, who intends applying to Parliament for Powers for a Provisional Order in respect to his undertaking. In reference to this proposal, a public meeting was recently held for the purpose of considering the question, which has been in the parish for a long time, and it was agreed to entrust the Local Board to obtain such professional assistance as they may require in the preparation of the necessary application. The opinion of the ratepayers present was adverse to any loss in the future; and the result was shown at a meeting of the Board held last Tuesday, when, after a long discussion, it was brought forward a resolution in favour of an increase in the price of gas from 4s. 6d. to 5s. per 1000 cubic feet. The result of the vote, by a majority of seven in the Board were, there was no option left but to increase the price in order to meet the expenses of the Bill, and the resolution was carried, subject to the assignment of the works. If other than the Board are sold off they could pay a lighting rate, but this could not be done until they had increased the price of gas to the maximum allowed by Act of Parliament. It was only after fully considering the position of the Board that he had resolved to promote legislation, and he did so with the consent of several shares. He trusted that shortly they would be able to announce a profit on the undertaking. The Bill would be introduced early next session. Consequent of the question he addressed could after the report of the Local Government Board Inspector had been received. The Chairman and several other members of the Board spoke in favour of the proposal, and the vote was, at the close to pay off the debt caused by the loss in working, and that it was absolutely necessary to adopt some means of clearing off the liabilities. After a long and angry discussion, it was decided by a majority of seven to one to proceed, to the Bill next Session.

The *Queenstown Gas Act* dissolves and reincorporates the Queenstown Gas Company, Limited, which was started in 1856 with a nominal capital of £10,000, of which £9000 has been paid up. The Company, however, meantime, have expended on works, money to the amount of £30,000 out of profits. By this Act the capital of the Company is fixed at £30,000, which is to

GAS LEGISLATION FOR 1879.

Or the six Companies who applied to Parliament during last session to be incorporated with statutory powers, five succeeded in obtaining the object of their wishes. The sixth failed by what may be called a mere slip, which is now the subject of legal investigation. The Acts passed were as under:—

The *Hamilton-le-Spring Gas Act* incorporates a Company for the supply of gas to Houghton-le-Spring, Newbottle, and East Rainton. The amount of capital authorized is £20,000, and power is given to borrow £6666, the rate of interest on which is not to exceed five per cent. In this case the Standing Orders were so far suspended that neither sliding scale nor sanction clauses are enacted; so the dividend payable will be regulated by the General Act, and is limited to ten per cent. Gas of fourteen-candle illuminating power is to be supplied, but nothing is said about purity. The pressure at which the gas is to be furnished is that which is now usually prescribed —viz., six-tenths of an inch from midnight to sunset, and eight-tenths from sunset to midnight. The maximum price for gas in Houghton-le-Spring is fixed at 4s. per thousand feet, and 5s. in Newbottle and East Rainton. On the whole, the Company have succeeded well in Parliament. They want for a 5s. maximum in Houghton-le-Spring and 4s. 6d. beyond, so that the terms granted cannot be considered illiberal.

The *Knutsford Light and Water Act* dissolves and reincorporates the Knutsford Gas and Water Company, and, so far as gas supply is concerned, authorizes them, with a present capital for that purpose of £11,000, which is to be converted into stock, to raise an additional £20,000 in £10 shares, with power to borrow £7500 on the original, and £5000 on the additional capital. The dividends on the new capital are limited to seven or six per cent., according as it is mixed as ordinary or preference. Auction clauses and sliding scale are inserted; but the latter has been somewhat modified from what it was originally (see Vol. CXXXIII., p. 839), and the initial price is now fixed, regardless of total annual consumption, at 4s. 6d. per thousand feet. The gas furnished is to have an illuminating power of fourteen candles, tested by Sugg's No. 1 "London" Argand burner. A testing-place is within twelve months to be established upon or within two hundred yards of the works. The pressure at which the gas is to be supplied is that which is now usually prescribed—viz., six and eight tenths of an inch, within the usual hours.

The *Worcester Gas Act* dissolves and reincorporates the Worcester Gaslight Company, hitherto carried on as a Limited Liability Company. The undertaking was started in 1836, with a capital of £2000 in £5 shares; but additions have been made from time to time, so that the original capital had reached to the sum of £24,000. By this Act, however, the amount of the original capital is reduced to £20,000, and power is given to raise an additional £16,000. It is prescribed that £12,000 of the original capital shall be converted into stock, and the remaining £8000 shall also be divided into 800 shares of £10 each. These old shares will, of course, be entitled, subject to the sliding scale, to ten per cent., but the dividends on the £16,000 new capital will be limited to seven per cent. if issued as ordinary, and six per cent. if as preference shares, subject to the sliding scale. These shares are, as a matter of course, to be offered by public auction or tender. Power is given to borrow £5000 on the original, and to the usual extent on the additional capital. Gas of fourteen-candle illuminating power is to be supplied, tested by Sugg's "London" Argand, No. 1. Subject to the sliding scale, the standard price which may be charged for gas is fixed at 3s. per thousand. The Company may manufacture, purchase, sell, or let on hire all kinds of apparatus for the utilization of gas for other than illuminating purposes, the charge for which is to be settled by agreement. The Act further authorizes the construction of a siding and a junction with the railway. Beyond this the Act makes all necessary provision for the transfer of the undertaking of the Limited Company to the Incorporated Company, with all rights and liabilities. The limit of the Act includes the town of Worcester and several surrounding townships and parishes. In one part of the district the Company come in collision with the Lancaster Gas Company, but it seems that any differences can easily be arranged.

Miscellaneous News.

METROPOLIS GAS SUPPLY.

COURT OF COMMON COUNCIL.

At the Meeting of the Court last Thursday—the Lord Mayor (Sir J. W. Truscott) presiding—the Gas and Water Committee presented the following report in respect to the proposed application to Parliament, during the present Session, for an annulment of the penalty clauses of the Gas Light and Coke Company's Act of 1876:—

"Your attention was called, in 1879, to the subject of the penalties to which, under the existing laws, certain of the Metropolitan Gas Companies are liable in the event of their failing to supply gas of the prescribed illuminating power, purity, and pressure, and we were subsequently instructed by resolutions from the Court of Common Council, dated Jan. 22, 1880, forwarding a letter from the Gas Referees on the subject, and directing us to consider what steps it was the present duty of the Corporation to take in the matter, and to report thereon to the Court, and asking the Corporation to favour the Board with their observations thereon.

A copy of the letter of the Gas Referees was also forwarded, and in this was a detailed statement of the difficulties which exist in the ascertainment of the illuminating power of gas manufactured at different places, and of ascertaining from whence the gas supplied to any house and the desirability of placing the testing-places in or near the localities where the gas is consumed, and not at the manufacturing stations, and under the Acts of 1845 and 1876, the provisions of those Acts seemed to be complicated, and as far as we can see, not to give the consuming powers, except of the, for the first half-year, very small penalty for defect of illuminating power. The Gas Referees further state that the alternative principle of fixing the testing-places at or near the manufacturing stations would meet the difficulties, but that the Gas Referees have no power to alter the testing-places, except on the application of, in every case for removal from the districts to which the gas is supplied, and as evidence is less scrutiny for the independence of testing. The Gas Referees also called attention to the difficulties which exist in the ascertainment of the purity of the gas supplied, and they ask the Board of Trade to consider the subject, and, on the grounds above stated, with a view to the amendment of the law in regard to these penalties.

Your Committee have considered the matter, and are of opinion that the present law relating to the penalties to be recommended may be limited to two—namely, (a) Whether the present penalty provisions could not be made for the testings for pressure; (b) Whether the testings for illuminating power, purity, and pressure should not be made of the quality of gas at some of the manufacturing stations, or within the districts where the gas is consumed.

In accordance with the request of the Board of Trade, we directed a reply to be sent to them, giving the views of your Committee with respect to the two points mentioned by the Gas Referees.

First, as regards the question of pressure. After careful consideration of the matter, your Committee are of opinion that the present penalties should be kept by means of self-registering pressure-gauges at the testing-places, and that the penalty should be increased. In addition, that observations of the pressure should be made at indefinite periods at certain of the street-lamps in various parts of the districts, in a manner to be determined by the Gas Referees, and that the penalty for a first default in such a case should be imposed from any examiner or other person in the Gas Referees' service, and that the pressure in any specified locality, he should take a test of the pressure at the nearest testing-place twenty-four within 24 hours of such complaint being lodged in writing at his office.

Secondly, as regards the position of the testing-places for illuminating power and purity, and having in view the difficulty of ascertaining from what manufacturing station the gas is supplied in a particular district, it is most desirable that tests should be made of the gas at the point where it is consumed, and your Committee are of opinion that experience has proved that testing near the manufacturing stations is unsatisfactory. Answers in the Committee to be desirable as a general principle that the testing-places should be placed in or near the districts where the gas is consumed; and they are also of opinion that the testings which would be thereby made would be more than counterbalance any possible objection which might be taken to the system.

In order to carry out this principle, it would be necessary to make an alteration in the law as regards penalties for deficiency of illuminating power and purity, and clause 30 of the Act of 1876 would require amendment. The penalty for a first default might be reduced to the present penalties in the aforesaid clause, in which a penalty for a first default for not a half a candle of illuminating power is fixed at 40s., and fixing a penalty for a first default for not a half a candle of illuminating power, taking into consideration as to whether such gas is manufactured, or its quantity. Your Committee would also recommend the amending of certain other clauses in the interests of testers which have been found to be inconvenient in practice. If these suggestions were carried out, the Committee believe that the Gas Referees would have no difficulty in so fixing the locality of the several testing-places as to enable them to carry on an actual testing of the quality of the gas delivered to each part of every locality.

We have since received a communication from the Gas Referees that, in accordance with the request of the Board of Trade, they have on occasion by your Committee, they propose to substitute three testing-places for the gas manufactured by The Gaslight and Coke Company within the City. After that communication had been received, a meeting was held at which your Committee, the Gas Referees, and the Solicitor to the Board of Trade were present, and at which the Gas Referees stated that the testing-places that corresponded with the three subscribers, through which all the gas manufactured by The Gaslight and Coke Company within the City was to be tested separately—namely, (1) Holgate Dept. Street, (2) Montague street, (3) Bridge Street, Blackfriars.

We have since received a further communication from the Board of Trade, stating:—"It will not be possible to effect the necessary alteration in the law during the present session, as The Gaslight and Coke Company's Bill, in which clauses giving effect to the proposals of the Gas Referees, and a special Bill dealing with the subject could not be brought in without the consent of the Standing Orders. In these circumstances the Board of Trade would suggest that the Corporation should not take any steps in regard to the application to Parliament for giving the necessary notices in the coming autumn of a Bill to be entitled 'The Gas Examiners Act' enables, and I am to add that, should the Corporation decide to take such steps, the Board of Trade will be prepared to support the Bill, and the Board of Trade will be prepared to give all assistance and information in their power."

We likewise received a communication from the Metropolitan Board of Works, requesting that the Court would memorialize your Committee upon the subject of an alteration in the existing law as to testing-places, and the recovery of penalties incurred by Gas Companies.

Under these circumstances, we beg to recommend that your Committee should be authorized to confer with the Metropolitan Board of Works as to giving the necessary notices, either separately or jointly with the Board, of the intention to apply to Parliament, during the present session of Parliament, in accordance with the suggestions of the Board of Trade; and further, that we should be also empowered to confer with the Gas Referees, the Solicitor to the Corporation, and the Solicitor to the Board of Trade, with respect to such Bill."

Deputy RIDDAY said the Committee had already given notice of a Bill, and he hoped the Court would sanction what had been done.

It was, however, agreed to defer the consideration of the question.

METROPOLITAN BOARD OF WORKS.

At the Meeting of the Board last Friday—Sir J. M. Hogg, M.P., in the chair—a Special Purposes and Sanitary Committee submitted the following report:—

Your Committee have to report, with reference to the letter from the Board of Trade, relative to the question of the difficulties which exist in the ascertainment of the law respecting the places for testing gas, and the recovery of penalties incurred, that they have had the matter under consideration, and are of opinion that it is desirable to apply to Parliament, during the present session, for such authority for the Committee to confer with the City Corporation on the subject, both with reference to the Board's Bill and to the Corporation's Bill, as your Committee may think fit. Your Committee recommended that the Board do resolve that the Committee are of opinion that, under existing circumstances, the most practicable course to be adopted is to apply to Parliament for the repeal of the 30th clause, that the preliminary notices on behalf of the Board and the Corporation be given separately, the Committee reserving for future consideration the advisability, and terms of the Board's co-operation with the Corporation in their application.

At the meeting of the Metropolitan Board of Works, held on Friday, the 30th ult., Mr. Richardson, the report was brought up, and the recommendation was agreed to.

At the meeting of the Metropolitan Board of Works, held on Friday, the 30th ult., Mr. Richardson, the report was brought up, and the recommendation was agreed to.

METROPOLIS WATER SUPPLY.

COURT OF COMMON COUNCIL.

At the Meeting of the Court last Thursday—the Lord Mayor in the chair,

The BRASSBRIDGER reported that notice had been given of a Bill to be introduced into Parliament, with power to purchase the Water Companies of the Metropolis; and he suggested that the question should be referred to the Commissioners of Sewers and the Gas and Water Committee.

This was agreed to.

The report of the Gas and Water Committee, upon the several references relative to the supply of water to the Metropolis, recommended that proceedings be discharged, and further that the Committee should be authorized to watch any proceedings that might be taken by the Government with respect to the Water Supply of the Metropolis.

Mr. Deputy DIMSDALE, in moving the adoption of the report, stated that the Committee having been authorized to communicate with the Government in regard to the measures which the Home Secretary had promised to introduce, a question of the London Water Supply, communication had taken place, and the Committee had been advised by Mr. Cross that any interference on the part of the Corporation would only lead to complicate matters. Under these circumstances the Committee proposed to content themselves with watching any proceedings that the Government might take on the subject. They were assured that in any arrangements that might be made the interests of the Corporation would not be overlooked.

This was also agreed to.

Lieut.-Col. Bolton, in his report to the Local Government Board, on the water supplied by the Metropolitan Water Companies, during last month, says:—"The state of the water in the Thames at Hampton, Molesey, and Sunbury (where the intakes of the West Middlesex, Grand Junction, Southwark and Vauxhall, and Lambeth Companies are placed), and in the Lea (where the Companies are situated) was indifferent from the last to the first month, when it became grayed, and afterwards continued good during the remainder of the month. Road state of the river at West Molesey during the month was 9 ft. 1 in., and the lowest 1 ft. 1 in. above the summer level, the rainfall at this place being 2·21 inch. The water in the River Lea was generally good during the month. [These remarks refer to the condition of the water previous to filtration.] The state of the intakes was generally in a much better condition during the month of October than it was in the previous month, and the filtration was efficient. The supply furnished by the various of the Metropolitan Water Companies was clear, bright, and properly filtered."

THE AMALGAMATION OF THE SOUTH METROPOLITAN AND PHŒNIX GAS COMPANIES.

THE SCHEME SUBMITTED TO THE BOARD OF TRADE.

The first thirteen clauses of the scheme submitted to the Board of Trade for the amalgamation of the South Metropolitan Gas Company with the Phœnix Gaslight and Coke Company, under the powers and provisions of the South Metropolitan Gaslight and Coke Company's Act, 1876, and the Acts incorporated therewith, are (excepting the change of name and date, and one or two minor alterations noted below) the same as and proposed and accepted in the case of the recently completed amalgamation of the Chelsea and Kensington Water Companies Gas Companies. These clauses were set out in full as recently as the *Journal* for May 3 this year (Vol. XXXIII., pp. 722-3), and need not be repeated at length. The variations only being mentioned.

1. Commencement of operation of scheme.—Jan. 1, 1880.
2. Amalgamated Company to be called South Metropolitan Gas Company.
3. Works and properties of the two Companies vested in the United Company.
4. Debts payable to the United Company.
5. Debts, &c., of the two Companies to be debts of the United Company.
6. Contracts, agreements, &c., to be those of the United Company.
7. Actions or parliamentary proceedings by or against, and proceedings in Parliament mentioned, so as to cover the notices issued by both Companies for Bills to be promoted next session.
8. Books to be evidence.
9. Accounts of the two Companies to be made out separately up to Dec. 31, 1879.

Dissolution of the reserve-fund.

11. Registers of amalgamating Companies to subsist until replaced.
12. Resolutions, &c., continued.
13. General saving of rights and claims.

Constitution and Regulation of United Company.

14. Provisions of existing Acts continued.—The Acts relating to, or affecting the South Metropolitan Gas Company, and the Phœnix Gas Company at the date of the commencement of this scheme, shall, except so far as the same are varied by, or inconsistent with this scheme, remain in full force; and all rights and powers of every kind, or any of them, conferred on and vested in either of the two Companies in relation to the undertaking of such Company, may be enjoyed and exercised by the United Company: Provided that in the event of the provisions of any Act of the Phœnix Company, or any Act incorporating any Act of the South Metropolitan Company, the appointment of the Auditors of the last-named Company shall (except otherwise specially provided by this scheme) prevail and be observed by the United Company.

15. Half-yearly Meetings.—The half-yearly general meetings of the United Company shall be held as soon after the 31st of December and the 30th of June in each year as the Directors may deem expedient, but not later than the 28th day of February and October respectively.

16. Directors of the United Company.—Upon the execution of this scheme, the Directors of the Phœnix Company shall cease from their own number five members to unite with five seven Directors of the South Metropolitan Company, and become Directors of the United Company; and thereupon the Directors of the United Company shall be twelve. Provided that on the retirement of the present Secretary and Engineer of the South Metropolitan Company, he may be appointed a Director, and thereupon the number of Directors may be increased to thirteen until the next necessary occasion, when they shall again be twelve in number.

17. Remuneration to the Directors.—The fees payable to the Directors continuing in office shall, subject to the provisions of the South Metropolitan Company's Special Act, 1862, and so long as there are 12 Directors, not exceed £500 per annum; but if that number be increased by the Board, the fees may be increased in the proportion.

18. Allowance to Directors for retirement.—[Provides for the payment of an allowance to Directors retiring from office, and for the continuance of the allowance to the widows of deceased Directors.] The amount of such retiring allowance shall be charged upon the general revenue of the United Company, and shall be carried to a suspense account, and be liquidated by equal annual instalments during the next seven years.

19. As to retirement of Secretary and Engineer of the South Metro-

The Potential Energy of Coal Illuminating Gas.

The potential energy of coal gas is taken as the average of the results obtained by seven different observers. In the "Treatise on Gas Manufacture," par 21, Pelouze, 1870 edition, Vol. I., pp. 156-7, is given the analysis of the gas of the Paris Gas Company, and its calculated calorific power. The analysis made by M. Rudelle is—

	By Volume.	By Weight.
Nitrogen	3·70	4·70
Oxygen	0·60	1·05
Carbonic oxide	7·10	8·80
Olefiant gas	6·60	12·90
Saturated hydrocarbons	6·30	10·50
Marsh gas	52·10	47·35
Olefiant gas	19·60	14·70
	100·00	100·00

Specific gravity, 0·600.

The calorific power of this gas is—

P = 0·608 × 34,462 + 0·256 × 2123 + 0·124 × 13,063 + 0·111 × 11,857 = 11,251;

and, making certain reductions, = 10,253 calories; or,

10,253 calories × 3·968 = 40,687 heat units; or,

1 cubic foot is equal to 627 heat units.

M. Morin makes 1 cubic foot equal to 695 heat units; Dr. Letheby, 620 and 705; Mr. J. J. Evans, 630; Mr. Goddard, 692.

We are now prepared to show the waste of energy.

Waste of Energy in the Production of Water Gas, based upon the Consumption of 100 lbs. of Anthracite Coal per 1000 Cubic Feet of Gas Generated.

Assuming that 100 lbs. of anthracite coal are required to produce 1000 cubic feet of water gas,

The theoretical energy of 100 lbs. of anthracite coal is
100 × 13,000 = ... 1,300,000
The theoretical energy of 1000 cubic feet of water gas is
1000 × 300 = ... 300,000
Waste of energy 1,000,000
Percentage of energy utilized. . . 300,000 ÷ 1,300,000 = 23·08
Percentage of energy wasted . . . 1,000,000 ÷ 1,300,000 = 76·92

We have data that show, under the most careful working, that 1000 cubic feet of water gas have been produced from 75 lbs. of anthracite coal, and we will assume this as the best work obtainable in practice, and base it as a basis of comparison, so as to give the water gas process every favor in energy.

Waste of Energy based upon the Consumption of 75 lbs. of Anthracite Coal per 1000 Cubic Feet of Water Gas Generated.

The waste of energy would then be as follows:—

The energy of 75 lbs. of anthracite coal is . 975,000 heat units.
The energy of 1000 cubic feet of water gas is . 300,000 "
The waste of energy is . . . . . 675,000 heat units,
or the
Percentage of energy utilized is . . 300,000 ÷ 975,000 = 30·80
Percentage of energy wasted is . . . 675,000 ÷ 975,000 = 69·20

100·00

We will now compare with this the energy theoretically and practically developed per cubic foot of 16-candle gas, making the water gas being a non-luminous gas. As in the case of the manufacture of water gas, we have taken the results obtained from the best practice for a comparison, so in the manufacture of gas from bituminous coal we have taken as a standard some of the best results actually worked, namely, the composition of our best coking coals:—

	By Weight.
Carbon	82·93
Hydrogen	6·00
Nitrogen	1·00
Sulphur	1·00
Oxygen	7·07
Ash	2·00
	100·00

and a coal of the above composition has a potential energy of about 14,000 heat units.

One ton of such a coal properly carbonized will produce—

12,000 cubic feet of 16-candle gas, weighing . . 672·00 lbs.
Weight of tar . . . . . 182·00 "
Ammonia liquor . . . . . 112·00 "
Impurities, CO_2 . . . . . 7·00 "
CO . . . . . 7·00 "
Ammonia . . . . . 0·00 "
. . . . . 980·00 lbs.
Add 2000 lbs. of coke . . . . . 2000·00 lbs.
Showing a loss of . . . . . 1020·00 "
. . . . . 2980·00 lbs.
Making total weight . . . . . 2980·00 lbs.

Energy Required for the Distillation of 1 Ton of Bituminous Coal.

To produce this gas there would be required, theoretically, taking the heat to be raised for each coal as 32, the gas at 95, and assuming the coal and tar the same as water, and the coke as 0·207 Fahr., and that the tar and gas leave the retort at a temperature of 950°,

2240 × (2200 − 32) + 672 × (950 − 95) + 980 × (950 − 32) = 4,860,480 + 574,560 + 898,960 = 6,334,000 heat units.

As required 1,680,000 heat units to raise 2240 lbs. of coke, or 28 per cent. of the total energy of 12,000,000 heat units, contained with the following energy of 1 ton, 2240 × 14,000 = ... 31,360,000 heat units.

Less, 28 of gas, with an energy of 6,334 = 7,240,000 "
24,120,000 "
40 = 12,000 of coke = 8,040,000
16,080,000 "

Waste of energy . . . . . 24,080,000 "

6,000,000 + 31,360,000 = 37·7 per cent., which is represented by the air not be credited with any waste by leakage, &c., although they do not part that the ammoniacal residuals are valuable, and, in an ultimate scale upon a commercial basis, would reduce the percentages of waste in the production of coal gas with a good setting of the retorts, and by the use of the gas-furnace, 1 ton of coal can be carbonized on the test of 30 per cent., or 932 lbs. of the coke produced. It is said that in some of the compliance with the terms of the lease, but the limit has not been reached by 15 per cent. of the coke produced.

The present extended use of the gas-furnace in France and Germany, and the excellent results obtained therefrom, seem to indicate that less than 30 per cent. of the coke produced would be required to be used for fuel, low cost of coke, personal percentages of coke, and the cost of working this system of generating our heat. Although in the conversion of the will feel little a gas there is a waste of energy of more than 30 per cent., still this waste is more than compensated for by the efficacy of the gas.

The application of the gas-furnace to an ordinary French boiler at the iron-works of M. Muller, at Ivry, showed that before the application the boiler and apparatus evaporated 6 lbs. of water per lb. of coal, which is very good work, and when converted to gas-fuel to 6·66 to 9·28 lbs. per lb. of coal—an average of 8·97 lbs.—showing a saving of 32 per cent. in favor of gas-fuel, or an economy of 32 per cent. in the consumption of coal. A full description of this boiler will be found in C. E. Clark's "Text-Book on Boilers and Engines."

In the practical carbonization of bituminous coal we have therefore—

Waste of Energy in the Carbonization of Bituminous Coal for the Production of Illuminating Gas.

1 ton of coal, with a potential energy of . . . 31,360,000 heat units.
12,240 cub. ft. of gas, with an energy,
7,000 = 7,392,000
992 lbs. of tar, with an energy of 21,840 = 2,167,680
1050 − 2·3 × 10,950 = . . . 13,040,720 "
23,380,720 "
Being waste of energy . . . . . 8,156,280 heat units,
and we have
Percentage of energy utilized . . 23,380,720 ÷ 31,360,000 = 74·9
Percentage of energy wasted . . 8,156,280 ÷ 31,360,000 = 26·1

Comparative Energy, in the Shape of Gas, Derived from the Pound of Coal by the Two Methods.

So that we have 1 lb. of coal in the shape of water gas giving, in its changed condition, a potential energy of

10,253 ÷ 2·2 = 4,660 heat units,

Whereas 1 lb. of coal in the shape of coal gas, tar, and coke, the gas having also an illuminating power as given, by a standard candle, a potential energy of

23,380,720 ÷ 2240 = 10,450 heat units;

or 1 lb. of coal, in the changed condition of coal gas, tar, and coke, gave the same illuminating power as given, by the use of coal in the water gas.

The question of the relative waste of energy of the two methods of gas-making, and the relative cost of transporting the coal and coke, is self-evident that 1 lb. of coal in the shape of coal gas gave twice as far as 1 lb. of coal in the shape of water gas. This is a most important consideration, and, moreover, is only one of the many considerations commercial value of the coal gas method, we have a good illuminating power, and, therefore, an increased income.

To make the above calculations of practical value, it is necessary to look at the illuminating powers of energy in the two methods from a commercial point of view.

We will take the following data as a basis, assuming that in the near future the price of coal, coke, and gas will reach a point where there is a fair profit to those producing them. There are now in the city of Boston, Mass., 100,000 gas-burners, consuming 5 cubic feet per hour, for 700 days per year, will advance to 7 daily, or 5 dols. per ton; but we will take the price of anthracite that would be required to produce the same heating estimates in this vicinity—viz., 6·50 dols. per ton. We will also fairly represent the price of coke at 5 dols. per ton, although the cost at 10 cents per bushel. The tar we could use as a fuel, and the price fixed somewhat low, at 2 dols. per bbl. We will take the price of gas at 1·50 dols. per 1000 for 25 cents. We will take the price of sulphite at 4 cents per cubic foot. We will take the cost of sulphite at 2 cents per cubic foot. We will also consider that in the manufacture of water gas, and the emoluments from the sulphite per cubic foot are the same. The volume of the two gases in question is the quantity of sulphite used. This must be accounted for by the difference in the quantity of sulphite used, on the average, for the same illuminating volume. So that under constant pressure and temperature, and to different kinds of gases, water, and there is still room for the globe full of other volume of sulphite to be used. This is the reason why we have stated that the globe will be charged with a certain number of three bodies under nearly the same conditions as if each were the only one present in the space. We will take the increased volume of the gas to be 25 per cent., or 1·25 volumes per cubic foot, and the commercial gas being specific gravity 0·45 and 1·25 × 0·45 = 0·56 specific gravity per cubic foot, the difference between the two gases in question will be 0·56 − 0·45 = 0·11 specific gravity per cubic foot, and the commercial gas being specific gravity 0·56

possible for the genuine coolness of the climate. New purifiers, scrubbers, condensers, meters, &c., had been sent out, and it is believed that the works and their generally are very efficient. The necessary repairs to the large gasholder were found more extensive than was at first supposed, and the tank has been entirely rebuilt. The gasholder has been enlarged against increase. The holder has been materially strengthened and improved, and the Manager reports that "it is now in a state of thorough repair, and will last many years without renewal."

Additional notice was held during the year to the extent of 322 miles.

It will be seen from the accounts that advance exchange has again proved a serious loss to the Company, and to the Country. There is now an improvement in the rate, which it is hoped may continue.

The services of the Resident Committee are appreciated by the Directors; as also the unremitting energy and ability evinced by the Secretary, Mr. Hewison, in the management of the affairs.

The Directors now recommend alone, a balance (after carrying the sum of £7,000 to reserve-fund) of £17,382 2s. 3d., out of which the Directors recommend a distribution of 5 per cent., free of income-tax, payable on the 6th of December, leaving with the present payment of 2 per cent. on the 6th of June last a total dividend of 7 per cent. for the year.

The Directors retiring by rotation are James Sydney Shepherd, and William Wells, Esqrs., and the retiring Auditors are Messrs. Lawrence Hammond, and Thomas Newton Baker, Esqrs., all of whom, being eligible, offer themselves for re-election.

The CHAIRMAN, in moving the adoption of the report, said it was not to him that he did not think there was much necessity for him to add to it. The progress of the Company had been so good, considering the great depression of trade which had prevailed in Europe, but the Directors hoped that they had now come to the end of the depression, and that matters were taking place. The revenue of the Company generally for the several new large progress were in every department. Since the last meeting they had been deprived from two extraordinary periods of last year, but less profits very much less than last year, and considering the receipts from which they arose, this was satisfactory. In the long-continued darkness of trade. However, there had been an increase in private lighting. Shops and streets had been well lighted by the Company, and there had been a great number of new customers, showing that they had very good light. During the first quarter of this year gas supplied [illegible] increase of about 60 lights, and during the last quarter no less than 90 more had been supplied here and during the last quarter no less than 90 more. The native customers [illegible] Company did all customers were satisfied they had no reason for lighting up, but the Company's gas liberally when customers. The Company had endeavoured to prepare for coming years and good the appliances were ready and as great exertions. Have been prepared for them, and figures [illegible] consumption of gas would [illegible] with regard to the prospects for carrying on the undertaking, and would be completed [illegible] with the existing [illegible] which is compulsory [illegible] The Company had had [illegible] number of lights. The Directors [illegible] entailed a heavy sacrifice [illegible] The Directors [illegible] new contract for 21 years from [illegible] 1879; and, although it was a very low rate of 2d rupees per [illegible] thought it should be [illegible] leave no room for competition. They had not [illegible] their position, and lighting in Colombo [illegible] [illegible] They had not [illegible] [illegible] but it did not prove a success. An agent of one of the companies [illegible] delay its last to obtain the [illegible] [illegible] [illegible]

WATER GAS:

ITS HISTORY AND MANUFACTURE.

By [illegible]

President of the [illegible] Institute of Engineers.

June 15, 1880. No. IV.

Since the publication of my last article on this subject in THE SANITARY ENGINEER of Nov. 1st, p. 399, I have seen for the first time a piece of testimony in support of the views there expressed which was very gratifying because altogether unconscious and spontaneous.

It appears that some of the gentlemen interested in the water gas manufacture considered my views as to the poisonous nature of carbonic oxide partially as expressed in the *Gas Light Journal* of March 2d and 16th, 1875,[1] as involving the conclusion that water gas was so practically dangerous (on account of the large proportion of carbonic oxide contained in it) that it should not be admitted into general use, even if it possessed such advantages of efficiency and economy as would otherwise entitle it to acceptance.

I am quite ready to admit that when the subject first came to my notice my impression was very much of that nature, but further consideration modified this view, and in the articles referred to I stated precisely the same opinion as is expressed in THE SANITARY ENGINEER of Nov. 1st, namely, that while carbonic oxide was unquestionably a virulent poison, and therefore an objectionable constituent in any gas, yet that the danger of accident being "at most a remote and occasional risk" it would be a question of economy and efficiency simply, whether water gas did or did not become "the gas of the future."

Further, however, to appreciate the force of my statements and seeming inconsistency, it must be remembered that because I had confined one of their too enthusiastic advocates who had unhesitated that carbonic oxide was not poisonous, but was rather a desirable anæsthetic, it would be necessary to outweigh my authority with that of another, these gentlemen addressed themselves to Prof. Adolph Wurtz, of Paris, member of the Academy, etc., and his reply, dated June 12, 1878, and referring to my articles of March 2d and 16th, is now before me. In this Prof. Wurtz, by way of correcting what he supposes to be my views, says: "There is no doubt whatever less danger in all gases containing carbonic oxide, but coal-gas is not exempt from this, as twelve per cent. of its volume may be carbonic oxide; but I think that this danger which exists only have serious consequences in most exceptional cases, or by a sort of fatality, has been very much exaggerated and need really not be considered, if one remembers that we use gas without hesitation for lighting our dwellings, in spite of the real danger of explosion and fire which exists, no matter what kind of gas is used."

Here I find fully confirmed my statement that carbonic oxide is a dangerous poison and that gases are more or less dangerous as they contain more or less of it, and that it is the only dangerous element of coal gas. That twelve per cent. of coal gas may be carbonic oxide, we may readily admit, even in face of the analytical results, which show that in fact it generally ranges from five to seven per cent.

That those poisoned by gas are "fated" so to perish, and therefore could not be saved by the absence of the fatality of accident with coal gas Prof. Wurtz is undoubtedly right and it only remains for experience to prove that a similar immunity will attend the use of a gas containing 20 to 30 per cent. of carbonic oxide.

It thus seems to me that my real views, as actually expressed in this and other journals, have been fully sustained even by one who was called upon to refute me or what he supposed to be my conclusions.

The question then, as I wrote nearly two years ago, is essentially one of economy of production and efficiency in use, the extra risk arising from the larger percentage of carbonic oxide being possibly compensated, or, where it is fully recognized, by extra care in putting in fixtures and in the use of the gas.

Let us see then what can be said on these subjects.

In the first place, as regards economy, I have now before me figures furnished officially by the Municipal Company showing the actual amounts expended for material and labor during the year 1878 and the actual quantity of gas available produced from the same (*i. e.*, amount sold exclusive of leakage and condensation).

These figures are as follows:

Anthracite Coal.....	$24,231.90
Gasoline.....	2,026.35
Coke.....	23,021.35
Crude Water.....	1,000.00
Residuum.....	2,631.51
Wages.....	413.91
	72,124.52
Gas sold during year.....	$52,901.80
Cost per 1000 cubic feet.....	$52,901.80 / 72,124.52 = 73.35 cts.

This, be it remembered, expresses only the cost of manufacture without any allowances for interest on capital, repairs, etc., or the "cost of distribution," which is the same with any kind of gas and, as all gas makers know, is a very large fraction of the total outlay involved in carrying on their business.

These figures, however, show that under the conditions of cheap naphtha, prevailing during last year as well as in 1878, the cost of making gas at the Municipal works was perhaps ten cents per thousand less than the average cost of making a coal gas of equal illuminating power by the old methods now generally followed.

Passing next to the question of efficiency. I have during the last year made a number of photometric measurements of the gas supplied by the Municipal Company in comparison with that sent out by the Manhattan Company which I selected because it was known to be a pure *coal gas* and thus convenient as a standard of comparison.

Greatly to my astonishment, I found that when *burned in the same burner* (*i. e.*, that known as the Sugg. G, argand of 33 holes) the amount of light yielded was essentially the same for either gas. In other words, if the coal gas which (burning in the old standard burner of 15 holes) gave only a light of about 17 candles, was burned in the new 33-hole burner, it gave about 20 to 21 candles; the consumption in all cases being the same, namely, 5 cubic feet an hour.

In other words, the difference in illuminating power, about which so much has been said, is due to the burner not to the gas. The water gas could not be burned in the old standard 15-hole burner (this burner would not feed 5 cubic feet an hour at ordinary pressures), hence the 33-hole burner was adopted as the "standard burner" for the water gas, and with it a light of from 20 to 22 candles was obtained, but it was not noticed that with this same burner pure coal gas would yield an equal light.

In other words, this improvement in burners went to the credit of the water gas.

To obtain the better light it is therefore only necessary to change the burner.

I find, moreover, that the regulated batwing burners give an equally good result.

[To be continued.]

DEWSBURY CORPORATION GAS SUPPLY.

We have received from Mr. Charles Armitage, the Engineer and Manager of the Dewsbury Corporation Gas-Works, the following details of their working during the half year ending Dec. 31, 1875:—

Gas made as per station-meter	61,505,100 cubic feet.	63,705,400 cubic feet.
Gas used for retort-purposes	2,200,300 "	
Gas sold for public lighting	302,300 "	
Gas used on works		56,850,000 "
Unaccounted for		6,713,000 cubic feet.

Equal to 10·5 per cent.

Capital employed—
£317,731 5s. 6d. or £23 9s. 6d. per ton of coal carbonized, or £3 13s. 6d. per 1000 cubic feet of gas sold.

Coal carbonized—

Cannel	4,522 tons or 10·56 per cent.	
Cannel	422 " or 9·61 "	
Total	4,950 tons.	

Illuminating power required by Act	14 candles.
Illuminating power supplied	14 "
Gas manufactured per ton of coal	10,351 cubic feet.
Gas manufactured per ton of coal	10,351 "
Gas made per retort-charge, per ton of coal	6,017 "
Coke made (including 12 cwt. per ton of coal)	5,111 tons.
Coke sold	3,716 "
Coke sold, per cent. on make	72·70 per cent.
Coke used in heating retorts	1,395 tons.
Ditto, per cent. on make	27·30 per cent.
Coke used for other than Gas Works	1,395 tons.
Ditto, per cent. on make	27·30 per cent.
Average price of coke sold	9s. 6d. per ton.
Tar made per ton of coal	11·77 gallons.
Average price of tar per gallon	1½d.
Liquor made per ton of coal	33·97 gallons.
Average price of liquor per 1000 gallons	10s. 7d.
Coke, tar, and liquor realized per cent. on cost of coal	8s. 7½. per ton; 30 per cent.

			Cost per 1000 Cubic Feet Sold.

[ANSWER BY MRS. HEMELLE, "RICHES' HOOKER."]

HARTFORD, CONN., *Dec. 26, 1875.*

To the Editor of THE SANITARY ENGINEER :

Should you kindly permit me to address your correspondent directly through the medium of your valuable paper, I should say—

Dear Madam.—My experience as mother, wife and housekeeper for thirty years and more has convinced me that healthful homes are to be looked for only through the intelligent watchfulness of the "women" who make the homes and who are the responsible guardians of their moral and physical purity; therefore I am glad to embrace every opportunity for conference with thoughtful women all over the country, that we may, through our common experiences of difficulty and mistake, help those who shall come after us to a greater measure of health, comfort and happiness than would otherwise be possible. Should my views correspond with your own I should be pleased to know it, and should it be otherwise, a plain statement of difference, with reasons therefor, would be most acceptable.

How to warm and ventilate a house, in this changeable climate of ours, seems to me a fundamental question, and one which may be made to include all others; therefore I begin with that; and have to say that, while I am not of those who talk much of "the good old times," in contrast with present days of "modern improvements," there are a few things which have gone out of use that should, it seems to me, be restored as fast as possible. The first is, open fire-places, with hearths of stone or tile, and large flues (flues should be twelve inches square, or in that proportion, whatever the shape of the flue) in nearly every room in the house, but especially in the chambers, and the smaller the chamber the more desirable the open fire-place. After much study of the many modern methods of ventilation my impression is that, both for private houses and and public buildings, heating school houses, there is no method of securing a gentle, *uncontrived* circulation of air through apartments quite equal to a smouldering fire on the hearth of an old-fashioned fire-place, with a heavy layer of wood ashes always accumulating under, and seldom removed from beneath the low brass andirons that lend an added glow to the domestic picture. "Oh, but the expense !—wood is as costly as gold in our cities," etc., etc. Yes, if used exclusively as a means of warmth, but if used in connection with furnace or stove heat for purposes of ventilation and cheerfulness, the expense would not be great, even at the present time, and when a steady demand should be felt, a competitive wood market would soon bring down the price to meet purses of very moderate dimensions. Considering present facilities of transportation in our country, and the immense forests waiting the use of the woodman to let in light and cultivation, also the need of new business avenues—considering also that the older countries of Europe will furnish wood to their large cities, having found it as legitimate a business to grow trees for fuel, as vegetables for food, we ought not to be deterred from at least considering the benefits to be derived from a restoration of the old fire-places, with its blessed chimney corner for the old, its cheerful paraphernalia of brass andirons, shovel and tongs, and dear old bellows also—anything for babies from time immemorial, and gentle inspirer of all quiet home thoughts.

As to actual cost I hardly dare attempt an estimate; but give me one old newspaper, eight or ten bits of pine shedding stuff, split fine for a fagot of brush-wood such as

Gas Lamp Makers in New York, 1876 1880

The nine-day's wonder of the Edison Lamp seems to have had its day, and now very little is heard of it, except an occasional short paragraph, either of promise or fun, in the daily papers, from which it would appear that the "perfect lamp" requires some further modification to make it just what is needed to supplant gas. In the meanwhile, there are some whispers in the street to the effect that some of the gas companies, at least, are not entirely satisfied with the present low price of gas. Two of the companies have declared dividends; but probably not from *earnings* during the past six months, but more likely from surplus on hand before the extreme reduction in price, or from funds derived from some other source. Certainly, no company with a stock capitals such as the New York companies have can be expected to earn and pay any dividend while selling gas at 75 cents to $1.50 per thousand. As to the policy of paying a dividend when it was not earned—we question the advisability of it. If it was a good thing to have a moderate surplus when good prices prevailed, it certainly seems to be a better thing to have it during a fight. There are one or two things that are quite encouraging in the situation to-day. The New York Mutual Company have called meetings of its stockholders for the purpose of ascertaining a reduction in the capital stock of that company from five to three million dollars; and as it is understood that a very large majority of the stockholders are in favor of the reduction, it will probably be done, although, at this moment, we are not aware that all the details are arranged. This is a noble example, and we wish that the lead taken in this matter may be followed by many other companies who would seem to have a capital out of proportion to the business they are doing. A moderate capital is an absolute necessity in order to sell gas cheaply and make a fair profit, and cheap and good gas is what the consumer demands, while a fair profit on investment is what the stockholder is justly entitled to.

The Municipal Company, on the other hand, have called a meeting for the purpose of increasing their capital stock from two to three millions. This is said to be necessary *for* purposes of extension. Subsequently to the issue of the call for the above meeting, an explosion or accident occurred at the works of the Knickerbocker Company, Second avenue and Ninety-third street, and connections were made with the mains of the Municipal Company for the purpose of getting a supply for at least a portion of the Knickerbocker's consumers.

The damage done by the explosion at the Knickerbocker's works is variously stated, all definite information being withheld by the company. The fact or their getting a partial supply, at least, outside, however, is undoubted; and another thing which transpired a few days later would seem to indicate that the damage was considerable—and that is that the Knickerbocker company is reported to have sold out entirely to the Municipal Company. If this is so it is another step in the right direction, for it practically consolidates two of the existing companies. The terms of the purchase are not made public; but it is a clever move on the part of the Municipal Company whether they continue the war of prices or not. The property and franchises are valuable, and it is not to be supposed that more was paid for them than they are worth. It simplifies the problem of ultimate consolidation immensely as there is one less company to negotiate. It is to be sincerely hoped that further amalgamation will follow, and that the business will be placed in the hands of one organization, with less capital than is already represented by the stock of the various companies; and that, satisfied with dividends of ten per cent., the price of gas will yield that, and keep all the works and plant in thorough order. This once done, opposition will cease and mutual benefit accrue to all.

profit has been made by the Company. One authority puts it at nineteen per cent., and another at ten per cent., or a little under. The one thing wanted by the Company is an Act to incorporate them with statutory powers, and for this purpose they have announced their intention of applying to Parliament next year. This will, it seems, satisfy the Local Board. Let us hope that it will.

Another column will be found the full text of the valedictory address of Mr. R. Mitchell, of Coatbridge, the ex-President of the West of Scotland Gas Managers Association, delivered at the meeting of the Association on the 29th ult. His remarks, as we said last week, that the electric "sense" has been beneficial to the interests of gas and others to look further afield for new means of advancing and improving the production of coal gas. We quite agree with Mr. Mitchell in his view that improvements are required in the retort-house and the means used for fixing the retort-settings. It is the opinion of many gas managers that great improvements in this direction may be effected by the use of the Siemens or Coxhill-lane regenerative furnaces. The employment of these systems by Gas Companies would, of course, leave them with a large stock of coke in hand. They would then, as Mr. Mitchell said, have to go in "for small profits and quick returns;" but this is scarcely satisfactory. We want to realize the full value of residuals, and not be content to make forced sales. Of course, the ex-President, in referring to the future of mechanical stoking, did so cautiously. He is cautious by nature. Which of them is destined to the supreme new under one we cannot venture to say. It is not our province to express decided opinions when comparing salients are brought under our notice, and we shall not do so on this occasion—the rival inventors must fight for the merits of their own specialities. We content ourselves with thanking Mr. Mitchell for his valuable and instructive address, and are sorry we shall not hear more from him in his late capacity as President of the West of Scotland Association of Gas Managers.

The vaunted superiority of the electric light for lighthouse illumination—a superiority, we are bound to say, not admitted by many of those who are able to judge of its merits in this special direction—is, for which we are indebted to Mr. J. O. Phillips, Secretary of The Gaslight and Coke Company, the small- following, which appeared in the daily papers at the close of last week:—"The crew of the steamer *Gaudetown*, of Aberdeen, which, bound from London for Dublin, with cement, landed at on the Skap Rock, near Stromness, their vessel having struck on the night of Wednesday morning, their vessel having struck on the night of Wednesday morning, their vessel having struck on the night of Wednesday morning

Engineering, June 6, 1890

To the Editor of ENGINEERING.

SIR,—During the discussion before your reference, on the 9th, 16th, and 23rd ult., on Mr. Dugald Clerk's paper, it was admitted that the "Otto" system economizes coal not contradicted by others, that gas engines in general, and particularly the "Otto" system, consume from 20 to 25 cubic feet per horse and per hour, power, as stated by Mr. Denny Lane, in his Cantor lecture (fifth inst.), quoting the manufacturers' numbers, or at the extreme rate of 28 to 32 for the smallest engines and from 17 to 20 cubic feet for large engines.

I have not figures to compare me, considering that one cubic metre (nearly 35.32 cubic feet) is the consumption of the engines of "Otto" system according to Le Compagnie Parisienne de Gaz at Paris' manufacturers of those engines in France, Mr. Arnergraud in his notable work "Polidectics—Industrial Gas and Heat Engines," at page 31, Appendix, page 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42.

The discrepancy between those calculations is too important to be accounted for by the different calorific intensity of gas in London or Paris, although some allowance must be made. If we assume that the calorific intensity of gas in London and Paris is 700 and 670 "calories" per cubic metre, respectively, the first corresponding to 19.83 "calories" per foot, and the second at a consumption of 1,000 "calories" per cubic metre, that is the calorific intensity of gas in Paris according to several French scientific works, and that the engine, of which the consumption of gas is supposed to be 31 cubic feet per hour and per horse power (as an average between the figures given by Mr. C. H. Cheesbrow and Mr. Denny Lane), is a perfect engine, which is not the case, as it is full well put, a scientific mistake (read to that of Paris, viz., 670 "calories" per cubic foot), the consumption of that engine would be augmented by about 21 per cent., viz., from 31 to 37.52 cubic feet. We shall require more explanation on the subject in order to account for the above difference; it is my opinion that either the "Otto" engine is not perfect, or that the quality of the gas supplied is lowered by the indicator and not by the friction indicator as Mr. Denny Lane says to be a general practice with the manufacturers. However, supposing that the power intended by the indicator (as the figure of 22 cubic feet per hour and per indicated horse power given by Mr. Bidder, Wilton locks are to believed), the power wasted away by friction would be approximately 15 per cent., as the ratio of the two figures 22 cubic feet and 19.25 cubic feet is such. Now let us suppose that the power has been estimated indicated horse power and that the waste on account of friction, &c., is only 25 per cent.; it is obvious that in order to obtain on the axle or shaft of the engine an effective power equal to the indicated one, the consumption of gas would be raised from 22.75 cubic feet per horse and power to 29.

With I take the liberty of addressing to you these few lines for insertion in the columns of your valuable paper, may only hope that either persons more competent than myself, and having the opportunity to make practical experiments, may accurately determine the consumption of "Otto" engines, I am, Sir, your faithful obedient

servant, FRANCISCO DE LA VIBORA.

Madrid, January 29, 1890.

The Economics of Coal Gas.

Electric lighting cannot, so far, be regarded as a success in itself, but, by putting the gas companies on their mettle, it bids fair to prove the means of developing the full powers of their commodity, both as a source of illumination and in many other ways. Until quite lately, from causes which had their origin, in some part, and at a very early period, in the ignorance of managements, gas has always been consumed in a most unscientific fashion; the excessive pressure, for example, at which it has been used not only wasting it, but needlessly reducing its illuminating power to an excessive degree, and the new burners and methods which the necessities of competition with electricity have recently brought into existence and notice are yet far from having got into general use. What can be done in gas lighting, and economically, too, when it is burnt on scientific principles, may be learnt from the displays at street refuges and other points of the metropolis, and what has been effected in the street may be profitably imitated in the dwelling. The waste or bye-products of the gas manufacture are now so valuable that they are understood to pay the whole cost of production of the gas; it is evident that the application of the latter to heating and cooking purposes, and as a source of motive power, is only in its infancy; and probably the profits from these subsidiary uses and from by-products would return a handsome dividend to shareholders, even if as a source of illumination gas should ultimately be wholly superseded by electricity.

Coal Trades Journal

June 16 1890

YESTERDAY afternoon, on the application of Mr. Baxter, Stock and Right Brokers, of 20, Cornhill, prices for insertion in the closing prices yesterday of some of the principal gas companies:—

PHŒNIX ENGINEERING WORKS:
LAND STREET, SOUTHWARK, S.E.

became part of my duty to superintend its erection, and to see to its working after the contractors had completed.

The site selected as being convenient for the machinery was the Corporation Depôt, situated 400 yards from one end of the Promenade, and 950 yards inland. Here was put up a substantial timber building, 60 feet by 25 feet, and inside, on the ground, was laid a framing, which formed the foundations for the machinery, the interspaces between the timbers being filled in flush with concrete, and then boarded over to prevent dust rising. Upon this frame work, as they arrived, two portable 16-horse power engines and boilers were fixed, and also the six gas-exhausters, each of which three were seven, all being driven from a countershaft placed between them and the engines. From each of the six machines a distinct wire was led to its own lamp, and one common return wire, so to speak, answered for the whole. You will, no doubt, wonder what the odd machines was for. Well, at first, the whole of the six machines had to perform the duty of producing their own electricity, but that duty is now taken from them by their having become a distance-electric machine to that purpose solely, and this was found to be better for the lights.

The first difficulty had to contend with was the laying of the wires inside the 3-inch iron gas-mains or pipes, it having been decided to place them underground, hidden from sight, and out of the reach of accident as much as the wire was in 50-yard lengths, and it was desirable to have as few joints as possible. It therefore cost as much to put the wires through as it did to make the tenders, so careful had we to be in order not to damage the insulation, and to keep off the water. The weather happened unfortunately to be unfavourable for us, as a day or two after commencing, a series of high winds set in, with their usual effect at Blackpool—namely, to drive the sea-water over to the amusement of visitors, but to the detriment of our fixings. Every tide, it filled the trenches and pipes with sea-water. However, as soon as the wind did stop, we persevered, and completed the 1500 yards in the course of a week, and were ready for the preliminary trial to take place on Saturday, the 15th; but, alas! all our efforts were unavailing, for the insulation of the wires had yielded to the water, and it was quite spoiled for the purpose, so there remained no alternative but to withdraw them. This was announced on the Friday evening, and drew out the whole and laid them on the ground to dry, and on the following night we had another trial, and connected the wires, and had two of the most splendid arc lights at work with good effect. By the following Monday morning all were connected together in neat suitable poles in the town, and immediately set to work, and placed them up telegraph fashion, and secured the wires thereto with iron staples, there being no iron to get insulators fixed. During the time the wires were being completed, experiments and trials were going on in the engine-room, and by Thursday, Sept. 18, all was finally ready, and the lights were lit at dusk with remarkable steadiness, considering the drawbacks we had to encounter in front of them.

I may tell you that it was with no small degree of pleasure I beheld, from the engine-room window, the vast crowd which had assembled to witness on the upturned faces of at least 10,000 persons who had come to Blackpool to witness the grand spectacle—to see the poor gas cease for all annihilated. Well, I may say the gas cut a sorry figure when placed in the lamps when the electric lights were lit, of which a good many of you present were eye-witnesses, and it became very useful as the night grew darker, and one of the new illuminants was suddenly extinguished, for it could have been used as the public is now left all in darkness as well as we might have occurred at any moment. As we got more accustomed to the management of the lights, and more confidence began to exist in confidence, because we found out how to supply the current. In nine-tenths out of ten the cause was the rock holding the carbons getting fast, and a man was usually on the lookout to deal with the line to the lamp. So frequently did this happen that ultimately the pasting, public and private, saved us the trouble by pulling the line as they went by. Sometimes, however, more serious mishaps would occur, owing to the enthusiasm of the public, who, in their anxiety to get a good look at the lights, climbed upon the particular lamp-post which supplied the lamp, and in such cases there was no alternative but to take the lamp down to the ground, and then the crowd would disperse, and the lamp be replaced. Another difficulty which we had to contend with was the fact of the lamps being fixed at different heights, for reason in the other? To say why our set of lamps were fixed at 30 feet, and the others at 40 feet, I am not able to tell you, but I suppose it was thought that the 30 feet lamps would be sufficient for the purpose, and that the 40 feet lamps would be required to throw their light over a greater distance. Such lamp-lighting of course was not to be wondered at, for it was the first time that the electric light had been used for such purposes, and I may say that, considering the difficulties we had to contend with, the lights were very successful. The results of working were very found to be in the most satisfactory manner, and if the public were not satisfied with their lights after the experiments which they had had, it was entirely their own fault, as well as the fault of the Committee appointed by the Council to watch the experiments. Another difficulty which we had to contend with was the fact of the lamps being fixed at different heights, and of their being of different candle-power

city of gas consumed, and the Secretary having proved the number of the meter.

Mr. *Betteridge*, the Official Meter Examiner, was called, and stated that he had examined and tested the meter which had been supplied to the defendant, and found it registering well; 159 feet per hour was the proper quantity for the consumer. He thoroughly tested the index that as far as power was concerned, the meter was all right.

Cross-examined by Mr. Pemberton, Q.C., he said he had not found anything the matter with the meter, and knowing that the index had been repaired, he had tested it with great care.

Mr. Dennis cross-examined with the object of showing that the index registered more than was actually consumed, and that the discount allowance made from the account was insufficient; the meter was in perfect order.

Mr. Leonhardt gave judgment for the full amount claimed, with costs. Payment in 14 days.

LAMBETH POLICE COURT—SATURDAY, JUNE 12.

Before Mr. Elliott, Deputy Coroner.

PROSECUTION OF THE SECRETARY OF THE

Matilda Flight, of Beech Cottage, Norwood Street, was summoned at the instance of the Lambeth Water-Works Company for neglecting to comply with the regulations of the Company's Acts to provide stand-pipes of covered cisterns with proper fittings, in the place of butts, to houses of which the supply was severed, in Hope Street, Villa Street, Wilcox Street, and Norwood Street, Norwood, Sydenham Hill, which last was also summoned for a similar offence with regard to houses of which the supply was severed in Surrey Street, New Inn Road.

Mr. Beasley appeared to prosecute, and stated that the Company had for some time been urging the defendant to carry out the constant supply system, as required by the Act of 1852, and £2000 or £3000 had been expended upon it. Most important work! Mrs. Flight was summoned and registered some 11 houses in which she had failed to carry out the requisite alterations. The Company had been most considerate in every matter, and all the cisterns which the Company had the power to do, and for a long time refrained from taking the present proceedings. Other time back a case was before them of a similar character, and the defendant in that instance was ordered to pay a fine of £5. Since then the defendant had promised to have taken out Mrs. Flight had signed an agreement to do the necessary alterations, but had not done so. If this was done the Company to complete the required work in 21 days. If this was done that it should not be ready to press for judgment, but they were anxious that these highly important works all through the district which they were carrying out should be necessary regulations must be carried out. The present case involved about 3000 houses, had been dealt with as regarded those in which the defendant served upon the owners of which had failed to comply with the notices served upon them.

Mr. *H. J. Calvert*, an Inspector of the Company, was called, and proved the case. He added, however, that since these proceedings had been instituted Mrs. Flight had put the work in hand, and about a dozen houses had been done.

Mr. Beasley, at the desire of Mr. Bayley, directed an adjournment for three weeks, and that if the work was not done the heavy penalties might under the Act be subject to be imposed.

In the second case, the case of the defendant proved, and declared he was unavoidable. It was, however, clearly proved that the property was the agent of his father.

Mr. Bayley said he had been given to understand that the property was to be sold, and therefore he would not enforce the alterations required by the Company's Act, which were highly important for the property owners, but that they must be carried out, and that the defendant must do so, or be heavy penalties. He ordered the defendant to pay a fine of £1 and £3 3s. costs.

BANBURY POLICE COURT—MONDAY, JUNE 14.

Before the Mayor and a *Bench of Magistrates.*

PROSECUTION FOR THE PROPER SUPPLY OF GAS.

Mr. *John Meacle*, an inconsistency, of High Street, was summoned for the non-payment of 12s. 11d. due for gas supplied to him by the Banbury Gas Company.

Mr. J. Gibson, who appeared for the Company, said the facts of the case were very simple. The price charged by the Company was 3s. 6d. per 1000 feet, but, owing to the sale of the Town Hall, the number of the Company had been reduced, and in order to obtain prompt payment, quarterly accounts were rendered. A notice was given notice that for payment would be allowed, and as the Company commenced quarters certain discount for payment would be allowed, and as the Company commenced quarters certain discount for payment would be allowed, and as the Company commenced quarters certain discount

British Association of Gas Managers—Inaugural Address of the Acting President, Charles Hunt, Esq. ..... i. to xiii.

TO CORRESPONDENTS.

L. M.—*Thanks for information and good wishes. Shall probably soon have an opportunity of referring to the facts to which you call attention.*

T. A.—*The proceedings are rather out of the work so far as our readers are concerned.*

Gas Meter Alde.—*Crowded out this week.*

No notice can be taken of anonymous communications. Whatever is intended for insertion, must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of good faith.

THE JOURNAL OF GAS LIGHTING,
WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, JUNE 8, 1880.

Circular to Gas Companies.

The Seventeenth Annual Meeting of the British Association of Gas Managers will have commenced its proceedings before this JOURNAL reaches our subscribers. The programme, which we published last week, contains material which promises to the large number of members who will doubtless attend, both interest and profit, and our expectation goes with such hope that the meeting of 1880 will prove in the truest sense a great success.

Our regret at the absence from the chair of the President for the year, Mr. John Douglas, will be generally shared. It will be remembered that when, last year, the choice fell upon Mr. Hulse, he was away on the Continent in search of health; but we hope that the trip has not unsuccessful, because it seems to say that the season was unsuccessful. We hope that for the sake of the Association which he has been a useful and valued member as well as for his own, he may soon be again the strong man we have known him. Under such circumstances, the Association is fortunate in having been able to fill, and that so satisfactorily, the gap by having Mr. Hunt thus called to "the front bench" as President of the Midland District Association, and the very able and practical character of the addresses he has delivered before the members of that Society, as also of the papers he has contributed to the Association itself, make us look with even special interest for the Inaugural Address this year. It is worthy of remark that this year, as last, the presidential chair of the present Association is filled by one who has held like office in one of the district offshoots. There has been much speculation in our columns and elsewhere, in recent years, as to the effect likely to be produced by the formation of these district societies [illegible] all over the country. Would they be an [illegible] or the contrary? It is difficult to say, so far, what, if any, has been the influence exerted. The proceedings at the meetings held have been generally of a distinctly valuable character to those who have attended or taken part in them, and anything which tends to benefit and improve the information of individual members should, and no doubt does, have a beneficial effect upon the Association as a whole. We think, however, that it is eminently desirable that some more positive gain should result to the central and representative body from such machinery as these district associations afford. The training of presidents is doubtless a high function; but there is a higher one—that of contributing as largely as possible to maintaining and increasing the high character of the Association; thus securing that the office of President will continue to be looked up to as one of distinguished honour by all members of the profession. In his address in 1878, the President of that year made a suggestion which, though well received at the time, does not appear to have borne fruit; it was that each of the district societies should charge itself with the responsibility of contributing from among its members one paper to the annual meeting. Last year Mr. Warner amplified this idea by proposing that the Association should depute certain subjects for investigation to the branches, and receive their reports at the annual meeting. How useful might be the results of such a practice may be inferred, not only from the illustration which Mr. Warner gave, but also from the excellent work which has been done by the Manchester District Association, in obtaining and tabulating information upon practical subjects from among its members. That the district associations should be in effect branches of the parent one, that the work in which they have been engaged during the year should produce some result, and find some record in the proceedings of the annual meeting, is clearly most desirable; and we shall rejoice if the proposals in this direction which have been repeatedly made should be referred to a representative Committee of the Association for consideration before the next annual meeting. With such a connection cordially accepted, the whole would enjoy the advantages and the strength of union; without it, the painful position might arise of the parent's pride in the growth of its offspring being checked by the spirit of unnatural rivalry, and by unseemly reflections upon the fate of the divided house.

Another question which has occupied much of the time and attention of the members at several of their too short meetings is that of the restrictions upon membership imposed by the present constitution. A letter which appeared in our columns last week, signed "An Assistant," stated the case very clearly from the point of view of those at present excluded. We observe that notice is given in the programme of an intention to amend the rules, and it is possible that the Committee may purpose substituting some proposition on this subject.

The formation of a class of Associates has much to recommend it, and we confess our inability to see what insuperable objections can be set against them. That the class, if formed, would embrace many men of greater information and culture, and of much higher social and professional position than some of those who by right are members of the one with the more dignified name, there can be no doubt; and that in the case in many other societies, and the feeling of "no sonship" can would be hurt by what is simply an inevitable necessity. From the numerous body of assistants in and outside gas-works—engineers, foremen, chemists, and others, there would be formed a class of earnest and intelligent men—the substance of to-day, the leaders of to-morrow—who would not only themselves derive help on their way, but who would, we feel sure, constitute much to the useful element of the Association as a whole. Such a class would, it seems to us, partake, if formed, of the characteristics of two sections of the Institution in whose home the meeting this year will be held—the Associate and the Student. There would be the same power in the hands of the Committee to veto the election of candidates. Members after, to determine the suitability of candidates, as under Rule 3, as amended a few years ago, there would remain to the Committee the right to nominate as members those whom the old rule excluded, and the proposed new one would relegate to the class of Associates. Retrial changes in any constitution should never be made lightly; but, on the other hand, neither should they be resisted when their expediency is clearly apparent. Especially is this the case if investigation has failed to discover evil likely to result from them as a set-off against the undoubted good. Burning questions are apt to become nuisances if their consideration is over-long delayed.

We are glad to observe that the number of papers on the

was reduced to 32° Fahr. at Munich, the loss of illuminating power, compared with gas at the ordinary temperature, was from 75 to 80—average 20 per cent.; whereas in my own experiments, when gas at 32° Fahr. was tried against the same gas at 280° Fahr., the disc of the photometer showed no change.

As already stated, I think there can be no question (supposing, of course, that the composition of the gas itself undergoes no change by deposit of illuminating substance) the better the gas at the point of ignition the more favourable will its temperature be to effective combustion; and that the lower in temperature the less favourable will it be to intensity of combustion.

Communicated Article.

EFFECT OF TEMPERATURE IN THE GAS AND AIR SUPPLY UPON THE ILLUMINATING POWER OF GAS-FLAMES.

By Mr. R. H. Patterson, F.S.S.

THIRD AND LAST PART.

The experiments made at Munich relative to the effect of the temperature of gas at the point of ignition upon the illuminating power of the flame, were carried both upwards and downwards from the ordinary temperature. As previously described, in my experiments in 1871 I found no difference in the illuminating power of the gas when supplied to the burner at the highest temperature employed at Munich, namely—212° and 288° Fahr. We come now to

THE DEFECTS OF COOLING THE GAS.

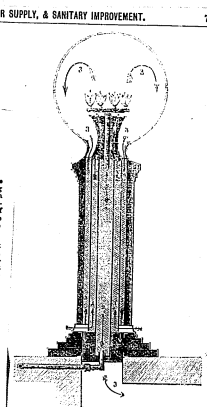
The results of cooling the gas below the ordinary temperature at Munich were as follows:—When the U-tube was immersed in snow, so as to bring the temperature of the gas down to 32° Fahr., the illuminating power was found to have fallen from 100 down to a point varying from 75 to 85; in other words, the light was reduced, on the average, to the extent of 20 per cent; and when the temperature of the gas was still further lowered by immersing the U-tube in a mixture of salt and ice (temperature 4° below zero), the illuminating power of the gas-flame was reduced by nearly two-thirds, ranging from 31 to 40, as against its ordinary illuminating power of 100.

The latter temperature (– 4° Fahr.) is one to which, in this country, the gas, as supplied to the public, is hardly ever subjected; and although I contemplated doing so, I did not carry the application of cold to this extent. But as regards gas at the freezing point (32° Fahr.), my experiments made in a very stringent manner as for the gas at this low temperature was tried against gas at the highest temperature employed at Munich. By means of a by-pass, gas at the freezing point and the same gas at a temperature of 280° Fahr. were supplied alternately to the burner, but without making the slightest difference in the readings of the photometer. The photometer was observed most carefully both myself and by Mr. W. Thompson, and we could not see the slightest difference.

Now, in this case I had expected a different result; not, however, of a kind affecting the real question at issue—viz., the effect of temperature in the gas upon the illuminating power of the flame—but owing to a change in the constitution of the gas itself, which would be a different matter. Just as a very high heat alters the composition of gas, greatly diminishing its illuminating power, so will extreme cold, from a kindred cause, produce a similar result. In the former case, there is a disintegrating chemical effect produced by excessive heat; in the latter, by the cold, a deposit of carbon; in the latter, there is the effective freezing, by which the water contained in gas in the form of aqueous vapour is deposited from the gas in the form of ice, and a portion of the illuminating hydrocarbons are condensed along with it. Neither of these circumstances, however, affected, to any appreciable extent, the effect of temperature upon the gas, so far as the illuminating power of the flame. Nevertheless I had expected that the effect of cold would have produced a perceptible loss of illuminating substance in the gas, and I found that this did not occur (as doubtless owing to the very brief time during which (not a moment) that the gas was subjected to the low temperature of 32° or even a little lower), was fully imparted to the gas, but that it took an instant before the gas sprang into flame at the point of ignition.

When results are obtained so discordant as those at Munich and in my own experiments, in which, I have to say, the co-operation of Mr. W. Thompson, the position of the gas is by no means satisfactory. For, as at Munich, both the gas and the air supply were at 32° Fahr., the illuminating power was only 4 candles, and at 288° it was 20 candles—was 16 per cent. But, theoretically (since the gas was cooled below the ordinary temperature is very striking; for when the gas

reaches it three-sixteenths (ibid., one-fifth) by a glass globe. At the lower part of the globe is an ordinary burner, with a regulating cock, and which serves chiefly to fill the globe with gas, and to supply it occasionally heat to them. The middle tube passing upwards, and the globe, is there burnt with the gas. The outside passing upwards tube is a chimney or ventilating tube. The arrangement and course of the current are shown in the figure. The products of combustion, in another space of the outside pipe, are then burnt with the products of combustion as they pass away from the globe, and the heat thus generated is imparted to the gas in the globe, and to the air in the connecting tube for its supply. The heat thus extracted is by conduction and radiation to the regenerators in the atmosphere, and also through the glass globe to the gas-flame. Air and gas are thus pre-heated, and the pre-heated air is burnt in proportion as the temperature of the flame, increased by the pre-heated gas, is raised above the temperature of the regenerators in the outer pipe. The increase of

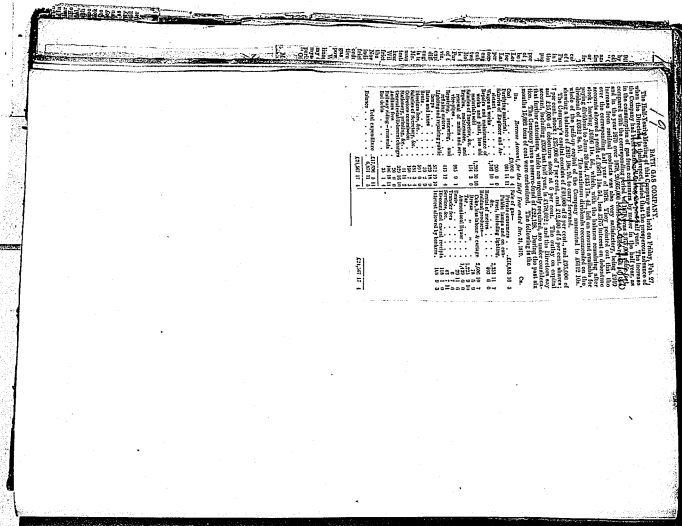


SIEMENS'S LAMP, VARIETY A.

temperature, and consequently of the illuminating power of the flame in globes of glass also until the cooling effect of the glass stops the direction of heat.

short, Herr Siemens places a burner (or several burners) on the of a pillar consisting of three concentric tubes, all of which are ed with wire gauze, in order to convey heat to the surface of the ne through the gas and air, instead of by direct contact between heating the gas. The central tube conveys the gas to the burner, ever, or middle tube, contains the air supply; and the outermost ries away the products of combustion, which, being at a y high temperature, communicate a portion of their heat to the gas in the two inner tubes. These passages, of course, lie next ne up to the burner, and the air-tube next to the gas-tube, so as ximum amount of heat to the burner; but the top of the burner is from the burner, in order that the products of com- may descend to the bottom of the outer tube, and there mix with the air ply and the burning gas.

this is a most ingenious and economical means of heating the air, ir, and consequently of the illuminating power of the flame in ases of combustion can in this manner be carried off without ing, as in the ordinary manner, the products of combustion would reduce the temperature of the products of combustion—i.e., accordingly but vapour into ith the gas-flame is resolved—absolutely into water and carbon. s lantern, immediately above the burner, and, descending in the e sides of the lantern, pass freely away down the tube into the space products of combustion (CO$_2$) are twice as heavy ounce of air, and would take such a course if they were cool; but is this case the products are very hot and lighter; and I think the general impression would have been that, in this lantern ing, the products of combustion would rise to the upper part, and at once, and would linger in the upper part, or indeed all through ere employed upon the construction of an "exhaust" lantern, of combustion are withdrawn from the lantern by means of a fan. of Herr Siemens's lamps is the lantern, or chimney tube; but Herr Siemens makes no mention of an exhaust, and also he does not refer solely upon the "natural draught." If this be so—and it cannot be doubted after Herr Siemens's statement to that effect—what Herr Siemens has thus accomplished, appears to me most valuable, as an example, with reference to the construction of gas-lanterns generally. The obvious inference from Herr Siemens's apparatus is, that it is not necessary to have any outlet at the top for the issue of



EXPERIMENTS IN IMPROVED STREET LIGHTING AT WOLVERHAMPTON.

On Wednesday last, at the invitation of Mr. Charles Hunt, Engineer of the Birmingham Corporation Gas Department, a number of Gas Engineers, principally from the Midland Counties, and others interested in the subject of improved street lighting by means of gas, assembled at the Windsor Street works of the Corporation, for the purpose of viewing a collection of lanterns and burners of large power which had been got together by Mr. Hunt for the purposes of comparative trials of their efficiency. Among those who were present were Messrs. J. Annan, Wolverhampton; T. Arnold, Borough Surveyor's Office, Birmingham; J. C. Bent, Birmingham; G. Bray, Leeds; T. Collett, Dudley; W. Cross, Leamington; W. Davis, Hereford; J. Deakes, Worcester; A. Dougall, Kidderminster; H. Hack, Saltley; T. Jackson, Birmingham; C. E. Jones, Chesterfield; A. P. Kerr, Birmingham; W. King, Liverpool; T. Layton, Redditch; J. Medir, Burton-on-Trent; W. North, Stourbridge; G. Parker, Oakengates; E. G. Paterson, Cheltenham; B. Peaty, Burslem; J. Pinnock, Hereford; T. Pryce, Birmingham; J. Rowley, Tipton; J. Reid, Derby; T. Roberts, Sheffield; T. Simpson, Rugby; S. Y. Shoebridge, Saltley; J. Shoosmith, Birmingham; E. Smith, Secretary of the Corporation Gas Department; J. Storer, Stafford; J. Taylor, Derby; T. Taylor, Derby; J. Tindall, Walsall; W. Winstanley, Newcastle-under-Lyme; H. Woodall, Leeds; J. Wright, Birmingham, &c., &c.

The burners and lanterns were fixed on the several parts of the works, three important ones being placed at distances of about sixty yards from one another on a large tract of unoccupied land to be eventually used for extensions. By this means the effectiveness of the burners in lighting a considerable and open area could be tested, a point much considered necessary to be pressed at the completeness of the trials. The following is a list of the burners and lanterns used, showing the consumption of gas by each burner, and the illuminating power afforded (when tested in the photometer-room), and the illuminating power obtained per foot of gas consumed :—

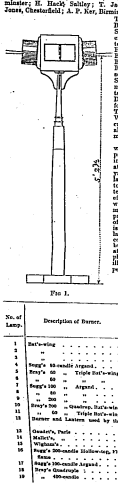


FIG. 1.

* A better result—viz., 2·24—was obtained with a consumption of 45 cubic feet of gas per hour.

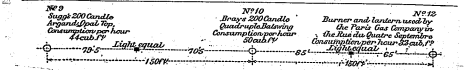

FIG. 2.

After a prolonged inspection of the various lanterns and burners, tests were made by a shadow meter (see sketch, fig. 1) between Sugg's 200-candle Argand (No. 9), Bray's 200-candle Quadruple Bat's-wing (No. 10), and the Burner and Lantern as used by the Paris Gas Company in the Rue du Quatre Septembre (No. 12), with the results shown on the diagram, fig. 2. These appear to agree very nearly with the photometrical results obtained from each burner, as shown in the preceding table.

The Argand and Bat's-wing candle that was made between the burners Nos. 9 and 10 on the diagram (the consumption of gas by each was raised to exactly 40·75 feet per hour) cast the shadow of the pencil-wood when the shadow meter was 21 ft. 2 in. from Bray's Quadruple Bat's-wing and 76 ft. 10 in. from Sugg's Argand.

It should here be mentioned that the Superintendent of the works, Mr. Alfred Colpe, rendered very efficient service in conducting these tests; in fact, to his able assistance Mr. Hunt is considerably indebted for the success which has attended the experiments all through.

In figure 3 is shown a sketch of one of the lamps of the Committee for the new lamp-columns to be erected in various parts of the town. These pillars, which have been specially designed and made for the Corporation by Messrs. Hart, Sons, and Peard, of London and Birmingham, were much admired for their substantial, yet ornamental and effective appearance.

At the close of the inspection, refreshments were served: after which

Mr. HENRY WOODALL proposed a vote of thanks to Mr. Hunt for affording them the present opportunity of witnessing the interesting experiments that had been carried through so successfully, remarking on the useful and judicious arrangements that had been made for the most reasonable comparison to be instituted between the various systems for public gas illumination now before the public.

Mr. S. O. PATTISON seconded the proposal, which was carried by acclamation.

Mr. HUNT, in returning thanks, expressed the pleasure he felt at seeing so many present. It might, he said, be desirable that he should offer a few words in explanation as to the circumstances under which the exhibition had been undertaken. Some experiments were initiated some fourteen months ago by the Chairman of the Gas Committee (Alderman Chamberlain, M.P.), who was desirous of showing in Birmingham what could be done with gas, in the way of street lighting, as compared with electricity. His (Mr. Hunt's) instructions were comprehensive: that he might say, liberal. He was to procure not only the most reliable burners, but also a lantern capable of diffusing the light to the greatest possible advantage, and, at the same time, of being fitted with the column, contributing rather to the ornamentation of the street than otherwise. As they all knew, the question of the burner involved considerations apart from the illuminating power obtained; but his experience was that the proper form of lantern was a far more difficult matter. He embraced this opportunity of acknowledging his obligation to the Committee for the indulgence they had shown him with regard to the length of time for the experiments had taken. He had contemplated for any one that the experiments had taken. He had contemplated for any one that the experiments had taken. He had contemplated for any one that he might say, liberal. He was to procure not only the most reliable burners, but also a lantern capable of diffusing the light to the greatest possible advantage, and, at the same time, of being fitted with the column, contributing rather to the ornamentation of the street than otherwise. As they all knew, the question of the burner involved considerations apart from the illuminating power obtained; but his experience was that the proper form of lantern was a far more difficult matter. He embraced this opportunity of acknowledging his obligation to the Committee for the indulgence they had shown him with regard to the length of time for

BURSLEM TOWN COUNCIL, GAS SUPPLY.

At a Meeting [illegible] Burslem Town Council last Tuesday—the Mayor (Mr. J. Meir) presiding—the report of the Gas Committee, which were presented, specified the report of the Gas Manager (Mr. E. Peake) as to the past year's working, the results showing a profit of £616 5s. 1d., being an increase of £1,000 over that of the preceding year. The Committee recommended a dividend of 5 per cent. and £616 5s. 1d. of these profits be placed to the credit of the sinking fund account.

Mr. W. Wardle, M.P., in proposing the adoption of the report, remarked that twelve months ago he had congratulated the Council upon the report the Gas Committee then presented, when £700 was handed over from the gas profits in aid of the rates. This year there had been an increase in the consumption of nearly 6 per cent., and he was happy to say that on the management account there was shown an increase of 10 per cent. upon the previous year. Consequently the Committee recommend the appropriation of £800 in aid of the rates. It must be remembered, however, that at the present time they were certainly embarking upon a period of trade that might be regarded as exceptionally favourable conditions. The value of coal, &c., was much in their favour, for it would be idle to hint they could expect to get it as they might, in years not very far distant, probably be subject to a increase in the cost of coal, &c. It would, therefore, perhaps be injudicious to look forward upon such large sums being appropriated from gas profits in aid of the rates. The policy of the Gas Committee had been to maintain the price of gas, and for that not for them, by improvements here and there as were found necessary, to increase the efficiency and enable depreciation which was always going on [illegible] connection with such works. The Committee, therefore, proposed to set apart, out of the profits, the sum mentioned in the resolution. During the four years that the works had been in the hands of the Council the total profits had exceeded £3000; but, as they were aware, a large sum was needed for working capital, and they had had to avail themselves of their profits at the bank, causing a very considerable charge from year to year for interest. A large sum of money had to be expended for carrying the Act of Parliament sanctioning the purchase of the works, and for the necessary loan for completing the purchase. The Committee, anyway, expected to maintain a sum that would represent the balance owing to the bank, which was decreasing; which, together with the fact that last year they had £700, and this year £800 [illegible], and the year £1000 in aid of rates, led him to think they had reason to be satisfied with the progress of the gas-works, and to feel that the Council were justified in purchasing them.

Mr. Sherratt seconded the motion, which was carried.

Mr. Worrall, then said that about a period time ago the Gas Committee [illegible] to their charge for lighting the public streets; but a very general feeling had been expressed in favour of the Council lighting themselves the whole of the streets, instead of for ten months of the year as at present, and in the Gas Committee's last report it was intimated that they were willing [illegible] same price that had been charged for ten months. [illegible] year he moved that the Gas Committee be instructed to light the lamps during the whole of the year upon the terms named.

Mr. Sherratt seconded that motion, which was also carried; and the Council proceeded to other business.

[illegible]TER SUPPLY, & SANITARY IMPROVEMENT. [May 11, 1880.

Manchester. In Liverpool, equal facilities for obtaining coal and canal cartel; and for a long period (during which the prices of gas was lower than in Manchester) the gas consumers here pointed to the price paid in Liverpool as the price which ought to be charged in Manchester. At the present time the price in Liverpool is 3s. 3d., whilst it is only 3s. 6d. per 1000 cubic feet in Manchester. Now, if Manchester gas consumers have a return of 10 per cent. upon the capital employed in the supply of gas ought to be obtained, for the benefit of the ratepayers generally? but—even if necessary to secure such return—it would be difficult to defend a higher price in Manchester than might be charged in Liverpool. The amount of profits made in any one year do not exceed the percentage allowed, or the appropriation of such profits, [illegible] Manchester, to the benefit of the ratepayers generally? But is it possible that the benefit of the profits should be enjoyed by the gas consumers?" The reply is easy and conclusive. The gas consumers do not pay for the improvements; they pay for gas, just as they do now when gone into the baker's shop pays for bread. The improvements are paid for by the ratepayers, and it is for them, and for them only, to determine whether the gas profits, which belong to them, shall (as now happens) be lavishly applied to be applied for that purpose, or whether such expenses shall be defrayed by means of an improvement-rate, and the gas profits be retained in the hands of the Corporation, to be applied for the purposes of the Corporation, or applied in any other way that may be deemed more beneficial to the inhabitants. Parliament would no doubt be quite prepared, at the instance of the Corporation, to alter the existing law, and to authorise the appropriation of the gas profits in any way and for any purpose which might be deemed to be most beneficial to the ratepayers. Having shown that the price of gas is altogether unaffected by the amount or the appropriation of the profits made in any one year, the inference, nothing more nor less than the question whether gas ought to be cheaper than it is, does not strictly refer to the proposal or suggestion made that the ratepayer, or a portion of the ratepayers, of the improvements should be defrayed out of, and by means of an improvement-rate. What is meant by this proposal is it difficult to understand. If it is proposed to keep down the price of gas below the market price, and by means of an improvement-rate to obtain the amount of profits which by such a course would, for the benefit of the gas consumers, be sacrificed, there is no doubt that such a proposal would be a most unwise one. The fact that an improvement-rate has to do with the price of gas appears not to be shown. It is quite possible that such rate may, in addition to the gas profits, be required to pay for improvements in progress or contemplated, but the exigencies or requirements of the Corporation in that respect, be they great or small, ought not in any way to affect the price of gas. When it was recently proposed to raise the price of gas 5d. per 1000, or to 3s. 5d. per 1000 feet, as charged in Liverpool per cubic foot, it is said would, considering the present low price of coal, be a most unwise proposal, and one which ought not to be subjected to, and it was argued that instead of any absence an improvement-rate should be levied, [illegible] such a proposal, if carried out, would affect the ratepayers, was clearly shown in a letter from a "Ratepayer," which appeared in the Manchester papers, and in which it was stated that "there are more than 30,000 householders who do not consume more than 650 cubic feet of gas per annum, which gives (at the additional price of 6d. per 1000 cubic feet) 1s. 10½d. per annum, and the consumption of the whole of these 30,000 would be represented by only the 100,000, and, calculated on the rental of 4 would be represented by only the 100,000, and, calculated on the rental of 4 would be represented by only the 100,000, and, calculated on the rental of 4

oppose the action of the London Gas Company to sell the sale of gas-stoves in its present duties."

The amendment was not, however, seconded; and the motion, on being put, was passed.

The only other paragraph in the report in reference to Gas Bills was the following:—"The Wandsworth and Putney Gas Company seeks power to raise further share capital to the amount of £100,000, and to borrow £50,000, the dividend on the share capital to be at the rate of 7 per cent. This Company is not exempt from the provisions of the Gas Works Clauses Act of 1860 only. Your Committee recommend that a petition be presented against the Bill, praying that it may be made subject to similar provisions as to auditing, mode of notice and dividend, disposal of new shares by auction, and other matters, as have already been applied to other Companies; and also that any new buildings to be erected by the Company may be governed by the provisions of the Metropolis Local Management and Building Acts."

This proposal was likewise agreed to.

The Artesian Metre System or Measuring.—At the meeting of the Kensington Vestry last Wednesday, the Gas Lighting Committee reported that The Gaslight and Coke Company have agreed to reduce the proportion of contract lamps in the parish from 1 in 20 to 1 in 21. The Committee therefore recommended that 40 matters be at once taken out of calculation. This was agreed to.

METROPOLIS WATER SUPPLY.

The Southwark and Vauxhall Water Company's Bill.—The Parliamentary Committee of the Metropolitan Board of Works presented a report at the meeting of the Board last Friday, in the course of which they say, in reference to the above-named Bill: "By the Southwark and Vauxhall Water-Works Company's Bill power is sought to enable the Company to raise additional capital for the supply of water within the Metropolis, subject to the consent of the Board of Trade. It appears to your Committee that it would be better that any proposal for enlargement should be brought before Parliament in a Bill, instead of being dealt with by the Board of Trade. The Company proposes to construct an additional pumping-station, reservoirs, and other works, and to raise £200,000 of additional share capital. The necessity for this should be fully proved by the Company, if the Bill be authorized; provision should be made for its basis by public notice or auction, in accordance with the

Canon Hawkins thought they could not do better than re-elect the same gentlemen, who had served them so well in the past. He proposed the re-election of Dr. Clay, who joined the Directorate at the time that he (Canon Hopkins) was Chairman, in the early days of the Company. He congratulated them upon the position the Company had attained, and the great benefit it was doing for the poor in providing them with an abundant good that it was doing for the poor in providing them with an abundant supply of wholesome gas at a cheap rate.

Mr. Chairman seconded by Mr. G. Fales, and agreed to.

The Master of St. Cuthbert's proposed the re-election of Dr. Percival as one of the Visitors, and, in doing so, took the opportunity of referring to the value of the shares of the Company, which had been disposed of at a recent sale at 14 15s. premium, which was the largest price that had ever been realized.

The motion was seconded by Mr. F. Pearce and adopted.

Dr. Percival returned thanks for his re-election, and spoke in complimentary terms of the way in which business was conducted by the Directors, and promised to do his best to serve the interests of the Company.

Mr. Clayton proposed, and Mr. Swan seconded, a vote of thanks to the Chairman, which was agreed to.

The proceedings then terminated.

ROCHESTER, CHATHAM, AND STROOD GASLIGHT COMPANY.

The Half-Yearly Meeting of this Company was held last Thursday—Mr. Thomas Wells in the chair.

The Secretary (Mr. W. Spicer) read the report of the Directors, which stated that the business of the Company for the past half year had been more favourable, the profits allowing of the writing off of a few items from the capital account in addition to paying the usual dividends. The new contracts were also about to be executed, and some other improvements made. The usual dividends at the rate of 10 per cent. per annum on the A and B shares, and of 7 per cent. on the D and E shares, were recommended. The statement of accounts showed a balance of profit on the half year's working of £1,000 4s. 10d.

The Hon. H. Nassau moved, and Mr. W. P. Hayman seconded the motion for the adoption of the report, which was agreed to.

The Chairman proposed the payment of the dividends recommended in this report.

Mr. Hayman seconded the motion, which was carried.

The retiring Director (Mr. J. Levy) was then re-elected; and Mr. W. Hayman, who was formerly Auditor, was elected a Director in place of the late Mr. N. H. Black. Mr. W. F. Hayman was appointed Auditor, vice Mr. Hayman.

A vote of thanks to the Directors, which was acknowledged by the Chairman, ended the proceedings.

EASTBOURNE GAS COMPANY.

A Special Meeting of this Company was held on Monday, the 21st inst. —Dr. Jeffray in the chair—for the purpose of considering and, if thought fit, of approving a Bill for conferring further powers on the Company for the purchase of land, the construction of works, the raising of money, and other purposes connected with gas-lighting.

The Secretary (Mr. J. H. C. Collins) having read the notice of meeting,

The Chairman stated that the Directors had, in the first place, consulted the Shareholders at the last meeting that the Directors received their sanction to apply to Parliament for powers to increase the capital of the Company. They had since then, with the assistance of their Parliamentary Agents, their Engineer, and their Secretary, drawn up a Bill which had been duly deposited with the Members and Standing Order of the House of Commons. The Bill had been referred to the Local Board, and examined by that body, and the only objection they had raised was that they desired increased pressure in the supply of gas. The Directors had taken the consideration, had, however, decided to let the Bill remain as it was, as a matter of opinion that what was sufficient for London was sufficient for Eastbourne. The only other objection raised was to a clause in the Bill, which, if passed, would give them the power to sell or let on hire gas-fittings, engines, machinery, &c. A municipal law had been received from the Solicitors of the Standing Orders Committee, which advised the exclusion of this clause from the Bill. The Local Board, however, had decided not to oppose the Bill, and would not have any objection to the Company supplying with gas-fittings, &c., those inhabitants of the town who asked them; and he could see why they had no objection whatever of commencing a gigantic trade in these articles. The Directors, however, had an opposed view, and reasons could only now be given from one reason—in opposition to the Bill meant putting it off for another year; while, on the other hand, to withdraw the Bill was to lose the custody of sixpence. The Directors did what they thought best, not only for the Shareholders, but for the town at large. It was not to the benefit of part of the Company to monopolize the trade of gas-fittings in the district; but they considered it would be to the advantage of the Company to have these powers, and if they obtained them it by no means followed that they would exercise them. The Bill had already, as he had said, passed the Examiners of Standing Orders, and no doubt Parliament would also pass it.

Mr. Hillman seconded the motion, and it was carried unanimously.

This was all the business of the meeting.

YORK UNITED GASLIGHT COMPANY.

The Half-Yearly Meeting of this Company was held on Thursday last—Mr. F. T. Tatham in the chair.

The Secretary and Manager (Mr. C. Sellers) read the notice of meeting and the following report on the Company's operations during the last six months:—

The profit upon the half year's revenue account amounts to £6612 2s. 8d. This sum, added to £23 4s. 6d., interest on money specially deposited at the Company's bankers, and £2 10s., balance of premium upon new shares issued, makes the total amount of profit for the half year, as per revenue account, £6637 17s. 2d. The Directors have appropriated £600 to the reserve-fund, and they now propose to apply the remainder to the payment of a dividend at the rate of £10 per annum on the old shares of the Company, and £5 per share, or £7 per cent. per annum on the new shares, for the half year ending 31st December. These payments will leave a balance of £37 17s. 2d. to be carried forward to the next account.

In accordance with the Company's Act of Parliament, a resolution to confirm the forfeiture of fifty-nine shares, not appropriated to the owners allocated to the Shareholders, was passed at the last meeting.

The two ventilators referred to

work. The Directors have in the last recent have been finished, and are now at work. The Directors have in the last recent have been finished, and are now at work. The Directors have in the last recent have been finished, and are now at

Canon Hutchens thought they could not do better than re-elect the same gentlemen who had served them so well in the past. He proposed the re-election of Mr. Glass, who joined the Directorate at the time of the amalgamation of Mr. Glass, who joined the Directorate at the time of the amalgamation of the Consumers' Gas Company with the Chartered Company, and the congratulated them upon the position the Company now occupied, and on the abundant good that it was doing for the poor, in providing them with an abundant supply of wholesome water at the low price of 2s. 6d.

The motion was seconded by Mr. H. Bates, and agreed to.

Mr. Glass, on behalf of the Directors, proposed the re-election of Mr. Perceval and Mr. Lawrence, two of the Directors who had been deputed to attend to the value of the shares of the Company, which had been disposed of at a recent sale at 71 10s. premium, which was the largest price that had ever been realized.

The motion was seconded by Mr. E. Pearce and adopted.

Mr. Perceval returned thanks for his re-election, and spoke in complimentary terms of the way in which business was conducted by the secretary, Mr. Cooke, and promised to do his best to serve the interests of the Company.

Mr. Clayton proposed, and Mr. Swan seconded, a vote of thanks to the Chairman, which was agreed to.

The proceedings then terminated.

ROCHESTER, CHATHAM, AND STROOD GASLIGHT COMPANY.

The Half-Yearly Meeting of this Company was held last Thursday—Mr. Horace Wigan in the chair.

The Secretary (Mr. Sydney Stone) read the report of the Directors, which stated that the Directors of the Company for the last half year had been more than usually successful, the profits allowing of the selling off of a few shares from the capital account in addition to paying the usual dividends. The new engineers were about to be erected, and some other improvements made. The usual dividend at the rate of 10 per cent. per annum on the A and B shares, and of 7 per cent. on the C shares, was recommended. The statement of accounts showed a balance of profit on the year's transactions of £3,000 odd.

Mr. Geo. R. Wheeler moved, and Mr. C. H. Hall seconded the motion for the adoption of the report, which was agreed to.

The Chairman proposed the payment of the dividends recommended in the report.

Mr. Wheeler seconded the motion, which was carried.

The retiring Director (Mr. C. Lovell) was then re-elected; and Mr. W. Hall, jun., was elected a Director in place of the late Mr. W. B. Hunt. Mr. W. F. Hayward was appointed Auditor, vice Mr. Hooper.

A vote of thanks to the Directors, which was acknowledged by the Chairman, ended the proceedings.

EASTBOURNE GAS COMPANY.

A Special Meeting of this Company was held on Monday, the 2nd inst. —Dr. Jeffrey in the chair—for the purpose of considering and, if thought fit, of approving a Bill for conferring additional powers upon the Company for the purchase of land, the construction of works, the raising of money, and other purposes connected with the undertaking.

The Secretary (Mr. J. H. C. Coode) read the notice of the meeting.

The Chairman stated that the Bill he approved. In doing so he reminded the Shareholders that at the last meeting the Directors were not in their sanction to apply to Parliament for powers to increase the capital of the Company. They had since that time, with the assistance of their late secretary Agents, their Engineer, and their Secretary, drawn up a Bill which had been duly deposited in accordance with the Standing Orders of Parliament. The Bill had been proceeded with by the Board, and examined by that body, and the only objection raised was that they wished for increased powers in the event of fire. The Directors were not unwilling to consideration, but, however, decided to let the Bill remain as it was, as they were of opinion that what was sufficient for London was sufficient for Eastbourne. The only other objection raised was to a clause in the Bill, which, if passed, would enable the Company to supply fire-grates, gas-fittings, stoves, meters, and gas apparatus generally. This was another introduction of the town dealing in gas-fittings, &c., who wished to exclude this clause from the Bill. The Local Board, however, withdrew their opposition to the Bill, and would not have anything to do with the removal from the gas-fittings. He (the Chairman) could not see that there could be any objection to the Company supplying with gas-fittings, &c., those who required them, if they wished to have them; and he might say they had an idea whatever of monopolizing a gigantic trade in those articles. The Bill, therefore, was an unopposed one, and he hoped would soon receive the Queen's assent. An opposition Bill was not contemplated for another year; while, at the present time, it would be promoted with a certainty of success. The Directors did what they thought best, not only for the Shareholders, but for the town at large. There was no wish on the part of the Company to monopolize the trade of the gas fitting in the town; but they considered it would be to the advantage of the Company to have them under their control. The Directors were of opinion that they would exercise them. The Bill had already, as he had said, passed the Examiners of Standing Orders, and no doubt Parliament would also pass it.

Mr. Hillman seconded the motion, and it was carried unanimously. This was all the business of the meeting.

YORK UNITED GASLIGHT COMPANY.

The Half-Yearly Meeting of this Company was held on Thursday last—Mr. Lee Norton in the chair.

The Directors and Managers (Mr. C. Sellers) read the notice of meeting and the following report on the Company's operations during the past six months:—

The profit upon the half year's revenue account amounts to £6152 9s. 5d. This sum, added to £23 0s. 6d., interest on money specially deposited at the Company's bankers, and £1 10s., balance of previous years the appropriations of fractional parts of shares, makes the total amount available for distribution £6,176 19s. 11d. The Directors have carried £500 to the reserve account, and they have now pleasure to apply the remainder in the payment of the usual dividend of 5s. per year per annum on the £50 shares, and at the rate of 7s. per year per annum on the £70 shares, for the half year ending the 31st ult., leaving a balance of £1,176 19s. 11d. These payments will absorb £5917 10s. 0d., and leave £59 9s. 11d. to be carried forward.

In accordance with the Company's Act of Parliament, a resolution to confirm the appropriation of profits shown, and apportioned in the usual dividend to the Shareholders, will be submitted to the meeting.

The two evidences referred to in the last report have been finished, and are now in use. The Directors also in their last report alluded to the remodelling of the retorts and the erection of a new purifier. This has been carried out, and now the whole of the retorting machinery, including the new retorts is occupied, and will overcome the heaviest demands of the coming winter. The purifier now awaits the completion of the new gasholder.

In anticipation of the latter circumstances, the main from Lawrence street Foss Islands road has been raised with a new 24-inch diameter, and forward to the Burnaby walk a 12-inch main is to proceed with on the part of the public that the Company should be in a position to meet the demands that have recently purchased on eligible site for offices in Coney street, York, which, from its central position, cannot fail to meet with public

TOWN AND COUNTY OF POOLE GAS AND COKE COMPANY.

The Eighth Half-Yearly General Meeting of this Company was held on Thursday last—Mr. Thomas Bond in the chair.

The Secretary (Mr. J. Bullen) read the notice convening the meeting, and the minutes of the last meeting.

The Directors' report, which was then read, stated that the Directors had much pleasure in presenting the accounts for the half year ending 31st December, and felt confident that the shareholders would be satisfied with the result of the year's operations. The profits for the half year ending 31st December, 1859, amounted to £1,000 19s. 6d., which, with £1 19s. 6d. brought forward from the last account, and £1 0s. 6d. interest on deposits, made a total of £1,004 19s. 6d. The Directors recommended the payment of a dividend at the rate of £5 per cent. per annum, leaving a balance of £4 19s. 6d. to be carried forward to the next account. The Directors had much pleasure in stating that the new gasholder, which was commenced in the autumn of last year, was completed, and in full operation. The Directors had also the pleasure to announce that the Company had been successful in obtaining the Parliamentary powers for the purchase of the Wimborne Gas Company's undertaking, and for the construction of works, the raising of money, and other purposes connected with the undertaking. The Directors were happy to say

The Directors have pleasure in submitting herewith, along with the previous notice on the 31st December last, the balance of the subsidiary revenue accounts, and the Consolidated Income and Expenditure Account for the year ended December 31st, 1879, as audited by Messrs. Lane and Mawer, which shows a most favorable result on the year's business. These shows £671, leaving (as stated in the report) £2607 applicable to dividend on the ordinary stock and shares.

The CHAIRMAN: It is now my business to move the adoption of the report and balance-sheet, and in doing so I shall not have occasion to detain you many minutes. I have made a few comparisons between the results of the last half year's business and those of the business of the corresponding half year, and I find that the balance of profit is £2607 in the last half year, while at the same period of 1878 it was £2776, so that the difference against us is £169. Now, gentlemen, dealing with the items which make up this difference, I find that the gas revenue account shows a decrease of £1,000 in the last half year, while at the same period of 1878 it was £1,169

REDHILL GAS COMPANY.

The Ordinary General Meeting of this Company was held on Friday, Feb. 20, when the following report of the Directors, on their operations during the past year, was presented:—

The reduction in the price of gas, referred to in your Directors in their last report, took effect on the 1st of April last; they are pleased to be able to report that the consequent diminution in the rental of the Company has been already to some extent compensated by the increased consumption, which has commenced to be felt; but at no very distant period they may be in a position to consider the propriety of a further reduction.

The anticipated better, for providing the necessary increase in the average capacity of the works, is being promptly carried out, as far as the state of the weather will permit. The castings are now in course of delivery, and the Engineer has every reason to hope that the holder will be completed and in working order early in the autumn.

The continuous increase in the business of the Company has rendered necessary the enlargement of the Meter Department, additions to, and improvements in the plant and machinery. These important matters concerning the special attention of your Directors, who are also maintaining the entire property of the Company in good state of repair.

Under such circumstances your Directors resolved to offer preferred scrip to the Shareholders, thereby creating 2500 additional £10 shares, which were taken up by the holders of those shares were all more applied for and allotted, and the first call has been paid.

The net profit on the working of the past year amounts to £3316 1s. 5d., out of which the Directors recommend that a dividend, free of income-tax, be made at the rate of paid-up capital of the Company of 10 per cent., with the addition of a bonus of 2 per cent. upon so much of the capital as was subscribed prior to July 1, 1870, towards making up the deficiency in the dividend paid thereon below the statutable rate in accordance with the Act of Parliament, leaving a balance of £1316 1s. 5d. to be carried forward.

The total shares and loan capital of the Company is £27,500—viz., £20,700 of 10 per cent. shares, and £3250 of debenture bonds. The sanitary on capital account, including £1623 expended last year, is £4,384; but the additional capital having been invested in anticipation of calls on the additional shares, the interest thereon, amounting to £219 4s. 10d., is paid out of the balance of the interest receipts account has been credited to the capital loan account, the interest on debentures not, and £266 carried to reserve fund (which will then amount to £2750), there will be £3050 available for dividend on the ordinary stock of the Company. During last year, 3106 tons of coal were carbonized.

Revenue Account, for the Half-year ended Dec. 31, 1870.

WOLVERHAMPTON GAS COMPANY.

The Fifty-sixth Ordinary Meeting of this Company was held on Tuesday, the 28th ult.—Mr. J. Cochrane in the chair.

The Secretary (Mr. A. Jones) read the following report:—

Your Directors have much pleasure in presenting their fifty-sixth half-yearly balance-sheet and statement of accounts, duly certified by your Auditor, showing the amounts of revenue and expenditure for the half year ending Dec. 31, 1870, and the appropriation of the balance. The gross revenue for the half year, including the small balance of last account, amounts to £7132 19s. 3d. From this gross revenue there is proposed the payment of 8 per cent. dividend upon the consolidated stock, and 2 per cent. (less income-tax) upon the paid-up capital of the preference shares.

Your Directors have also much pleasure in submitting detailed accounts of the working of the Birmingham Corporation Gas-Works in connection with the results of the working of the Wolverhampton Gas-Works during the last year. The production of gas in Birmingham was 1,870,000,000 cubic feet, against 1,700,000,000 cubic feet in Wolverhampton, and the cost of manufacture and distribution in Birmingham, 2s. 2d. per thou., against £2s.2d.in Wolverhampton. From this it will be seen that the cost of production in Birmingham was 2d. per thou. more than in Wolverhampton. The coal-gas in Birmingham was £19,000, or against £20,000 in Wolverhampton, or 1d. per thou. more than in Wolverhampton. The total in Birmingham ranged from 16 candles to 17 candles, and in Wolverhampton from 17 candles to 18 candles. The price now charged in Wolverhampton is 4s. per thou., and in Birmingham 3s. 6d. per thou., with a discount of 10 per cent.

At the meeting three of your Directors retire by rotation—viz., Mr. Insemanger, Mr. Hordern, and Mr. Cochrane—who are eligible for re-election. Your Auditor, Mr. Smith, also retires, but is not eligible for re-election.

In conclusion, your Directors beg to assure you they will continue to devote their best attention to the interests of the Company.

The Chairman, in moving the adoption of the report, said that it met the balance-sheet were, as they had been regularly for many years past, the satisfactory. The increase during the half year, but he thought that, owing to the improvement of the mains and other things, which had been considered at their meetings from time to time, they had had fewer complaints of the quality of the gas during the past winter than they usually had. He was glad to say that the Directors had had the opportunity of visiting the works of the Birmingham Corporation Gas-Works and their own works. They found that the production of gas in Birmingham was about 1s. per thou. more than in Wolverhampton, but the quality was considerably better, and about eight hours as much. The latter was a feature in their corporation rarely ever knew that where there was a larger return the article was not better. The Directors had also had the opportunity of comparing the charges (as 4s. 6d. to 4s. 3d. per 1000 feet), whereas the Directors of the Company, after long consideration, had seen no reason to alter their

works is considerably higher in comparison than that of the water-works; but it is confidently anticipated that, with certain improvement, the annual result will, in the end, benefit by the purchase of the works, although it may be some time before the Company derive any direct advantage from the improvements that had been carried out. Upon the negotiations with the Town Council of Wolverhampton, he hoped, he should be able to report that the terms in the market, £17, and latterly, it is said, speculative buyers have given more than £20 for them.

OUR GAS CONTEMPORARIES AND THE ELECTRIC LIGHT.—

The *Journal of Gas Lighting* and the *Gas World* (organs of the gas interest) are recently given by some English and French papers to the fact that the Paris Gas Company was ill at ease in regard to the electric light, and asserted superiority of this light over gas for the illumination of public buildings and extensive establishments of the kind. Those were too indifferent or too prejudiced to inquire very closely into the matter. We find, however, that a class of persons who must be admitted to have some slight knowledge of what is a good and what a bad light for a picture—the artists themselves—have protested against the use of the electric light at the *Salon*, this being stated to be the most unfavourable kind of illumination for effectively showing their productions. The protest, however, comes rather too late. The agreement entered into with the Jablochkoff Company for the supply of the electric light has been carried out, and the latter, we suppose, remain in use until the end of the season, artistic protests notwithstanding. Again, when sober-minded, right-thinking people ventured to express a doubt as to the permanent adoption of the electric light by those shopkeepers in Paris who had been so ready to take it up as a novel and attractive, not to say startling kind of advertisement, their remarks were received by the worshippers of the rising luminary with all the impertinent contempt usually manifested towards opponents by converts to a new faith. Yet what do we find? The *Figaro*, whose office in the Rue Drouot was one of the first buildings to be illuminated exteriorly by means of the electric light, has positively abandoned that system, and substituted for it two gas-lamps similar to those used by the Paris Gas Company in the Rue du Quatre, Septembre, where, by the way, only half the original number of burners are now lighted, and yet the general illumination of the thoroughfare is, we learn, if anything, a trifle better than that of the neighbouring Avenue de l'Opéra, where the electric light still reigns supreme."

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, FEBRUARY 24, 1880.

Circular to Gas Companies.

THE Bill in Parliament promoted this session by the Corporation of the City of London, which passes under the somewhat complex title of "The Gaslight and Coke, Commercial Gas, and South Metropolitan Gaslight and Coke Companies Bill," was read a second time last week, in spite of the mild opposition offered to it by Colonel Makins. We have already given an abstract of the numerous provisions in question, and are bound to say that the one made out by Colonel Makins was a long one. Although provisions have been inserted, in recent Metropolitan Gas Acts, for testing the pressure of gas, they seem to have remained in abeyance, and it is only now that it is sought to bring them into active operation. We may say at once that these provisions must prove vexatious to the Companies concerned, and are likely to lead to some loss. The day pressure at six-tenths need not be objected to; but the pressure of one inch required from sunset to midnight, and which must be kept at some excess, may possibly increase the amount of unaccounted-for gas. Perhaps, too, it is hardly fair to saddle the Companies with the cost of the self-registering pressure-gauges that will be required. The tests are made in the interests of the consumers, and as a self-registering pressure-gauge is a somewhat expensive instrument, the cost might very well have been divided between the Corporation and the Companies. But as the latter have been required to furnish all other apparatus for the testing-stations, we suppose that this fresh imposition must not be objected to. We feel somewhat sorry for the Gas Examiners, whose duties will be considerably added to under the operation of such an Act as is now proposed. Their daily attendance at the several testing-stations will be requisite—not necessarily at any fixed hour, although it would be most convenient to change the registering papers daily at the same time. It will be seen, too, that the Examiners will have to diligently study an almanac, inasmuch as they will have to report on the maximum and minimum pressures between sunset and midnight and midnight and sunset. The duty that is proposed, requiring the pressures to be taken twice a week at the public lamps, is altogether new, and must cause some trouble. We therefore recommend the Examiners to ask at once for those additional duties to be considered in their salaries. In some respects the Bill as it lies before us is, as we have previously pointed out, favourable to the Chartered Company, inasmuch as it repeals the clause in the Act of 1876, which requires the Company to keep a register of the quantity of gas made at each of their stations, and fines them for deficiencies in illuminating power according to the amount of gas manufactured. Under the new Bill it is provided that a Company—say the Chartered—having a deficiency of illuminating power recorded at one station, shall only forfeit a specific sum, according to the amount of the deficit; and it is further provided that the same Company shall not be fined for defects at more than one station on one day. Considering how the gas from the several manufacturing stations of one Company is now mixed up, this is only a fair provision. The testings for purity are to remain as under the Acts of 1875-6, the average of three days being taken to represent the purity of one day.

Perhaps, however, it is superfluous to go on pointing out the provisions of this measure, as, from the opinion expressed by the Parliamentary Secretary of the Board of Trade, it seems clear that the Board will not allow the Bill to pass in its present form. It has been sent to the Metropolitan Gas Referees, with a request that they will give their opinion upon its provisions, and send a report, on receipt of which the Board will consider what shall be done. We can hardly too much admire the grandmotherly attentions of the Board of Trade to the interests of Gas Companies. The naughty boys of the controlling Authorities and the Companies might have had, in a committee-room of the House of Commons, a stand-up fight, which would have proved very expensive to all but the Metropolitan Board of Works, who, by obtaining a modification of the 21st section of the Bill, have left the Corporation to pay all expenses attending its promotion. The Board of Trade, however, propose to induce the parties to forego this fight, by calling them together to listen to a little lecture, and bidding them to shake hands and be friends. The proposal is that Companies and controlling Authorities shall consent to a measure to be called an "agreed Bill," which the Board of Trade promise to push through. Perhaps this will, after all, be the best course that could be pursued. If we might raise an objection, it would be that it virtually makes two of the Gas Referees the arbiters of the fate of the Gas Companies. There is no fear that the powers conferred on the Referees will be injudiciously exercised; but we must confess that we shall look with some curiosity for the report they may present on the Bill.

People have long complained of the lighting of Blackfriars Bridge, and their complaints have at last been brought to the notice of the Common Council. The Committee of the Bridge House Estates presented, at the meeting of the Council last Thursday, a report in which they proposed an alteration in the shape of the lamps, noticing the fact that the lamps at present in use are often broken, and more often extinguished, especially in gusty weather. The lighting of the bridge, as a member remarked, has been a disgrace to the Corporation. Advocates of the electric light naturally proposed that this mode of illumination should be tried on the bridge, the power being obtained from the electric station of the Metropolitan Board of Works at Charing Cross railway bridge. We fancy that the suggestion may be carried out, notwithstanding the past experience of the Corporation with the light upon the Holborn Viaduct. We cannot agree, however, that the electric light is superior to gas in the case of a fog. *A friend*

just state that Alderman Chamberlain speaks of a reduction of threepence per thousand feet having been made in four years, since the purchase of the undertakings by the Corporation. There is, however, no necessity to base upon a reduction which must have been made. The Corporation were, so to speak, gorged with profits, and there was no other course for them than to lower the price to the consumers. The fact is, that another reduction ought to be made about the present time, and this the Corporation can well afford if they will only give up their practice of applying profits in aid of rates. It may be said this is no business of ours; but the matter involves a principle. Alderman Chamberlain considers that as the ratepayers are responsible for the gas undertaking, they, quoad ratepayers, have the best right to the profits made. We, however, who do not consider that the ratepayers have any responsibility at all in the matters, think that the consumers should be first considered. Of course, seeing that the ratepayer and consumer are generally one, it follows that any benefit conferred by a low price for gas would be equally shared in. Alderman Chamberlain tells us, truly, that if twopence be taken off the price of gas for the benefit of the consumer, fivepence must be added to the improvement rate; and he sees very clearly that many consumers would pay the increased rate willingly if they could get a reduction in the price of gas. These would, of course, be the large consumers; but there must be in Birmingham a numerous class of persons occupying tenements of low rateable value, to whom low-priced gas would be a greater boon than a low improvement rate. But it is of no use to argue this question. A majority of the Birmingham Town Council have made up their minds that a large proportion of the gas profits shall be devoted to the improvement rate, while a very considerable balance is carried to the sinking-fund, which is calculated, at its present rate of increase, to pay off the purchase-money in twenty-eight years—a debt which Parliament has allowed them eighty years to wipe out. It is well, however, to make bay while the sun shines. The consumption of gas in Birmingham has relatively diminished, and the profits have, to a slight extent, decreased. There is also a prospect of their being smaller at no distant date, for coals are rapidly rising in price, and it is estimated that they will cost the Corporation £20,000 more for the present year than last. Consequently, if the Corporation do not make a reduction in the price of gas shortly, they will be compelled to do so in the future. Meanwhile, we would remind the consumers of Birmingham that, as the Corporation brought down their price to 2s. 3d. per thousand feet?

The annual meeting of the Imperial Gaslight Company was held last week. The balance of revenue account admitted of the payment of maximum dividends—namely, ten per cent. upon the A shares and seven and a half per cent. upon the B and C shares—and to carry forward a balance of £208 the B and C shares—and to carry forward a balance of £208 to the next account. In past times great complaints were made both of the illuminating power and of the sulphur impurities in the gas furnished by the Company, and the Directors seem now to have not rigorously to work to prevent any such complaints occurring. Their exertions, too, have made extensive improvements in their works, and are about to have erected new purifying plant of the most improved kind. For the time the Corporation and the Company appear to be at peace; but from what passed at the meeting it seems likely that the question of purchase may soon crop up again. The Company are about to issue new capital, which the Directors wished to put up to auction, but to this course the Shareholders objected, and it was eventually decided to allot the shares *pro rata* among existing Proprietors. The Bury St. Edmund's Gas Company held their half-yearly meeting on the 13th inst. The Company have been so far successful under the sliding scale that they are able to pay an additional one per cent. dividend. This is something, but the Chairman does not hold out any hope of being able for the present to make another reduction in price, so there is no prospect of further increased dividends. Nothing unusual occurred at the meeting except a dispute as to the duties of a Company's Auditor. The Solicitor to the Company sent in a bill claiming a lump sum of £250 for his services in obtaining the Company's last Act of Parliament. The account stated shortly that the amount charged was for "innumerable attendances and correspondence relative to the "new Bill," and other duties in connection therewith; and, without specifying each item, really gave a summary of all the work done. The account had, of course, been passed by the Directors, and was placed before the Auditor with a receipt as usual. This officer objected that details should be given in the account, and refused to pass it. The Solicitor, however, declined to do so, and the matter was referred to the Directors, who, after a long discussion, decided that the account should be paid. The Auditor, however, refused to sign the receipt, and the matter was left in abeyance.

STATE INSPECTORS AND GAS COMPANIES.

With the Report of Mr. Hinton, the Inspector of Gas and Gas Meters for the Commonwealth of Massachusetts, the above-named State upon the Atlantic seaboard has been favoured. Mr. Hinton appears to be a gentleman who has some knowledge of the subject of which he treats. Our readers have been made familiar, from time to time, with the views of Mr. Hinton's colleagues in other States, and with the history of legislation which could seem to be necessary to the proper performance of the duties established by the various Acts. Mr. Hinton appears to somewhat different lines of the generally-accepted lines of the average disgruntled gas undertaking—the gas authorities, who, as they [illegible] to do [illegible] justice to the gas consumer, even though that justice is sure to be injustice to their own pockets.

While Mr. Hinton, in the main, appears to be willing to do most what is right, his feelings always run to the side of the consumer. In making up his report, he has evidently had the interests of the consumer at heart, and has not regarded at all save omitted in the second table. Another curious statement which we find in this report is the statement that he found one meter which registered correctly. This is the first time we have heard of such a thing. He finds that the average error of all the meters about which complaints were made was 2·3 per cent. in favour of the gas company. Of course, we will consider that the average per centage of the mass of Massachusetts meters will be considerably more than this, and that the average error will be in favour of the consumer.

Another very suggesting feat to the constitutional gremlin will be apparent when he reads that "in each case, a careful inspection showed the gas to be of good illuminating power and free from ammoniac." The Inspector adds that the gas was "fairly well purified."

The most seeming thing in connection with this report (and the same unmistakable chorus which is evidenced towards the gas maker. The Inspector is often disposed to think that he is treated with injustice by the managers of a gas company should be suspected of such devious ways and the determination of interested consumers as to the best manner of manufacture and distribution are conducive upon sound and honest principles, and which, in the long run, will be found to be the best for all concerned. Then, this subject can only be dealt with by an Inspector who is thoroughly conversant with the whole question, and who is not hampered by any fear of [illegible] but who is free to have their doubts confirmed or dispelled by the proof of a practical test.

The reason why the Inspector thinks this is that he fears the gas-maker will take advantage of the notification, and instantly turn his energies to the production of illuminating power at the expense of purity. This is a fear which we do not entertain. The remedy proposed to obviate this evil is that the gas should be made at irregular intervals, not without previous warnings, but without any fixed time. This remedy appears to us to be worse than the disease. It would be impossible to obviate the evils that the Inspector fears by any such means as he suggests. The remedy proposed to obviate this evil is that the gas should be made at irregular intervals, not without previous warnings, but without any fixed time. This remedy appears to us to be worse than the disease. It would be impossible to obviate the evils that the Inspector fears by any such means as he suggests. The remedy proposed to obviate this evil is that the gas should be made at irregular intervals, not without previous warnings, but without any fixed time. This remedy appears to us to be worse than the disease. It would be impossible to obviate the evils that the Inspector fears by any such means as he suggests.

When this comes to pass, and we hope it will shortly, the latter it will be for all concerned. With fairness on all sides and with a disposition to do away with the old-world animosities—the gas meter—can be fairly trusted to do [illegible]

Printed by Messrs. Salmon and Son, Their Parliamentary Agent had been paid £ [illegible] Number of Words [illegible]

House of Commons, now submitted to the Proprietors, is approved of by them."

Mr. NORTHCOTE presumed it was the same Bill as that promoted by the Company last session.

The CHAIRMAN: It is very much the same. It does differ slightly in this way: In our original draft last year we took powers to manufacture and supply electricity, but we have thought it better to omit that clause now. The Bill will be subject to any modifications Parliament may introduce.

Mr. NORTHCOTE inquired whether there was any intention to ask for increased capital.

The CHAIRMAN: No; we have plenty. We do not anticipate that this will be an expensive matter. We may spend £100, £200, or perhaps even £1000; but we shall not spend a shilling more than we can see profit for.

Mr. BENJAMIN seconded the motion.

The CHAIRMAN: There is an amendment, so I will put the resolution that the Directors be authorized to take such steps as they may be advised to apply for Parliamentary powers.

The motion was carried unanimously.

Mr. NORTHCOTE supposed it would be somewhat irregular to ask any question outside the business on which they had been called together, otherwise he would have liked to ask if any progress has been made as to amalgamation.

The CHAIRMAN: No; not in any way. I may answer that question myself.

Mr. NORTHCOTE said he was not at all an advocate for amalgamation unless they could do so on proper terms.

The proceedings then terminated.

LIVERPOOL UNITED GASLIGHT COMPANY.

The Half-Yearly General Meeting of this Company was held last Tuesday—Mr. D. O. HAYMAN presiding.

The SECRETARY (Mr. P. P. Garnett) read the Directors report, which was as follows:—

The Directors have ceased to be required and submitted to them an estimate of the cost of the necessary for the half year ended at the 31st of December last, in accordance with the Company's Acts of Parliament, and have, out of the profits, resolved to recommend the Proprietors to declare a dividend, for the half year ended as above stated, of £3 on every £100 ordinary consolidated stock, and at the rate of £3 10s. for every £100 of the 7 per cent. and 5 per cent. stock, and on the capital paid up in respect of the new £7 10s. shares.

The consumption of gas has of late increased so rapidly as to necessitate an immediate enlargement of the Company's Gasworks at Bootle, and a Bill to give the necessary powers for the purpose has been deposited in Parliament, and is now before it.

The Directors have to record, with deep regret, the death during the past half year of one of their colleagues, JAMES LEIGH, Esq. The vacancy thus caused in the Board has been filled up by the appointment of THOMAS HERBERT, Esq., in Mr. Leigh's place.

The CHAIRMAN, in moving the adoption of the report, said that the Company had, during the past six months, been going on in their usual satisfactory manner and usefulness. During this time nothing had occurred that he knew of which required any apology or explanation from him. They had been allowed to go on quietly, and had not been the subject of any attack in the newspapers, whilst their arch-enemy, electricity, did not seem to have made very much progress—at all events, not such progress as to have done the Company great harm, if they might judge from the increasing requirements upon their supply. As the accounts were made up only in the previous week, he regretted that at this meeting, but the Directors had satisfied themselves that they had quite sufficient at the credit of profit and loss account to be able to pay the dividends recommended in the report.

Mr. J. A. TYLER seconded the motion, which was carried unanimously; and the dividends recommended in the report were declared.

A Special General Meeting was then held, for the purpose of considering the Company's Bill in Parliament, entitled "A Bill to enable the Liverpool United Gaslight Company to create additional gas-works, to extend their limits of supply, and for other purposes connected therewith."

The SECRETARY explained that though the Bill, as proposed to be now enacted, contained clauses empowering the Company to borrow further sums of money, these clauses had, by a resolution of the Board of Directors, been ordered to be struck out of the Bill, and would not be presented to Parliament. The Bill, as now proposed, would, he presumed, be read on the clauses, showing that the object of the Bill was to extend the limits of the Company for the supply of gas so as to include the townships of Bootle and Toxteth, in the parish of Sefton, and to enable the Company to enlarge their works at Linacre.

The CHAIRMAN said the Proprietors would pretty well understand what they were going to Parliament for. They owned 24 acres of land at Linacre, and 10 acres at Bootle, and the remaining portion of the land (making 34 acres was purchased at a subsequent time, and upon this the Company had no power to build; and as the Legislature was very jealous about the erection of any works which could possibly be a nuisance, the Company were obliged to go for powers to build upon this land, because the 10 acres at Bootle were not sufficient for the works they erected. Orrell and Ford formed a small district to the north-east of Bootle, where in which there was a large amount of building going on just now. They proposed to extend into the territory of the Company; and the new proposed straightened their boundary—in fact, gave them a more "scientific frontier." He went down to inspect the district with their Engineer (Mr. Thomas Hogg), and they found that they could light half-any-town seven streets, whilst the Company could only light one street. They could supply gas to them at one-sale they could light one of two houses under the same contract, and not the other. The proposed extension would cost very little; it would bring in a certain amount of revenue; and it would confer benefits on the inhabitants of the district. He moved—"That the Bill now submitted to the Proprietors, entitled 'A Bill to enable the Liverpool United Gaslight Company to create additional works, to extend their limits of supply, and to borrow further sums of money,' be approved by this meeting." He said, could quite understand that last section was rather obscure, and that they did not go for borrowing powers. The money clause they would have to defer until a future occasion, and there was no doubt that it would not be long before they went to Parliament with a more comprehensive Bill. The present Bill, therefore, that the powers it sought would be passed without opposition.

Mr. TINNE seconded the motion.

Mr. COPE asked if, in addition to studying the requirements of the out-townships, the Directors had ever turned their attention to the great good they might do by lighting up working men's houses in the parish of Liverpool. He was sure that no person could go round the town at night and see the hundreds of houses in the back streets, courts, and entries, without wishing there could be some mode of lighting up these places at a small charge, without the costly meter and deposit system. He would suggest a monthly payment guaranteed by the landlord, and that the houses should be lighted, say, for four hours a night. The cost would be about 1s. 6d. a month, and he was sure that it would be a source of incalculable good for the health and welfare of the inhabitants. When they saw them sitting in their miserable houses, lighted by a farthing candle, they could see a weather at the luxuriant going away to the bright, well-lighted public-house, and he was rather astonished that it had not suggested itself to the Board to appoint a Committee to consider whether the consumption of gas could not be more extended amongst the poorer inhabitants.

The CHAIRMAN said their price for gas was fixed; and they could not make fish of one and flesh of another. They were not a philanthropic company. They were not intended to supply gas for the benefit of the poor, but primarily for their own private benefit.

Mr. COPE said he was not aware that they were a philanthropic company; and he did not want them to supply gas for nothing, but he thought they might combine the two things—making money and philanthropy. He did not advise that the gas should be given away, but that it should be sold at the usual price, supplied for a certain number of hours, and then turned off by a tap.

The CHAIRMAN said he thought this was more a landlord's question. The Company were bound to sell the gas by meter.

Mr. COPE said he had not made the suggestion in their Act of Parliament obtaining all this difficulty. He thought the time was coming when meters would be abandoned to a certain extent.

The CHAIRMAN said it was quite clear they could not insert such a clause in the present Bill, which had been deposited.

The SECRETARY said it would have to be covered by the notices.

Mr. COPE asked whether, as he considered it a subject of vast importance, the Directors would appoint a Committee to inquire into it?

Mr. HARRIS said he thought the matter was to assist one of self-interest, the question having been made, they might safely leave it to the Directors.

The CHAIRMAN said the Board would remember what Mr. Cope had said, and would talk the matter over, and, if anything could be done which would not militate against the interests of the Company, they might consider it. In reply to a question, he said it was possible the Company would go to Parliament in a couple of years, but he believed that all the shares which were unsalled up on the 27 lbs shares would be spoil before they did so.

Sir THOMAS EARLE said he thought all the calls would be wanted for the works proposed in the Bill they were now going for.

The CHAIRMAN: We expect so.

The motion was then put and carried, and a vote of thanks to the Chairman, moved by Mr. DARBY, seconded by Mr. GASKELL, terminated the proceedings.

NEWCASTLE AND GATESHEAD GAS COMPANY.

The Annual Meeting of this Company was held on Wednesday last—Aldermen HEDLEY in the chair.

The SECRETARY, Mr. W. Hedley read the following report of the Directors:—

In accordance with the Newcastle-upon-Tyne and Gateshead Gas Act, 1873, the Directors have now to submit to the Proprietors a statement of the receipts and expenditure for the half year ending Dec. 31st, 1879, and to elect the Directors and Auditors for the ensuing year.

As announced in last year's report, the ordinary annual meetings will in future be held in the months of February and August instead of March and September, as formerly, and Dec. 31, which will thus be the date to which accounts are made up.

Although no half-yearly accounts have hitherto been published, the Directors beg to state that the quantity of gas manufactured during the half year was 1,000,000,000 cubic feet, viz. 10th, and the expenditure £94,284 9s. 10d., showing a profit, after full and account of £22,342 9s. 11d. After paying out of this sum £5,000 10s. 8d. Income-tax allowance and other charges, leave £17,341 19s. 3d., the balance brought forward from last year, £10,383 6s. 6d., which the Directors propose should be appropriated as follows:—

That year's Dividend, at 6 per cent.	£15,000
To reserved fund (making this fund £12,500)	1,500
Balance carried forward	225
	£16,725

The Directors propose that, from the 1st of January of this year, the price of gas be reduced from 3s. 6d. to 3s. 4d. per 1000 cubic feet, less 10 per cent. discount, which will make the net price 2s. 8d. per 1000 cubic feet—the lowest, they believe, that is charged in any district where the Company's Acts of Parliament are in force.

The Directors have to report that the Engineer-in-Chief, Mr. Thomas Hedley, and their Solicitors have been engaged in promoting the Company's Bill in Parliament, and that it has been laid aside for the present session. The Bill proposed to authorize the Company to make additional gas-works at Dunston, to extend the limits of their district of supply, and to raise additional capital. The Directors have also had under consideration the question of the Company's Act of Parliament, which expires in 1880, and have resolved to promote a Bill in Parliament for their own private purposes.

In order to meet these and future extensions, the Directors, a short time before the end of the year, purchased seven acres of land, on which the wrought and cast iron work necessary to complete No. 7 retort-house, at Redheugh.

The Directors have to report that, in accordance with the provisions of the Act of Parliament, they have called a Special General Meeting of the Proprietors, to be held at the termination of the ordinary meeting, at which resolutions will be submitted for the purchase of additional land, and for the erection of additional gas-works.

At the end of last year, the total mains and service pipes laid down amounted to 300 miles.

The Proprietors, at the present meeting, will have to elect Directors to hold office for the ensuing year, three of those who retire by rotation, and are eligible for re-election, being Messrs. Thomas Hedley, Thomas Hedley, junr., Thomas Hedley, Joseph Pleasance, James Douglas, John Bennett Alexander, Thomas Hedley, Joseph Addison, William H. Wilkinson, and Charles Henry Young. They retire, but offer themselves for re-election.

The Auditors are Messrs. J. H. Richardson and Mr. R. Y. Green, also retire, but offer themselves for re-election.

In addition to these gentlemen, there is to be a Public Auditor of the accounts of the Company, and the Directors have to recommend the appointment of Mr. Thomas Hedley, the elder No. 2, Gateshead, of the firm of Messrs. Hedley, Gateshead, whose duties and emoluments will have to be approved by the Corporations of Newcastle and Gateshead.

The CHAIRMAN moved the adoption of the report. After congratulating the Shareholders upon the very satisfactory condition in which the Company was, he said the balance-sheet showed that, after providing for a full dividend at the rate of 7 per cent., there was a balance of £15,725 to be carried forward to the next half year's account, and £1000 to the reserve fund of the reserved fund. In consequence of this balance the Directors had recommended that the price of gas be again reduced. Five years ago the price was reduced from 3s. 6d. to 3s. per 1000 feet, and in about two years the price was reduced to 2s. 8d., and now they proposed to reduce the price to 2s. 8d. less 10 per cent. discount—2s. 4d. net—to the ordinary consumers. This reduction would be followed by a like reduction to the general consumers in the large districts supplied by the Company. A reduction of 3d. per 1000 feet on the gas sold in the district amounted to about £20,000 a year. If nothing extraordinary occurred this year the Directors hoped to be able to pay the full dividend of 7 per cent., and somewhat their last Act of Parliament allowed them to do—pay 8s. more for the year. The Directors were not, however, in a position to declare more than 7 per cent. on the year if they could have for the twelve months of the present law price. It, in consequence of the improvement now going on in the low trade, coal advanced to higher prices, the Company had power to go back again to the price of 3s. 4d. per 1000 feet without reducing the dividend below 7 per cent. The balance of £15,000 carried forward, which was equal to a full half year's dividend, strengthened the Directors in their recommendation to reduce the price of gas, and to meet the ever increasing consumption. During the past year there had not been that great advance in the consumption of gas which there was in previous years; but they had held their own. Their works were still large and extensive enough to meet the heaviest demand in any week in the year. This heavy demand seldom continued more than two, three, or four weeks; but still they must have plant to meet the demands, or great complaints

HOUSE OF LORDS.

TUESDAY, FEB. 19.

Petitions against the following Bills were presented:—
Rathmines and Rathgar Township Water Bill, from Dublin Tramways Company.
Wakefield Corporation Water Bill, from Corporation of Halifax.

FRIDAY, FEB. 20.

Petitions against the following Bills were presented:—
Sea Water Supply to London Bill, from (1) Conservators of the River Thames; (2) Lambeth Water-Works Company; (3) Fulham District Board of Works.
Sligo Borough Bill, from Right Charles Parke.
Wakefield Corporation Water Bill, from (1) Henry Savile; (2) Owners, &c., of mills, &c. on R. Hebden and others; (3) Lancashire and Yorkshire Railway Company; (4) Aire and Calder and Aire and Calder Navigation Companies.

HOUSE OF COMMONS.

MONDAY, FEB. 16.

Petitions against the following Bills were presented:—
Burton-upon-Trent Corporation Bill, from Sir Henry Flower Every, Bart., and the Rev. Rowland Morley.
Dagenham and District Farmers (Optional) Sewage Utilization Bill, from James Stormonth Darling (by guardian of the estate of Peter Lauri Mackie, an infant).

MR. FAWCETT.—To-day I gave notice that he would ask the Secretary of State for the Home Department, on Monday, the 23rd inst., if he could state whether the answer the Bill relative to the Water Supply of London will be introduced.

MR. ROWLEY HILL delayed till yesterday the question of motion, originally fixed for Tuesday last, the 17th inst., "To ask the President of the Local Government Board whether, in view of representations from various districts to take water for their own supplies from watersheds with which they have no natural connection, the Government are prepared, in anticipation of legislation, upon the subject, to institute an inquiry into the whole question of water supply."

TUESDAY, FEB. 17.

GASLIGHT AND COKE COMPANIES, AND SOUTH METROPOLITAN GASLIGHT AND COKE COMPANIES BILL.

Alderman COTTON: I beg leave to move that this Bill be read a second time. The objects of the Bill are to enable the Companies to adopt a means of ascertaining the pressure of gas supplied over any particular district, by self-registering pressure-gauges known as a constant register at the testing-stations, and also by testing at the pressure at a certain number of the street-lamps, such number to be determined by the Metropolitan Gas Referees. It is necessary to adopt some means for obviating the present difficulty of ascertaining from the public manufacturing stations the gas supplied to any particular district, and to render it possible by those means to assess the penalties, which, under certain circumstances, cannot be done, the gas from many receiving stations being mixed before it reaches the district where it is consumed. The honourable member for the Chairman of the Metropolitan Board of Works is with us on this Bill. Originally, the Metropolitan Board opposed the Bill; but as they are now excluded from the first clause, they will not oppose the second reading.

Colonel MAKINS: I move that the Bill be read a second time this day six months. I am aware that the course I am asking the House to take is unusual, to reject a private Bill on its second reading—it is a course that is unusual one. At the same time, where a Bill is exceptional in its character, and is at all in principles and provisions in contrast to those recognized in the practice of the House, I think I shall have no difficulty in obtaining from the House that such a course ought to be taken. The Bill promoted by the City of London Corporation, and its objects are to regulate the testing of the illuminating power, purity, and pressure of the gas supplied to the City—points which have been very much dealt with in the Acts of the various Gas Companies. Both of these Acts were passed so recently as 1875 and 1876; and the Companies themselves, in a petition they presented last year with reference to measure brought in by The Gaslight and Coke Company, and in connection with other provisions, similar provisions to those contained in this Bill, stated that the regulations contained in the Act of 1876 had been most carefully considered, and were found to be most useful in their operation, having tended greatly to improve the quality of the gas. The Bill was read by the Corporation not later than last session; yet they bring in a Bill to alter and amend those regulations. The Bill is a Bill which, though promoted by the Corporation, deals with matters not outside their limits. We have heard the honourable member state that the Metropolitan Board are busy in promoting this measure. This, I need not say, is a recent conversion on the part of the honourable and gallant member for Truro will explain to us why it is that the Metropolitan Board of Works have changed their opinion on this subject, for no later than the 6th of this month they passed a resolution that the Board petition against the Bill. It may be that the Board of Works would be glad to have the Bill named, if they could bring it forward without having to call on the ratepayers for the necessary money. Knowing that the City has plenty of funds at its disposal, I may here point out that some such arrangement has been made between the City Bill and with these Companies, two of which supply gas outside the City. The third—The Gaslight and Coke Company—supplies an area more than five times as great as that of the City. Therefore the controlling power of the City is small compared with the power which the Bill seeks power to deal. My honourable friend (Lieut.-Col. Makins) will perhaps explain how his opposition on that point has been withdrawn. There is only one other objection—but it is a rather strong one—which we urge against the Bill. In all former arrangements for testing the purity and illuminating power of gas, the provisions have been placed on the Companies only, as to speak, by Parliament. The Companies have petitioned Parliament, and asked for increased powers to raise capital, Parliament, in exchange for the powers granted, required the Companies to submit, in the interest of the public, to certain restrictions. We have now a new way of dealing with

HARROW DISTRICT GAS COMPANY.

The Half-Yearly General Meeting of this Company was held at the Guildhall Tavern, Gracechurch-street, on Wednesday, the 19th instant.—JAMES GLAISHER, F.R.S., Esq., in the chair.

The Secretary and Storekeeper (Mr. J. L. Chapman) read the notice convening the meeting, and the following report and accounts were presented:—

The Directors have pleasure in again laying before the Proprietors the half-yearly statements of accounts.

There is a slight decrease in the amount received for the decreased condition of trade, but the full dividend of £2 per cent. for the last half-year has been favourably.

The balance of profit and loss account shows a total of £1,021 3s. 6d. The Directors recommend that a dividend at the rate of 3 per cent. per annum, free of income-tax, be paid for the half-year ending the 31st December last, which will leave a balance of £2 13s. 6d., to be carried forward to the next account.

One of the Directors, Mr. A. H. Haynes, F.S.A.S., and one Auditor, Mr. F. G. Preston, retire by rotation, who, being eligible, offer themselves for re-election.

The CHAIRMAN, in moving the adoption of the report, said it was very much like the others which had been presented at their half-yearly meetings, but the Shareholders attention possibly might have been attracted to the fact that there was a slight decrease in the receipts. The Directors, however, were pleased to see from the fact that they found the Proprietary Company laying pipes, and were within two or three yards of the boundary of the Harrow Company's district, and that the former Company were really coming into the Harrow district to supply a very large house. The Board at once prevented them from entering their district; but, of course, it became a matter of anxiety with them as to whether they should go into the Harrow district. They had a perfect right to go there, and they had done had, and with a spirit to rivalship; but it seemed to the Board that this spirit to rivalship might be only for a time, and that as the Company would do all probability get a return for their money, they had better maintain their rights; and the decision of the Board was to lay the pipes into the Harrow Weald. They had done so, and they accounted for the increase in the capital account. It was sure that the matter was carefully considered by the Board, and they had done it with a view to the future interest, because the capital had entered a fair account into the present time, and he had no doubt it would return an increased account in the future. It would be seen in the second paragraph of the report that mention was made of there having been a slight decrease in the gas-rental. This was breaking the rule they had hitherto had, for usually there had been a slight increase; but in looking to the cause of it—it was stated in the report to be owing to the depressed condition of trade—it was found that one of their largest customers, the Greenford Colour-Works, had been so affected by the depression that they had consumed only half their ordinary quantity of gas; they had used about 500,000 to 1,000,000 feet of gas per quarter, but they had been in the habit of using more. Then the loss in the half year was to the extent that the stations the railways had applied to the Company to the extent that the stations the railways had applied to the Company to the extent that the stations the Company supplied had used about 150,000 feet less of gas. This Company supplied had used about 150,000 feet less of gas. This accounted entirely for the slight decrease they had had in their rental. The sentence announcing this fact, however, closed with the statement in the sentence announcing this fact, however, closed with the statement in that the profits had been increased, and this enabled the Directors to recommend the customary dividend, to pay one and a half per cent from the parliamentary expenses, and to carry forward a small balance; so that, looking to the report, it would be seen that they thought it would be seen to be looking to the report, it would be seen that they thought it would be seen to be satisfactory. The report which he had alluded on different occasions to as being in course of preparation that he was told it would certainly be opened on the 1st of June, and if this were so, he thought there was a certainty that the Company would have their coal very much cheaper in the ensuing winter than they had ever had it, and as low as they had ever had it before, whatever reduction they obtained in their coal they would employ in lowering through the heavy charge that they had for their gas. They looking through the heavy charge that they had for their gas. They looked on the consumers as their friends, and they wished to be looked on the consumers as friends as possible. Therefore the full advantage of any reduction which the Company might obtain would at once be given to them, and it would be a pleasure to himself to do so, because he had always looked on the price of 6s. as being something they must get as soon as they possibly could. This would be the first opportunity of reducing the price of gas since there was any question of gas-light had. He did not know that there was any question of gas-light had. He did not know that there was any question of gas-light had. He did not know that

SOUTH SHIELDS GAS COMPANY.

The Ordinary Meeting of this Company was held on Thursday last—Dr. R. Wallis, J.P., in the chair.

The Secretary (Mr. J. H. Penney) read the notice convening the meeting, after which the following report was submitted :—

The Directors beg to submit to the Proprietors the accounts for the half year ending Dec. 31 last.

After the balance of the profit and loss (net revenue) account amounts to £3197 3s. 8d., a sum of which the Directors recommend the payment of a dividend for the half year ending Dec. 31 last at the rate of 7 per cent per annum.

The gas consumption for the past half year is 32,197,100 cubic feet, which shows an increase over the corresponding period of last year of 2,707,600 cubic feet.

The Directors have much pleasure in stating that the new purifying and meter-testing machine has been at work during the same period, and has given great satisfaction.

The Directors have effected a new arrangement by cancelling the contracts for a new gasholder and erecting the same on the site in the centre of town.

The Directors beg to recommend a reduction in the price of gas, to take effect from the beginning of the present quarter, which will be equal to a penny per thousand cubic feet. This will make the price of gas, in the parishes of South Shields and Jarrow, after delivering the usual discount, 3s. 4d. per 1000 cubic feet, and 3s. per 1000 cubic feet respectively.

The retiring Auditor is Mr. John Forster, who, being eligible, offers himself for re-election. The Directors retire from office each year in rotation.

The Chairman said since the Shareholders last met the Company had obtained the Royal Assent to the Bill they promoted in Parliament, and which, as they would see, created extended powers for the Act, and by which they were placed in a different position in regard to gas legislation. They would all have received the circular which explained the provisions of the Act, and if they would peruse that they would find the clauses were presented in a more comprehensive manner than formerly. The Directors had also consulted with counties with their Secretary and other officials. As they were aware, under the new Act of Parliament the old Shareholders of the Company were now in a position to divide over capital that might be created by new issues according to their interest in the Company, and the result of the Act was that it would be offered for sale by public auction. They had already disposed of one sale of shares, and the shares met with a very ready sale, and at a premium. This in itself was one of the most signs that the Company was in a sound and prosperous position. They had recently purchased the Jarrow Company, and the commercial relations which existed between the two companies would help to maintain their position amongst other mercantile concerns in the county. This decrease they had reason to believe would be closed, so that they might look forward to a new state of matters in regard to the development of the coal and industries of this country. They, in fact, saw on all hands a great revival in trade, and he was glad to observe that the receipts of the Stour Tyne Company, which for four had gone up 12 per cent. The iron and coal trades were looking forward to something more prosperous. With regard to the coal trade, he might say that the Directors had secured contracts, on most favourable terms, for the ensuing year—in fact, he might say that since they signed their contract coal had increased from 1s. to 1s. 6d. per ton. These were all signs of the times, and he was glad to say the Company were keeping pace with them. Comparing the corresponding half of the previous year with that of last year, they were in a most favourable position. Respecting the make of gas, in comparing the half year of 1878 with that just closed they had sold 2½ millions of cubic feet of gas more than in the corresponding half of the previous year, and in money value the increase was £991. These were all just sources of congratulation. Respecting the question of new legislation, he might say that the regulations of the Legislature were very strict, although at the same time fair and just. Instead of dividing the stock into shares of £100 each, as at present, the shares were sold at £10. The Shareholders, however, did not altogether lose the benefit, seeing that the premium realized went to increase the capital without increasing the dividend, and thus tended towards the reduction of the mortgage debt.

Mr. Ed. Jackson, in July and August cubic feet them 16s. 6d. per ton; in September and October, 15s. 6d.; and in November and December, 14s. 6d. The result was for the half year ending Dec. 31, 1879, 1s. 6d. per ton less than the corresponding period of 1878. He was glad to say that in the last month

MELBOURNE METROPOLITAN GAS COMPANY.

The Fourth Ordinary General Meeting of the Shareholders in the Melbourne Metropolitan Gas Company was held on the 30th ult., at the Offices of the Company, Collins-street, West, for the purpose of receiving the Report of the Directors, and the Statement of Accounts for the year ending 31st December, 1859.

The Chair was taken by Mr. Alexander Fullarton, and the Report was read by the Secretary, Mr. Thomas Bowman, as follows:—

The Directors have much pleasure in presenting to the Shareholders the Fourth Annual Report of the Melbourne Metropolitan Gas Company, and in stating that the Works have been completed and in operation for the supply of Gas to the Public Lamps and Private Consumers since the 1st of January, 1859.

The Directors have to report that the Gas Works, Mains, Service Pipes, Meters, and Fittings, have been laid down and fixed in accordance with the Contracts, and the Company has been supplied with Gas of the quality required by the Act of Parliament, and in accordance with the Contracts

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, MARCH 23, 1880.

Circular to Gas Companies.

After a delay which is unaccountable to us, the scheme for the amalgamation of the South Metropolitan and the Phœnix Gas Company has received the sanction of Her Majesty in Council, and all, so far, is now settled. The delay of which we complain has, however, put the South Metropolitan Company to some inconvenience, inasmuch as the Bill they are promoting in Parliament this session, and which is highly necessary to them, still lingers at its second stage; though the Parliament which will break up to-morrow, and will be scattered the day after, might just as well have had the opportunity of passing this Bill. The duty of considering it is consequently relegated to the new Parliament about to be elected, it being understood that the measure will be taken up at the point at which it stands to-day. The importance of the combination just sanctioned can hardly be exaggerated. Nearly the whole of London south of the Thames will, for the future, be supplied with gas by one Company, whose interests will be at once to maintain the quality of the gas and reduce the price to the lowest possible figure. The arrangements as to the charge will be found in the copy of the scheme which we publish in another column; but we have referred to these in former issues, and need not here recapitulate them. It is sufficient to say that the consumers in the late Phœnix Company's district will reap an immediate benefit, and in the course of twelve months will share the complete advantages of the alliance with the South Metropolitan Company.

The Bill of the South Metropolitan Company, which may be called the Bill of the United Company, has been proceeded with as far as it could in the present Parliament. There is really no opposition to it, and but for the delay caused by the Board of Trade it might by this time have passed its third reading in the Commons. As matters stand, however, we must wait to see how it will fare in the new Parliament. We do not expect to see any great changes in the *personnel* of the representation in the south of London; but if any should occur, local influences could hardly affect the fate of this measure. All who are in any way acquainted with the position of the United Company will see how essential it is to them that the Bill should become law as speedily as possible. It is no wonder, then, that at the South Metropolitan Company's Whitsuntide meeting, held last Friday, a resolution of the Shareholders, consenting to the promotion of the measure, was passed unanimously. Some matters were pressed upon the attention of the meeting which really did not concern it. One of the Shareholders, for example, wished to know what the Directors were about to pay for the land they have engaged to purchase. We are astonished that any question should have been raised as to the necessity for the quantity of land, or as to the price it is proposed to pay for it. It seems to be forgotten that the Metropolis grows, and that the gas-works supplying it remain stationary, being in some instances utterly incapable of extension. The case of the late Surrey Consumers Company is almost one in point. They had space for small additions to retort-houses, but no possibility of making further storeage arrangements. The area occupied by the original South Metropolitan Company is extremely valuable, and offers peculiar facilities as a site for gasholders. Under these circumstances, it seems highly desirable that additional manufacturing power should be furnished in one quarter, while further storeage should be provided in another. We gather that the present works of the Phœnix Company are almost incapable of extension. It will thus be seen how urgently needed are the powers which the South Metropolitan Company's Bill proposes to confer. It is extremely unfortunate that a dissolution steps in before the completion of the work which had been cut out for the present Parliament. However, we are all victims of political vagaries; but in the present case we cannot help thinking that a few weeks will find this Bill far advanced towards receiving Royal Assent.

We are very glad to say that the Metropolitan Board of Works have withdrawn all opposition to the Bill of the London Gaslight Company. The objection raised by the Board to the Bill was of a most puerile character. It simply concerned the amount of capital which the Company should be allowed to employ in the new branch of their business which they are about to undertake—that of supplying cooking and heating stoves, and apparatus for the use of gas for other than lighting purposes. The Metropolitan Board were willing to sanction the use of £25,000 in conferring what we must regard prospectively as a great benefit to gas consumers; but the Company, very properly reviewing all the circumstances, found that they could carry on their stove business with loss, and so have agreed that only £20,000 shall be engaged in it. This amount of capital is small enough, and we are almost astonished that the Company should have proposed so low a figure. We have said before that for a business like the one projected, to be successful, it must be carried on in a most liberal spirit. There is a great future in store for any Gas Company who will enter upon the business of supplying gas-fittings, &c., on hire, and at the same time of furnishing gas at a fairly low price. We could point to many gas undertakings in the kingdom which have largely benefited by taking up the supply of gas stoves and apparatus for other than illuminating purposes; and the London Gaslight Company will, no doubt, be as successful as the rest. But the business must be carried on in no niggardly spirit. Of course, gas will be supplied at the customary rate; but, for the cooking and heating utensils, we should hope that the minimum price for sale and hire will be charged.

The Bristol United Gaslight Company held their half-yearly meeting on the 15th inst., at which, it is scarcely necessary to say, maximum dividends were declared. The new works of the Company at Stapleton are now in full operation, and the greatly increased demand for gas during the past dark winter has been fully satisfied. This is extremely gratifying, both to the Bristol and Clifton public, who will now find themselves fully assured of having an efficient supply of gas for some years to come, without further calls for capital and loud. We can hardly say that we entirely agree with Mr. Fiddes's determinations of light

DRAY'S BURNERS AND LANTERNS FOR STREET ILLUMINATION.

The accompanying illustrations show the burners and lanterns as manufactured by Messrs. George Bray and Co., of Leeds, for improved street-lighting purposes, the system which they advocate being, as our readers will know, the employment of large flat-flame burners in a specially constructed lantern. The system Messrs. Bray and Co. are introducing, though it may be said to be of only very recent date, has been tried by the public authorities of many of the principal towns of the kingdom, and in the Metropolis; and everywhere, as far as we have heard, is giving complete satisfaction.

Fig. 1 is an elevation, and fig. 2 a vertical section of the burner and lantern which Messrs. Bray and Co. have adopted for general use. The top ventilator is composed of two cylinders, *a* and *b*, and a cover, *c*, at the top. The chimney, *d*, is open at the top and bottom, and terminating at the top of the lantern, *d*, opens directly into it. Its top terminates in such a position in the

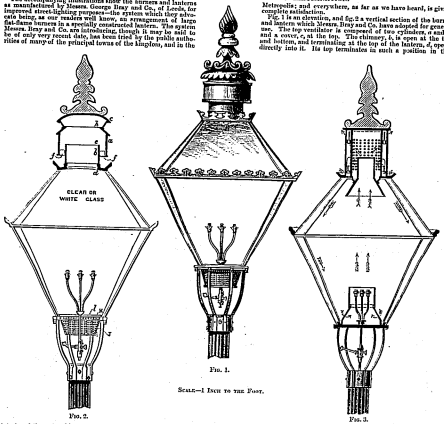

Fig. 1. Fig. 2. Fig. 3.

SCALE—1 INCH TO THE FOOT.

interior of the outer chimney, *e*, as with the aid of the tee cover, *c*, to prevent the wind getting into the interior of the lantern in whatever angle it strikes the ventilator. Between the inner and outer chimneys *a* and *b*, is an annular space, *f*, of about the same capacity as that of the inner chimney. The outer chimney, *e*, is open at the top, and is fixed a sufficient distance from the top of the lantern to allow a perfectly free downward exit of the products of combustion and air. The inner chimney, *d*, is contracted at the top, so that the area or aperture of about the same area as that of the inner chimney. This contracted portion is carried to a sufficient distance above the top of the inner chimney, so as to allow of the products of combustion and air to escape down through the annular space, *f*, when the top of the outer chimney, *e*, is almost entirely, as in fig. 2, a strong wind. It will be seen that the inner and outer chimneys, as well as the top cover are so arranged, that, while perfect freedom of exit for the products of combustion and air is provided, it is not possible for any current to pass into the lantern.

The inlet ventilator at the bottom of the lantern is composed of two distinct parts—the intake or diffuser, *g*, and the box of louvre boards in external at the top by a sheet of wire gauze, *l*. The diffuser takes in the air at the bottom of the lantern, and is, as will be noticed, quite it flares or diffuses it, while the small tubes in the centre, against each other, with the gauze on the top, conserve its passage into the lantern, forming a sort of vertical and quiet main. The intake or diffuser is made of perforated metal, of sufficient depth to take in the requisite quantity of air, and has concentric rings of perforated metal placed vertically inside. It deals with the air as follows:—When the atmosphere is at rest, the air passes in on all sides of the diffuser, and rises vertically through it; but when there is on one side of the diffuser only, and, striking against the convexities of it, has its force and eddies reduced by a small portion only, being turned up at a time in the passage horizontally through the ventilator, and by the currents being mixed up and turned in various directions by the perforations in the concentric rings.

Thus a proper proportioning of the respective capacities of the inlet and outlet ventilators is secured, and a perfect draught for the purposes of dealing with the flames are obtained, and are protected in all weathers by the louvre. In this column of air for the flame burners are set either slight, double, or in clusters, to suit the circumstances and the power of flame required. The burners are fixed either vertically or at a slight inclination from the vertical, so that the heated products may cause the flames to thicken and become empty in a current of air of the description the burners are slightly inclined, and the under sides of the flame are protected by projections, as shown in the engravings. By these means the flames are made to emit round the reverse way of the inclination, and are brought within the influence of more air, and the heat of the adjacent flame; the result being that the edges are made intensely white and brilliant, the flame being empty, as each burner is fixed in the centre.

Fig. 1 and 2, as before stated, are the lantern that Messrs. Bray and Co. have adopted for general use, in preference to figure 3, because of the necessity there is in that arrangement of a conductor chimney for conveying the required current of air to the flames. Fig. 3 is taken from the drawings of their first patent (No. 1451 of 1878), and is an arrangement wherein the top ventilator is made to answer as an inlet and outlet combined, the fresh air admitted through the perforations at the bottom of the outer cylinder passes over the conductor, and enters the lantern down its sides. The air is then conducted up to the burner—but before the flame—by a cylinder or chimney perforated at the bottom (seaborn in the drawing), or raised above the bottom of the lantern at a sufficient distance to enable the products of combustion to find an exit. In this manner a certain quantity of fresh air is conducted to the flame, and the heat of the flame is made to pass up to such volume and at such a rate of speed as will steadily increase the brilliancy of, and give control over the lighting power of the flame or flames admitted to its influence" and in the colours of air to "pass the flames, singly, doubly, or in clusters, and to each close proximity to each other, without touching, but that by the burners be increased, and the smoking tendency diminished."

Messrs. Bray and Co. have also more recently introduced an improvement in the rim of which the lanterns are made, which gives a maximum of strength with a minimum of light-obstructing surface. It consists of a doubled strip of metal being placed lengthwise, vertically, along the centre or gutter of the inside of the lantern rim, which, by this means, is made sufficiently strong to support the sash upon which the panes of glass rest, to form a squeezing bearer between the panes, and to prevent each pane encroaching upon the other portion of the rib.

SHEFFIELD WATER-WORKS COMPANY.

The Annual General Meeting of this Company was held on Monday, the 12th inst.—Mr. W. COCKAYNE, Chairman of the Board of Directors, presiding.

The following report was presented:—

"The supervising committee of the Company, formed on debenture, the sum of £25,000 10s. dividends on preference shares, £41,666 13s., the dividend after the rate of 2 per cent. per annum on the ordinary capital of the Company for the half year ending 31st December last, and the sum of £2,000 to the reserve fund, there remains in the net balance of income account as at that date, the year 1879, the sum of £29,310 7d. 9d., published with the report of last year, the sum of £29,310 7d. 9d., the balance of the

Mr. White's machines about the same time Mr. Wood bought his. I did that a great deal

and have obtained some very good results; but I have never made a thorough test at that pressure.

Mr. Vanderpool—Is it your impression that you could get as good results from a stove working under half an inch pressure as you could from one working under an inch pressure?

Mr. Goodwin—I think so.

Mr. Neal—How do you answer the objection that the stoves are returned in a great many instances, and that the reason given is that there is not pressure enough, when the pressure is an inch?

Mr. Goodwin—I would answer that by saying that I don't think they had anything like that pressure; there must have been a mistake.

Mr. Stinson—Mr. Neal has spoken about Mr. Gerould having stoves returned. I think he is mistaken about that, for my impression is that Mr. Gerould has told me to the contrary.

Mr. Gerould—I have never had but one stove returned, and that burned too much gas.

Mr. Goodwin—The great difficulty is that when the persons who are using the stove get through they do not turn off the gas. We got up a sort of lead pipe connection with a double back-action contrivance that would always turn down the gas the moment a pan or utensil was lifted from the stove and would turn it on when the pan or utensil was set on the stove; but that added to the expense of the stoves; they are too expensive." You see where I am drifting to now, and I want to say a few words upon that point right here.

A gentleman, at the head of a large gas company, and whom you all know, called at my office one day and we had a long conversation on this subject. During our conversation he said, "You charge too much for your stoves." I said to him, I will tell you what I will do; I will give you the cost of my stoves, and you shall name the price; the result was the present price. We introduced several thousand dollars worth of machinery in our establishment in order to reduce the expense of manufacture; but we had no sooner done so than the price of iron went up to such a figure that the advantage was entirely lost. Take, for instance, the foot of the stove. Where a man could make one dozen a day before, we have machines now by which he can make over 100 a day; but, as stated, we have lost the benefit of that by reason of the rise in the cost of materials. Wherever it is possible to introduce machinery we have done so.

In reference to this stove question, I will say that five years ago I bought a sample of every gas stove made in this country that I could get hold of, and I found they were not what was wanted—in my judgment. I tried in every direction, but could not get what I felt was wanted. I then sent one of my employees to Europe, and told him to travel in every direction where he could get any information. I kept him abroad five months, visiting England, France, Germany—everywhere that there was any information to be had; and he brought home all the information he could collect, as well as samples of the best gas stoves he could find.

Last year I sent another person abroad, and he was gone several months. He brought home all the information he could obtain, and other samples; and those stoves are the outgrowth of that investigation.

Mr. Harkness—What kind of coal did they use in the Cincinnati hospital where those tests were made?

Mr. Goodwin—The regular gas coal such as they use in the gas works there. They use nothing else in that part of the country but soft coal.

Mr. Neal—There is a gentleman present, Mr. Scott, who uses a gas stove every day in the year. Perhaps, he will favor us with his experience.

Mr. Scott—My stove is a retort stove. My family is small, and we use a gas stove every day, and find it economical, convenient, and very satisfactory.

Mr. Vanderpool—Mr. Goodwin asked me about the correctness of some figures that he gave in reference to the utilization of energy.

It is well worthy of consideration that the efficiency of gas engines, as evinced by their conversion of heat units into work, is very high. The consideration of this fact, and their successful running, have drawn the highest engineering journals to express the opinion that their adoption for light or for motive power is certain, and a mere question of time. It is probable that, with increased attention (there having been but comparatively little investigation in this direction) the gas engine will be much improved, and the consumption of gas will be reduced below 20 cubic feet per horse power per hour.

As just stated, the most perfect engines using at the rate of two pounds of coal per horse power per hour, convert into power about nine per cent. of the energy of the coal; whereas, an engine using at the rate of 10 pounds utilizes less than 2 per cent. A cubic foot of 16 candle coal gas has a calorific power of about 650 heat units; and if 20 cubic feet produce a horse power it is evident, the thermal equivalent of a horse power being 2555 units, that the utilization of energy is 19.3 per cent. The efficiency of the gas engine, as thus considered, is more than twice that of the best steam engine. There is another way of looking at this question; if we take one ton of coal, carbonized in the best manner, the weight of the ton actually used, in gas, coke, and waste, to produce 11,200 cubic feet of gas is 1781 pounds, and there should be left, of soluble residuals, in the shape of coke, tar, and liquor, 1461 pounds. The yield of gas per pound of coal, actually used, is evidently 11,200÷1781=6.3=14.4 cubic feet. As the cubic feet of gas make a horse power, we have one horse power produced by 20÷14.4=1.38 pounds of coal. If the gas engine is so perfected that 10 cubic feet of gas produce a horse power, as has been claimed by some engine builders (but these figures require verification) it is evident we will obtain one horse power by the consumption of less than three-quarters of a pound of coal. The theoretical consumption of 16 candle coal gas per horse power is 650÷600=3.88 cubic feet. Some interesting calculations upon these matters, by Mr. Lane, may be found in recent issues of *Engineering*.

There are evidences of a large demand for the gas engine in this country. I was informed recently, in a conversation with a representative of a certain engine, that there were unable to supply the demand, and that there were already in operation, in the city of New York, thirty of these engines that had been erected within a short time, and without particular solicitation on the part of the builders. It also appears that there is a large and increasing demand for gas stoves for cooking.

The indications are that, with proper attention on our part, we can largely increase our day consumption, which we know is of great importance, as bringing into use plant that lies comparatively idle during most of the 24 hours, and an increased consumption on the same capital means the capacity to sell at lower prices.

(To be continued.)

Spence's Metal—A New Metallic Compound.

We insert below a condensed report of Dr. Cole's lecture on this new metallic compound, read before the Society of Arts at a recent meeting, and followed by an interesting and useful discussion:

DISCOVERY OF THE METAL.

Nearly a year ago Mr. J. Berger Spence discovered that the sulphides of metals, combined with molten sulphur, formed a liquid. This liquid, on cooling, became a solid, homogeneous mass, possessing great tenacity, and having a peculiar dark grey—almost black—color. Nearly every metallic sulphide which is known combines, as experiments have proved, with an excess of sulphur, and curiously enough, all these combinations have the same properties. The combination, of which I have specimens here for inspection, consists of an ore of iron pyrites containing both lead and zinc sulphides.

CHEMICAL COMPOSITION.

Dr. Hodgkinson, chemical demonstrator at the Science Schools, South Kensington, has kindly sent me the following facts:

"It appears to be the easiest thing in the world to obtain homogeneous castings with it. Specific gravities of portion sent gave 3.3743 to 3.7006 (reduced to 0° C).

"When finely powdered, it is acted upon slowly by concentrated HCl and NO_2HO in the cold; in large lumps, little or no action takes place. As yet I have not been able to determine the organism equivalent accurately; it will require, however, to be small. The fraction is not estimable, as might perhaps have been expected, but somewhat like that of cast iron.

"I have not had time to try many 'utilization experiments' on the substance, but I have no doubt it would be exceedingly useful in the laboratory, even, for instance, for making the air-tight connections between glass tubes by means of caoutchouc, and a water or mercury jacket, whatever else is no disadvantage; the fusing point is so convenient, about 240°, that it may run into the outer tube on to the caoutchouc, which it grips on cooling like a vice, and makes perfectly tight.

"I don't know what you may call the material, but should think, as it seems to be more than a mere mixture, 'ferric thiide' would not be a bad or inappropriate name."

PROPERTIES OF THE METAL.

It has a comparatively low melting point, viz., 320° Fahr., or rather more than 100 above the temperature of boiling water. Here, then, we have in its favor the small amount of fuel needful to supply the necessary heat for reducing the metal to a condition for use.

2. It expands on cooling, a property not shared by the majority of other metals or metallic compounds. I believe that type metal and bismuth are two exceptions. Later on I think I shall convince you that, for an operation like the joining of gas and water pipes, this expanding property is of great importance.

3. It claims to resist atmospheric or climatic influences, as compared with bronze and marble. I noticed only a few days ago how the statues in bronze on the Holborn Viaduct, had been affected by our London fogs. And I have evidence to produce in the direction of showing the imperviousness of the metal to such degrading influences.

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, MAY 25, 1880.

Circular to Gas Companies.

THE communication which we publish elsewhere from the Gas Engineer to the Leeds Corporation, coupled with the announcement which we are able to make that the South Metropolitan Company have determined to reduce the price of gas in the district of the late Phœnix Company to the one thousand cubic feet from the 30th of June next, form a remarkable commentary upon the observations in our last "Circular" as to the municipal acquisition and conduct of gas-works. As our readers are aware, the scheme for the amalgamation of the South Metropolitan and Phœnix Companies authorized the United Company to continue the price of 3s. 4d. in the Phœnix district for twelve months from the date of amalgamation—that is, until Jan. 1, 1881—without detriment to the dividends of the original South Metropolitan Shareholders. This would remain to the Company some £30,000 of revenue on the year—a sum probably especially welcome just now, as helping to cover the necessarily heavy charges incident to the amalgamation. By conceding the reduction from the earlier date, however, the Directors expedite to the same degree the payment to the holders of South Metropolitan and Phœnix shares an increased dividend of one-half per cent.

The initial price in the Act of the South Metropolitan Company being 3s. 6d. per thousand feet, the price now and for some time past charged in their district—viz., 3s. per thousand—warrants the payment of a dividend of eleven and a half per cent. The proportion of profits paid by the stock of the late Surrey Consumers Company (B) to that of the original £—th Metropolitan (A), under the scheme for the amalgamation of those two Companies, enabled the latter to share last half year a dividend of eleven and three-quarters per cent, while the former was reduced to eleven per cent. Although the usage of equal division of profits was raised in the Phœnix amalgamation scheme to eleven per cent. from ten and three-quarters, at which it stood in that of the Surrey, yet the great increase in the amount of B (contributing) capital, due to the absorption into that class of the whole of the Phœnix shares and stock, will enable the A whole of the Phœnix shares and stock, will enable the A holders to receive from June next twelve per cent. Shareholders to receive from June next twelve per cent. Thus the while the B take eleven and a quarter per cent. This while the B take eleven and a quarter per cent. This arrangement assents itself at once and naturally in its thirteenth place and congenial home, by inducing the earliest possible reduction of price and increase of dividend, or increase of reduction of price and increase of dividend, or increase of dividend with reduction of price, whichever way our readers may prefer to put it.

The action of the Directors of the South Metropolitan Company and their chief adviser, Mr. George Livesey, in this matter, is, as we have said, a perfectly natural and proper one. We think it is a particularly happy circumstance that the price is so promptly made uniform throughout the district, and we congratulate Directors, Shareholders, and Consumers alike. At the same time we feel that this prompt reduction points to one serious evil attaching to the present position of legislation on the subject of the sliding scale, and position of legislation on the subject of the sliding scale, and to it we draw the attention of our readers. How does it to it we draw the attention of our readers. How does it happen, we ask, that these considerable reductions in price happen, we ask, that these considerable reductions in price in the districts of the Phœnix and Surrey Consumers Com- in the districts of the Phœnix and Surrey Consumers Company's are possible *immediately* after amalgamation? The panies are possible *immediately* after amalgamation? The panies are possible *immediately* after amalgamation? The time which has elapsed is not sufficient to have brought time which has elapsed is not sufficient to have brought about any considerable economies in management or other- about any considerable economies in management or otherwise, and we are forced to the conclusion that the condition wise, and we are forced to the conclusion that the condition of the Companies themselves *before* amalgamation was such of the Companies themselves *before* amalgamation was such as to warrant, it not to require that the price of gas as to warrant, it not to require that the price of gas should be reduced. The Phœnix Company, for instance, need should be reduced. The Phœnix Company, for instance, need not to think that the filling up of the reserve-fund to the very not to think that the filling up of the reserve-fund to the very letter should necessarily precede a concession to the consu- letter should necessarily precede a concession to the consumers, and there can be little doubt in the mind of any one mers, and there can be little doubt in the mind of any one conversant with the character and traditions of the Com- conversant with the character and traditions of the Company that, under ordinary circumstances, the price charged pany that, under ordinary circumstances, the price charged would not have been kept at the price it was. The season is would not have been kept at the price it was. The season is not far to seek; The Company were under the necessity of not far to seek; The Company were under the necessity of applying to Parliament for more capital; with the increased applying to Parliament for more capital; with the increased powers they sought they must inevitably accept the sliding powers they sought they must inevitably accept the sliding scale; the initial price from which the sliding scale operated scale; the initial price from which the sliding scale operated would be determined by the rate at which gas was actually would be determined by the rate at which gas was actually supplied; therefore it was desirable to keep as high a price as supplied; therefore it was desirable to keep as high a price as possible, consistently with some regard for appearances and possible, consistently with some regard for appearances and fairness. fairness.

The unfortunate departure, in the case of the South Metropolitan Company, from the idea of an uniform initial price, which obtained when the principle of the sliding scale was which obtained when the principle of the sliding scale was accepted by the Commercial and Chartered Companies, opened accepted by the Commercial and Chartered Companies, opened the way to a fight in the case of each Company seeking powers; and the punishing of a well-conducted and successful Company, by giving them a low initial price because their position of affairs is objectionable on both sides. Companies legally the action of all those others to whom an application to Parliament was in any degree imminent. Thus the present position of affairs is objectionable on both sides. Companies may well complain if an honest fulfilment of their legitimate duty to their consumers—that of giving them the advantage arising from times of cheap production—is to be used as a scourge when they go to Parliament; and, on the other hand, the consumers have a clear and manifest ground of complaint if the price of gas is being kept up unnecessarily high, so that Companies may make out a better case for a high initial. How this condition of things is to be met is not easy to see. The application of the sliding scale to all statutory Companies alike would answer to *The Times* definition as "heroic" treatment. It would involve probably a laborious inquiry in half the towns in the kingdom, for the chances are that the acceptance of the present selling price as the normal one would be resisted in some cases by the consumers and in others by the Companies. Some way, however, will have to be found to reconcile the present antagonisms. For ourselves, we have not professed in the past, and we do not now affect an admiration which we do not feel for the sliding scale. We are old-fashioned enough to retain our preference for the earlier legislation, and to believe and maintain that the true interests of Gas Companies in the long run would have been better served by a faithful and loyal observance of the Gas-

INSTRUMENT TO DETECT COLOR BLINDNESS.—Herr D. Aubourg has devised an improved instrument for detecting color blindness, which embodies the principle of Young's theory, and distinguishes colors by placing much attention to the spectrum. The instrument is an adaptation of the spectroscope to the examination of the special case. The spectroscope contains a fixed and a movable collimator tube, so that two spectrums can be moved above the other. By means of a slide in the eye-piece any portion of the double spectrum may be presented to the eye alone, and will then constitute a good object for comparison.

Nov. 1 1879

to see the consistency of the Mayor's action. [illegible] the defunct Gas Company was present, and made the statement that, under the circumstances, the Company would have reduced the price of gas, the position of affairs fully warranting a reduction of threepence per thousand feet. This course, however, was rejected, as above stated, the decision eventually arrived at, causing some surprise in the Council—a feeling which is likely to be echoed outside.

Negotiations are to be entered into between the Corporation of Newcastle-under-Lyme and the Gas Company at present supplying the town, for the purchase by the Corporation of the undertaking of the Company. The question has been in abeyance for some time since it was first mooted, for various reasons, the chief apparently being that some of the more progressive members of the Corporation, at the time when the idea first took shape in a clause inserted in the Corporation Act of 1877, authorizing the purchase, have since failed to retain their seats in the Council, and the eclipse of these ardent spirits appears to have so far daunted the remainder of the members of the Corporation, that they have not moved in the matter with any great energy until the present time, when the imminent lapse of the period during which the Corporation will be allowed to make up their minds has induced them to bestir themselves. The whole question having been referred to the Lighting Committee, that body has reported favourably of the proposed purchase, and the Council unanimously resolved to take action in the matter, and we shall probably soon see whether the transfer is to be settled amicably or otherwise, as it seems to be inevitable.

The details of the gas accounts of the Rochdale Corporation, given in last week's issue, are eminently explicit. The item of most interest observable in the prefatory statement of the general results is the great success claimed for the St. John purifying apparatus and carburetter, which in six months winter working is credited with effecting a saving of £370, or an average yearly economy of about £1000. This is a surprising statement, and one which is scarcely intelligible on any theory of condensation generally accepted at present, by which gas may be enriched by its own accompanying liquid hydrocarbons. The production of gas was over 5 million cubic feet in excess of the corresponding period of the previous year, and the illuminating power was more than 18 candles—the usual standard for Rochdale gas—while the consumption of cannel was about 2100 tons less, the difference being made up with ordinary coal, the total weight of coal and cannel used being only about 40 tons more than in the period with which the comparison is made. The difference in the two results is certainly remarkable, and will doubtless attract attention from other quarters. It is difficult to believe that it is owing entirely to an apparatus of the kind mentioned; but no other explanation is offered, and we are bound to suppose that all other conditions have remained the same. Setting aside the increased rate of production, it is evident that a great impulse will be given to the solution of the question of the treatment of gas in contact with tar and hydrocarbons, by the publication of statements of this kind, of independent origin, and of accuracy guaranteed by the irrefutable logic of cash expended for work performed. Such are the facts as they are given to us, and we shall look with much interest for the production of any further evidence leading to confirm or refute the inference which in this instance has been drawn from them.

Chesterfield has the advantage of having its gas and water supplied by one and the same Company, which, in these days of trading Corporations, is an assurance of increasing rarity. Still the Chesterfield Corporation can scarcely be called happy, and some of their grievances have found their way into the local newspapers. A complaint is made that although the price paid for the public lamps was raised in consequence of the high price of coal in 1875, the subsequent fall in the value of the latter commodity has not been followed by a reduction to the old prices of the era before the coal famine. The Directors of the Company state, however, that the price even now paid does not give them a profit, so that eventually we find that the existing terms were agreed to for another year. Respecting the selling price of the gas to private consumers, the wish was expressed by a deputation of the Council who recently waited on the Directors of the Company, that a reduction from the present charge of 4s. per thousand feet might soon be made; but as the Company barely pay an average dividend of six and a quarter per cent. on the whole of their stock, and the consumption of gas is not of an elastic nature at present, the Directors did not see their way to promise an early reduction. We may indulge the hope, however, that the consumers will be allowed to participate in

Another of those [illegible] familiar, respecting the disposal of the surplus profits of undertakings belonging to Corporations, arose at the final meeting of the St. Helen's Town Council, when a very close division took place on the question whether a certain portion of the gas profits, left after various apportionments of the gross accumulated profits to capital account and reserve-fund, should be handed over to the borough-fund for the general benefit of the ratepayers, or be added to the reserve-fund recently established by the Committee. Strangely enough the vote was taken on an amendment which did not express the point upon which the discussion had really turned. The Gas Committee presented a report in which, after placing the round sum of £2000 to the credit of a reserve-fund, they proposed to hand over to the borough-fund £1126; when a rather vaguely-worded amendment to the effect that this sum should be applied to reduce the price of gas, was moved, and met with many supporters, including the Mayor, who, when the final vote was taken on a revised amendment dividing the sum[illegible] in dispute to the reserve-fund, found himself in the position of having to give a casting vote, the numbers being equal, and he then distinguished himself by voting against the proposal which he had permitted to take the shape of that to which he had previously given his adhesion. Certainly the two amendments were not identical; but the same principle—that the gas profits belonged to the gas consumers—was common to both, and it is therefore difficult

sibility. I may, however, say that the investigation is still proceeding.

In order to make the results strictly comparable, an experimental gasholder was filled before each series of observations. To effect contact of the gas with the tar, an apparatus 7 feet in height and 9 inches in diameter was used, which is accurately represented in the diagram, on a scale of 1 inch to the foot. The tower was filled with clinkers saturated with the tar, and the gas was passed through at the rate of .5 feet per hour. The tower was surrounded with a jacket, into which steam could be passed to increase the temperature; but it was not used in the experiments I am about to describe. The temperature of the gas was estimated by an accurate thermometer placed at the exit from the column. The lowest temperature recorded was 50°, the highest 60° Fahr. Before washing the photometer passing over the tar at the same rate, the gas gave, as a mean of 100 photometric observations, an illuminating power of 14·39 candles. This indicates a loss equal to 1·85 candles. In a second series of trials, a fresh sample of gas before contact with the tar gave an illuminating power equal to 15·10 candles, and after contact with the tar 13·01 candles; the loss being equal to 2·12 candles. As the difference between the first and second series of experiments is only 0·3 of a candle, it may, with perfect safety, be said that, under the circumstances indicated, the gas is injured to the extent of 2 candles. The photometric observations were made with Mr. Methven's standard light, which I found admirably suited for experiments of this kind.

Allow me to return to the coal tar colours for a moment, as I wish to remove an absurd impression which prevails among some persons that all aniline dyes are poisonous, and contain arsenic. It is true that magenta, as prepared by Medlock's process, contains traces of arsenic, but only enough to do the slightest harm to any one wearing any article dyed with the colour. All the other dyes are perfectly free from arsenic, and Mr. Anthony Nesbit has fed rabbits for weeks together upon food containing most of the dyes I have mentioned to-night, and, strange to say, their general health, if one may judge from their appetite and condition, was not in the slightest degree impaired. It is true that some pigments—cited, in error, as dyes—like orpiment and emerald green, contain large quantities of arsenic. Orpiment should never be used, as it gradually fades, and the deplorable way in which Sir Joshua Reynolds's pictures have deteriorated is partly due to the use of orpiment and carmine; this last colour, although perfectly harmless, becoming grey in the course of time.

Future of Coal Tar.—Permit me, in conclusion, to say a few words on the Future of Coal Tar. It may confidently be said that some of the products of coal tar are useless. A well-known chemist, several years ago, in a work which in many respects showed great cleverness, was unwise enough to reproach chemists for the enormous labour which they had bestowed on what he called such worthless substances as aniline. He, however, lived to see it become one of the most valuable substances in existence. It is true that the lucoline and pyridine series have not as yet been utilized; but to doubt that they will one day yield valuable derivatives would be to neglect all the teachings of our glorious science. Nothing exists in vain, and the chemists who, for the sake of pure science, study the physical and chemical properties of new and as yet useless substances, are preparing the way for the practical man, who will one day be thankful to those pioneers who have smoothed the road, and made the advance into new realms comparatively easy. Although the lucoline series have not yet been utilized, I found a quantity of a century ago that its isomer, chinoline, by alternate treatment with iodide of methyl and oxide or sulphate of silver, yielded superb coloured reactions; and doubtless, by suitable processes, the lucoline series will be made to afford valuable products.

I found also that chinoline treated with iodide of amyl, and then with caustic alkalies, yielded the superb blue colouring matter cyanine. This colour, from its peculiar constitution, forms quite a new departure in organic chemistry, and recent researches show it to be closely allied to our subject; as, from the observations of Hofie and Dewar, there seems to be little doubt that chinoline at times, and perhaps often, accompanies or replaces benzoline in coal tar.

There are also many other substances which have not yet been utilized, among which I may mention the solid hydrocarbons chrysene, retene, and pyrene. It needs no prophetic eye to see that, with the substances already known, there is room for an absolutely endless number of new combinations; and the Future of Coal Tar will be far more brilliant than the Past or the Present.

To me, gentlemen, coal tar, though "black," is "comely," and if I have failed to impart to you some of my own enthusiasm for it, the fault lies with me, and not with the subject, which I feel is worthy of treatment by a master-hand.

PAPERS READ.

(I)

EXPERIMENTS ON THE THERMAL POWER OF GAS HEATING APPARATUS.

By Mr. T. Travers, of Cork.

In a paper which I had the privilege of reading before you two years since, your attention was called to the fact that gas cooking and heating stoves did not, as a rule, give the full thermal effect practically available from them. To us this is a matter of importance, as one of the points with which we have to contend is to demonstrate the economy of gaseous fuel. At present this can only be done when gas is consumed under the most favourable circumstances.

Manufacturers of gas cooking and heating apparatus are succeeding very well in making them attractive to the eye. Both in style and finish they are suitable to grace, in many instances, a well-furnished room; but to render them more popular, attention must be paid to the mode of developing the largest amount of heat from the smallest quantity of gas. What I purpose showing is that in the majority of instances this is not obtained, and it is desirable that additional pressure be put on the stove makers, so as to enable us to speak with more confidence to our consumers. As a kindred case in point, you are aware that some years ago gas burners then in use did not give the same amount of light per foot of gas as we now obtain. If the electric light did no other good than to rouse the burner makers to the sense of the injustice they were so long perpetrating on gas makers and gas consumers, by impeding the full development of the illuminating power, it has done good work. In like manner let us spur on the stove manufacturers to that which will certainly prove to be of mutual benefit.

In order to be able to recommend to the gas consumers of Cork the best and most economical apparatus, I made, during last year, some experiments, and from the results of them I think it will be seen that the apparatus in general use are capable of such improvements as will lead to better results. I am fully aware that the effect of any kind of fuel is much greater on theory than in practice. I have, therefore, made the experiments on a plain, practical method, such as may be applied to the doings of every-day life.

Intimately connected with this subject is that of the thermal power of gas of various qualities, and I commenced operations by making some tests under this head. I noticed that the results are not quite in accordance with some I have seen in the journals. The apparatus with which I operated was capable of carbonizing 30 cwt. of coal per day. I was, therefore, able to make a comparative calculation of the cost of the gas from coal of various qualities. The coal was Scotch cannel, Newcastle coal, and coal from South Wales. The points noted were—

The illuminating power.
The evaporating power of the gas.
The net cost of coal per 1000 feet of gas.

Coal.	Illuminating Power.	Water Evaporated.	Gas Consumed.
Cannel	240 candles ..	1 gallon ..	2040 cubic feet.
"	220 " ..	1 " ..	1975 "
"	206 " ..	1 " ..	2000 "
Newcastle	175 " ..	1 " ..	2000 "
"	185 " ..	1 " ..	2000 "
"	168 " ..	1 " ..	2020 "
Scotch, Wales	190 " ..	1 " ..	2000 "
Do. do. and 25 per cent. cannel	240 " ..	1 " ..	2250 "

Of course the thermal theoretical efficiency of the various descriptions of gas is far greater than the results which are given above.

On the average it will be found by the experiments that 16 lbs. of water were evaporated by 1 lb. of gas. Newcastle

(From "Engineering.")

Gas Illumination.

When illuminating by means of gas was introduced in our thoroughfares on a prescient scale about 18 months since it formed such a marked contrast to the ordinary methods of gas illumination, greatly distancing them in brilliancy, that it was not unnatural that it should appear to the unreflective public mind that the days of gas were practically numbered. The possibility of gas illumination for public thoroughfares being capable of improvement was the last thing to be realised by some, while others, to whom such a possibility did occur, greatly doubted the possibility on account of the great cost which they conceived anything like a substantial increase in light would involve. True, they knew what could be and what was being done in shops and private houses of which a good light is one aim, but they also knew what the luxury cost, and they inferred that the cost of a proportionately liberal display of gas in our streets would be simply prohibitory. And so it would if the gas were burnt upon the ridiculous and unscientific principles which have hitherto very largely obtained in private houses and other establishments, and which still do obtain to an almost incredible extent. That the deficiencies of our street illumination, however, are not due to the impossibility of obtaining a better light by the aid of gas except at a prohibitory cost was amply proved on a large scale in three instances during last year. Those were the special lighting of a portion of the Waterloo Bridge Road, of Waterloo Place and part of Regent Street, and Queen Victoria Street, a generous, but not extravagant display of gas being exhibited in each case. The immediate result of the experiments was to show most conclusively that in order to obtain a good light the conditions of illumination must be considerably modified and the cost somewhat increased but not to anything like the prohibitory extent imagined by some. All this we clearly pointed out at the time, and our facts and figures remain for reference. The practical outcome of these experimental displays has been the adoption in many parts of London and the suburbs, and in many of our provincial towns, of the methods of gas illumination then employed. These applications have not, however, been made indiscriminately. The improved burners have been judiciously distributed on refuges, in wide streets, and at the intersection of thoroughfares where the traffic is heavy. Their success continues, while their adoptions increases.

The reason why gas illumination in general is so inferior is largely due to the prevalence of motives of economy, which economy is, as a rule, a false one, owing to a prevalent ignorance of the correct principles upon which gas should be burned. It is almost universally assumed that if the gas is not "blazing," as it is called, with an ordinary bat-wing or fish-tail burner, or not issuing forth in red flames from the chimney of an Argand burner, all must be going on well. Never was a greater mistake, for without these palpable indications of waste the veriest extravagance may, and generally is, going on, and this from the absence of any controlling power over the pressure of the gas from the main, which science has of late demonstrated to be one of the first essentials of economy. Nor is it only the consumer who is ignorant on these points; many a gas fitter to whom he entrusts his interests is similarly uninformed. Were it not for his ignorance, the fitter might be suspected of playing into the hands of the gas companies, as the son of the gas-waiting-fittings he supplies to his and their customers. Nor should the action—or rather inaction—of the gas companies pass without notice here. They remain perfectly apathetic under the circumstances, and, although it is not compulsory that they should show their customers how to use in an economical manner the gas that they supply to them, they at least lay themselves open to suspicion when they knowingly allow users to waste it from sheer ignorance. That "they manage these things better in France" is perfectly true in this, as in some other respects, inasmuch as the Paris Gas Company have several depots in the city for the exhibition of such burners and other gas appliances as they can recommend their customers to use.

The company, we believe, are not traders in this respect; they are simply the exhibitors of other people's goods, but they exhibit nothing of which they do not approve. Gas users make their selection at the depot, and order either through their gasfitters or purchase for themselves at the stalls of such burners or other articles as they may require, knowing that they bear, more or less, the guarantee of the Paris Gas Company.

The exercise of a controlling power over gas during burning has formed one of the chief studies of gas engineers ever since the first practical introduction of gas lighting. And it moreover continues to do so, notwithstanding the great advances which have been made in gas lighting in recent times. The power of control is the key to the efficient and economical use of gas—that is, the production of a good light at a low cost; and this governing power largely underlies all the most substantial improvements that have been made in gas lighting. It was the satisfactory solution so far of this question which enabled the gas companies to show a bold front when the electric light threatened to invade their territories, and it is that which will materially assist them in meeting the invasion now that it has practically commenced. It is unquestionable that to the electric light and some of those means of improved gas illumination have been brought prominently before the public, while it is not less due to it that others have been developed into existence. It may therefore prove interesting in the present lecture if we point out the direction which improvement in gas lighting has taken, and the means whereby such improvement has been accomplished. To render this clear it is desirable that we should revert to the first principles and the early practice of gas lighting, and briefly describe the gradual stages of development through which gas burners have passed from their primary crude state to their present comparatively perfect condition.

Upon the introduction of coal gas as a means of artificial illumination the object of the inventors was to render it an efficient substitute for the oil lamps and candles which were the only practical means in general use for obtaining artificial light. They therefore imitated the flame of a candle by forcing a little gas from a stopped end of a small cylinder, through which gas issued under a slight pressure. On being lighted a flame resembling that of a candle was produced, and this kind of burner is known as the single jet or nat-tail burner. It is of little use in artificial lighting, and has long since become obsolete except for illuminating devices and cigar lighters. The imitation of the old Argand oil lamp flame was readily effected by adapting the burner itself. The top of the annular space where the wick came out was covered in with a flat metal ring perforated with a number of holes, the gas being admitted where the oil was previously supplied to the lamp. Many old oil lamps were in this way converted into gas lamps. It was, however, soon found that if gas were made to issue under pressure from a slit cut across the stopped end of a cylinder it produced a flat flame. This kind of burner, being much less complex than the argand, and not requiring a glass chimney, consequently came largely into use. This burner received the name of the "batwing," from the fancied resemblance of the shape of its flame to the expanded wing of a bat. It does not appear to have occurred to any of the early gas engineers that the loss of illuminating power in these gas burners was very great, in consequence of the over-oxidation of the flame through the velocity with which the gas issued from the orifice. Another kind of burner even more destructive to the illuminating power of gas of such a quality as usually supplied for public use was also invented at a very early period in the history of gas lighting. This is the fish tail burner, which is made by piercing two holes in a diagonal direction at about right angles to each other in the burner top. The jets of issuing gas impinge upon each other, and produce a broad sheet of flame. This burner still continues in use, and at the present time is more extensively adopted throughout Great Britain than, perhaps, any other, its scientific defects notwithstanding. It is, however, very rarely used on the Continent.

At the outset of gas lighting a rapid deterioration in the manufacture of burners arose in consequence of the manner in which gas was supplied to consumers. Before gas meters were invented gas was supplied by contract at so much per light per quarter, and it was important to gas companies that consumers should not use more gas than they paid for. They therefore got their orifices or burners to use burners having very small—about one-hundredth part of an inch in diameter—so that the gas issuing from the burner was propelled with extreme velocity into the atmosphere. Thus it could not remain long in contact with the oxygen of the atmosphere to become thoroughly incandescent. It developed a greater amount of heat than it did of light. The difference between the method of burning gas adopted before the introduction of meters and the present method of burning gas by means of the best kinds of modern burners is very striking. With the old argand and fish tail burners the gas issued from the small holes at the point of ignition with a velocity of from 60 to 90 miles per hour. With the best known modern burner—Sugg's London argand—the gas issues from the holes with a velocity of only a little over one mile per hour. This forcibly illustrates the necessity for the governing power to which we have before alluded. It is a singular fact that the highest results in illuminating power are attained when the gas issues from the burner with the lowest velocity. The discovery was made by Sugg, in 1858, previously to which, however, several inventions were patented for reducing the velocity of the issuing gas, but these were mainly in connection with fish tail burners, and the inventors do not appear to have realized the fact that they were raising the illuminating power of the gas, or if they did, they did not proclaim it. The reduction of velocity attained in my case, however, was but small, and the most notable of these inventions were those of Belmer and of Desrioth. Both inventors adopt similar means for effecting their purposes, which consist in placing under the burner a small cylindrical chamber, through which the gas passes on its way to the burners, which has a much larger orifice than that through which the gas passes from the little chamber. The lower orifice admits the gas at a high velocity, and it issues at a reduced rate of speed from the burner, the speed varying with the kind of burner employed.

Notwithstanding the efforts of gas engineers and others to substitute economical for wasteful burners, there are a great number of burners in use at the present day which destroy the latent illuminating power of the gas consumed to the extent of from 20 to 50 per cent. In fact, there are burners in the market which are said to be both durable and economical, but which sadly lack the latter quality. For a consumption of five cubic feet of London gas per hour they should give 16 candles' illuminating power, whereas careful experiment has shown that they only give six candles for that quantity. In further respect to the Board of Trade, dated January, 1870, the Gas Referees state that the result of an examination of a large number of burners in use was the discovery that in London alone an annual saving of at least £250,000 might be effected by the use of good burners. But the possibility of using gas for lighting purposes by means of the crudest apparatus, combined with the ignorance and apathy of the public, still leads to its wasteful and unscientific abuse. Read by the light of the £250,000 wasted in gas in London alone each year, the indifference of the gas companies, too, can be understood, and they may perhaps be pardoned for not interfering in a matter which, commercially speaking, it should be no business of theirs to see sic right. The advent of the electric light, however, has roused them into action, and the immediate results were the examples of improved gas lighting to which we have already referred.

[To be continued.]

Société Technique de l'Industrie du Gaz en France.—The annual congress of the above Society will be opened in Paris on Monday next, and will probably extend over two or three days. The number of members who will be present is expected to be unusually large, and the nature of the communications submitted, before the body at the meetings, even this year will be a particularly interesting one. It is highly probable that permission will be granted by the Paris Gas Company for the members of the Society to visit the new works now in course of erection at Clichy, and if this should be the case, we feel sure that all who avail themselves of it will derive much gratification therefrom.

London: Printed by Watkin King (in the office of Clowes & Co., 17, Beaufort Street). First Growth, and published by him at No. 11, Bolt Court, Fleet Street, in the City of London.—Tuesday, June 13, 1871.

not until they had generator furnaces. Then they had to get water-jackets, and tried several things, and were now putting up a little different arrangement. With regard to the compensating holder for reducing oscillation, the retorts they lighted up last year had not shown the slightest appearance of carbon on them, and had not been scurfed once. This was a different experience from that of Mr. Mitchell, and he could not understand how it was that that gentleman still had the same amount of carbon on his retorts after the oscillation was reduced. Mr. Morton said, "Would not the gas in the holder come in contact with the tar?" but he (Mr. Somerville) must remind him that it made all the difference what the specific gravity of the tar was. It did not matter about the tar of light specific gravity coming in contact with the gas. At the same time the tar in the holder was partly covered over with liquor which was nearly of the same specific gravity as the tar.

The PRESIDENT said it was very evident that the plan that had been described to them was a step in the right direction; but it was also apparent that more remained to be done. It had been pointed out by one speaker that what they had to aim at was to establish contact with the gas and tar under certain conditions of temperature, but also—which was of no small importance—to determine when this contact should cease, and to separate the heavier portions of the tar as soon as possible. This latter was partially effected by Mr. Livesey's arrangement, as proved by the specific gravity of the tar drawn from the first receiving main; but it was evident that the process required to be carried a little further. Mr. Morton had pointed out the undesirability of contact as promoted in the balanced gasholder, when the tar was comparatively cool. Mr. Somerville had answered this by saying that contact with tar of such light specific gravity would not injure the gas. He (the President) thought, however, that the question must naturally arise, how was this tar made? Was it not by union of the heavy particles carried forward with the lighter naphthas, the presence of which, could it be secured, would materially enrich the gas? Their aim should be to promote the separation, at as high a temperature as possible, of as much as practicable of the heavy carbon particles of the tar. To a certain extent this was done by the arrangement before the meeting, but more remained to be effected.

(IX.)

STANDARDS FOR ESTIMATING ILLUMINATING POWER.

By Mr. F. W. HARTLEY, A.I.C.E., of London.

The subject to which I request your attention on this occasion is an old one, but one which is of as much importance and interest now as it ever was; indeed, it may be said to be now of greater importance than in the distant past, inasmuch as testings for illuminating power are more general throughout the kingdom, are made in a more stringent and more refined manner, and, if statutory obligations are not met, entail penalties, dissatisfaction among consumers, and bickerings between gas companies and corporate bodies; causing discomfort to directors, and more especially, perhaps, to their engineers and managers.

That the method by which the illuminating power of coal gas is ascertained should possess, as far as is possible, the characteristics of accuracy and of constancy in indication of values, no one will dispute, and that such should be the case is of the highest importance to gas companies, for as long as the method pursued is one which is liable to fluctuations, which sometimes cause the value of the gas to be underestimated, and on occasions to be over-estimated, so long it will continue to be a necessity for companies to make gas of 1 or 1¼-candles greater illuminating power than mere legal obligation requires. This necessity in many instances involves the use of a considerable percentage of cannel coal, which might probably be dispensed with if the tests were made under conditions of a more certain and absolute nature.

I do not wish it to be supposed for a moment that I am an advocate for the reduction of the illuminating power of coal gas to the lowest statutory limit in any case; for companies best serve their own interests as well as those of the public by supplying gas of the highest quality which is consistent with possibilities and the rights of the shareholders. It is usual to do so now; but this is very different from being compelled to supply gas of superior quality in order to overcome and neutralize the evils which might arise under the present uncertain state of matters.

The estimation of illuminating power can only, in my belief, be satisfactorily arrived at by visual, or photometric comparisons between the light of flames, one of which is adopted as a standard. Upon this point, Mr. Vernon Harcourt observed in a paper "On a New Unit of Light for Photometry," which he read before the Physical and Chemical Sections of the British Association in 1877, "that since the value of an illuminant depends solely upon such parts of the total force radiating from a flame as affect the human eye, no test of illuminating power can be satisfactory which does not depend upon vision; at least until it has been proved that some other effect of radiation . . . is for all flames in direct proportion to the effect upon the optic nerve—a relation which seems very improbable, and which cannot be established until some exact mode of measuring the visual effect has first been found."

At the time when the foregoing extract was read, the radiometer was still attracting a good deal of attention, and some scientific men, accepting too readily the theory that with this instrument light was the sole operating force, jumped rather hastily to the conclusion that the radiometer was capable of being used for estimating illuminating power. As, however, the instruments were made more delicately, and especially as their chambers were more perfectly exhausted by the aid of the most improved form of the Sprengel pump, it became manifest that heat rays operated as powerfully as light rays in producing the rotation of the vanes. I have a radiometer which is so sensitive to heat rays that its vanes will revolve with considerable speed if the hands are placed round, but at an inch distance from the instrument. This rotation has been produced by the warmth from the hands, even when they have felt cold if applied to the face.

The selenium photometer also excited the attention of scientists for a time, but all interest in it seems to have died out. With this instrument an electrical current of regulated strength was caused to pass through a piece of crystallized selenium, which was shielded from light in a closed box. The current then traversed a reflecting galvanometer, which was so adjusted that under the conditions specified the spot of light produced by the reflection of a ray from a burner fell upon the zero of the scale. The box was then opened, and the selenium exposed for ten seconds to rays of light, which caused a diminution of the resistance offered by the selenium to the electric force and consequent motion of the galvanometer. The extent of motion or throw of the galvanometer appeared to be inversely proportionate to the distance of the source of light, or as the square root of the illuminating power, and therefore analogous to the indications of an ordinary photometer. This was a very interesting instrument, as it served for one thing to show that crystallized selenium was an exception to the well-known law of electrical science, that the power of an electrical conductor diminishes as its temperature increases.

The jet photometer and the dumbility test are both admirable instruments by which, with due care in using, to obtain approximate indications of illuminating power; but both fail, it appears to me, to satisfy the conditions which are essential in a standard test. Some reasons why they must so fail will be found in my observations on the jet photometer in the paper entitled "Remarks on Photometry" which I had the honour to read before the Association in 1870.

The visual determination of the relations in strength of light from flames which are contrasted with each other seems, then, to be the only method which can at present be deemed satisfactory, and in order that results may be expressed in terms which may be generally understood, a standard is required. As you are all aware, the sperm candle burning (nominally) at the rate of 120 grains of sperm per hour has long been, and is now, the photometric standard in this country as well as in some others. This standard has been tolerably well denounced, and, to a certain extent, deservedly so, for it is uncertain in value, as the light it affords varies greatly under conditions which appear identical, and with the slightest disturbance of the surrounding atmosphere, while its lighting power bears no known ratio to the rate at which the sperm is consumed. Nevertheless, and with full experience on the matter, I have spoken and written in favour of the sperm candle as a standard; and although I shall presently bring something under your notice which appears to be greatly superior, I am not prepared to propose the immediate abolition of the candle standard. It will be needful to retain the candle for some time, certainly until scientific men and Parliament are satisfied as to the constancy and convenience of any proposed substitute. The candle standard is a troublesome one, because, unless candles are tried, examined, and the imperfectly burning ones rejected, grave discrepancies may arise. Even when all these things have been done, the results obtained from one pair are not to

by the lime in granular aggregates from the gas purifier, but there still remains enough unchanged lime capable, under the influence of water, of absorbing carbonic acid from the air equal in amount to that first performed. This is Mr. Harrie's process.

By far the second quantity of work out of its lime, Mr. Harrie proceeds as follows:—The spent lime is taken from the purifiers, and is thoroughly air-dried through it, which in turn is made to traverse an order of iron purifiers, as it is found necessary to remove the sulphuretted hydrogen, which would otherwise in time impair the purifying quality of the lime if left in it. The lime is then removed from the purifying vessels, and is ground to a fine powder, and is then passed over sieves by revolvers with shovels, and then returned to the purifying vessels, where it is again exposed to the action of the gas. This exposure of the partially saturated lime to air destroys the lime and results in their conversion into carbonate of lime, and the sulphuretted hydrogen interfere the portion of lime still in the condition of hydrate, and which is capable of absorbing carbonic acid from the gas, is of this purified manner. The process, however, does not in any way affect the sulphur in the lime, which remains in the same state entirely differs from his process of exposing cakes of lime to air. A process as a cleaning and inert compounds of the whole. The partially exhausted lime, after the sulphuretted hydrogen has been removed from it, is finally exhausted, and is removed as waste.

Some experiments have been made on lime which is only partially spent, but which has been exposed to the air for a long time, in the purifiers of gas-works. The condition of my process is that in which it is returned to the purifiers, and not that in which it is removed from the purifiers. Lime which has the presence of free sulphur has not been experimented upon by me, but I have no doubt that a process could be devised for extracting the sulphur from the lime, and for thereby increasing its value per cent. There is also a large quantity of calcium hydrate in the lime which is spent, and which is not carbonated. The subject has been to devise a ready and efficient method of determining this quantity. I have found that the ordinary means of calculating its purifying capacity when it is again returned to the purifiers.

The surprising soluble character of calcium hydrate prevents the ordinary method of ascertaining the purifying capacity of the spent lime. The process I have devised for my present purpose is as follows:—A weighed quantity of the spent lime is put into a flask, with a weighed quantity of the lime. The calcium hydrate furnishes a precipitate of hydrate of copper, the carbonic acid and sulphuretted hydrogen having no effect upon it. Knowing how much copper salt was first added, and then determining the amount of copper left in solution, I am able to calculate how much of the two represents the amount of copper thrown out of the solution by the calcium hydrate. I then calculate how much copper hydrate in terms of calcium hydrate is the amount of calcium hydrate in the quantity operated on. I have practically found that 100 grains of spent lime, as it comes from the purifiers, will require 100 grains of copper salt (between 30 and 40 grains) was placed in a 100 cubic centimetre flask, and water added to the measuring line. The whole was allowed to stand for a few hours with occasional agitation, and then withdrawn by means of a pipette placed in a suitable cylindrical vessel, and some of the standard cupric chloride solution run in until the same depth of blue, white surface, was obtained. Ascertaining how much of the cupric chloride solution is equal to that present in 10 c.c.

Calcium carbonate. Free sulphur.
" hypersulphite. Naphthalines.
" sulphate.

Calcium carbonate is, of course, the most abundant constituent. Free sulphur is often found in spent lime, and does all that is possible under ordinary conditions. Sulphur is present in at most three forms, the total amount of the

cent. The difference represents a very appreciable value, as will be seen when we look at the total manufacture.

Reverting again to the beginning of the decennial, we find the total quantity of gas sold by the London companies was 8,895,807 thousands of cubic feet. The quantity made we are not told. Last year the gas sold was 17,324,000 thousands of cubic feet, showing that in about a couple of years more the consumption of 1870 will be doubled. The quantity of gas supplied to the metropolis is immense, amounting to about 4500 cubic feet per head of the population per annum, equivalent to nearly half a ton of coal. This represents an average of rather more than twelve cubic feet of gas per head per day. We are here travelling out of the bounds of Mr. Field's admirable "Analysis," though working on a basis which he has given us. We thus find that the light of nearly forty candles is available for each individual for the space of an hour. As a certain portion gas for heating purposes, we must make some deduction in order to get at the amount of illumination; but we may at least reckon the light as that of thirty candles for one-hour, or half a dozen candles for five hours. On the whole London ought to be pretty well lit, but there is a demand for more light, and either by means of gas or electricity the demand will have to be met.

The rapid increase in the consumption of gas in the metropolis is shown if we compare the figures given by Mr. Field with those of the population tables. Thus the population of London at the census of 1871 was 3,254,260, the middle of last year the estimated population was 3,620,968. The gas sold in 1871 was 11,316,914 thousands, whereas last year it was 17,324,000 thousands. Accordingly, we see the population increasing by little more than ninth, while the consumption of gas rises more than a fifth. The gas rental of 1871 was £2,104,863. Last year it was £3,001,263. The head of the metropolitan population there is a much larger consumption of gas than there was eight years ago. There is no doubt that the reduction in the price of gas has greatly promoted its use, and the companies may take encouragement from the fact. Comparing 1870 with its immediate predecessor, we find an increased consumption of gas to the extent of 1,341,132 thousands of cubic feet. This is obviously a much higher ratio than the increase of population, the growth of the latter being little more than 1·75 per cent., which would only account for an addition of 244,692 thousands of cubic feet to the quantity of gas. The increase in the sale of gas is in a ratio fully five times that in which the population increases. The companies, therefore, have no great reason to feel alarmed at the approach of the electric light.

By the sale of residuals last year the companies realised £789,023. The year before this source of revenue brought in £746,115. In 1869 the residuals realised no more than £573,053. The gross profit of that year was £746,987, whereas last year it was £1,166,104. The economy effected by consolidation is strikingly shown in the case of the Chartered Company. In 1869 the expenses of management in respect of this company amounted to 19·82 pence per ton of coals, and 2·21 pence per thousand feet of gas. Last year, the Chartered Company having previously absorbed the greater part of the gas undertakings of the metropolis, the expenses of management were only 10·64 pence per ton, and 1·12 pence per thousand feet. Among the exceptional items of the year we notice an item of £1785 by the Chartered Companies for "experiments street and electric lighting."

The coals carbonised last year were 7 per cent. cannel, and the average cost was 15s. 1·45d. per ton. In 1869, when cannel gas was more extensively used than now, the proportion of cannel coal was 12 per cent., and the average cost of the entire quantity, Newcastle and cannel, was 16s. 2·75d. In last year's accounts, deducting the receipts for residual products from the cost of the coals, the net cost appears as £624,603, being at the rate of 6s. 9·15d. per ton, and 9·74d. per 1000ft. of gas sold. In 1869, the net cost of coal was £581,955, or 9s. 11·21d. per ton, and 14·13d. per 1000ft. Deducting working expenses and the net cost of coal from the gas rental, and also deducting the expenses of lighting and repairing the public lamps, the profit on gas last year appears as £1,167,960, or rather less than 13s. 6d. per ton of coal, being a fraction under 1s. 4d. per 1000ft. In 1869 these two latter amounts were respectively 12s. 7·47d. and 18·66d., the entire profit on gas being £768,710. The actual net profit of the metropolitan gas supply last year was £1,031,531. Of this amount the standard dividends took £937,189, and the additional dividends £37,081, leaving a surplus of £97,261. The net profit on stock and share capital raised was 9·73 per cent., the standard dividend being 8·60 per cent. The total reserve fund and balance on net revenue account, after providing for dividend, was £693,792, in addition to £248,207 for insurances and other funds. In 1869 the whole of the reserve funds only amounted to £129,187, and the insurance or contingency fund to £43,003.

THE ENGINEER.

JULY 2, 1880.

PROGRESS OF THE LONDON GAS SUPPLY.

In 1869 London had thirteen gas companies, employing an aggregate capital of £7,888,844, and carbonising 1,171,598 tons of coal in the year. The number of the companies has now fallen to four. At the commencement of last year the number was six. Mr. Field's annual "Analysis of the Metropolitan Gas Companies' Accounts" is shrinking rapidly in its array of figures, but continues to grow in its totals. The slender but skilfully compiled book just published shows that the capital employed last year was £12,681,818, and the quantity of coal carbonised 1,602,847 tons. The coal employed in 1869 was at the rate of 20·12s. 6d. per ton, whereas in 1879 it was 2s. higher. The quantity of gas sold was 10s. 10d. in 1869, whereas last year it was 14s. 6d., thus showing a reduction. The gas sold per ton of coal carbonised was 8438 cubic feet at the commencement of the decennial, but has now risen to 9431. This saving of very nearly 1000 cubic feet per ton of coals represents no enormous gain, though perhaps a little drawback in respect to residuals. But some portion of the improvement is due to diminished waste. What this amounted to in 1869 does not appear. The first year in which Mr. Field calculated the amount of waste was in 1874, when gas "unaccounted for" appeared as 6·76 per cent. on the make. Last year it was 5·38 per

Dublin possessed in the Vartry scheme that which was undoubtedly the finest and best possible water for any undertaking anywhere in the world. The Vartry water supply in the very face of the Rathmines and Rathgar scheme, which, as he understood, there was no engineering difficulties, nor any of any other kind that had been mentioned, that should prevent the Rathmines and Rathgar township from participating in the Dublin supply. But there was a fear on the part of the township that if they obtained a supply of Rathmines water from Dublin the project of amalgamating the Rathmines and Rathgar township and the extra-mural portion of the city of Dublin would be facilitated, and that consequence would be very much to the advantage of the city of Dublin, but not to that of the township of Rathmines and Rathgar. He had no right to remind the House that there was at present, and had been for some years, a Commission sitting in Dublin to inquire into the question of re-adjusting the relations of the city of Dublin with the surrounding districts. This Commission was about to present its report, and it was understood that it had no doubt it would recommend that all the districts which should be amalgamated would be brought in, and they might avoid the difficulty complained of in the City of London, and which had prevented the carrying out of the great principle of local self-government. This, as far as he understood it, was the only objection that had been urged by the Commissioners had to obtaining their water supply from Dublin. Undoubtedly, if this scheme were carried out, the great inequality in the rating of the boroughs of Rathmines and Dublin would be remedied, and Rathmines would undoubtedly have to pay somewhat more, and Dublin somewhat lower, and the grievance of which they would be deprived. He had no right to refer to the negotiations of the water supply in Rathmines, he might mention that the Government supplied the barracks in the midst of the Rathmines and Rathgar township with the Vartry water at a cost of £500 a year. Every penny of this amount would have to be contributed by Dublin, and this would mean raising the Dublin taxes. Then with reference to the rate at which the Corporation of Dublin supplied, there would be no difficulty, because the Corporation were willing to leave that question to be decided by arbitration.

Mr. Very Lea supported the second reading of the Bill, and thought it was only necessary, depending on the part of the honourable member for Dublin to first interfere with a matter that had already been before the ratepayers, and had been fully discussed by them, with the result that out of 3000 ratepayers, only 12 expressed their dissatisfaction at the scheme. Mr. Pim Fletcher) was a ratepayer in Rathmines, and had every confidence that the Commissioners would carry out the scheme in a fair way. In 1871 that the Commissioners excluded the ratepayers of all the districts which did not pay any rate would be entitled to take water from the Vartry, unless the present time they were asking to rescind that Act. In 1875 they entered into negotiations with the Commissioners of Rathmines for the purpose of supplying the township with water, and after the Dublin Corporation decided they were requisitioned by certain members of the Corporation, and the agreement was not carried out. It was quite impossible for the Government they could go into the merits of the question on the preliminary moment they could go into the merits of the question on the preliminary moment of the House of Lords. There was no question of surplus in regard to the Bill, as all the facts brought forward by the honourable member for Dublin had been fully stated before the Lords Committee, and he (Mr. Pim) did not consider that to be a most unusual and improper attempt to throw out a Bill.

Mr. Dowsing said he did not propose to go into the merits of the case, but it appeared to him that the Bill which had received the sanction of the House of Commons and the House of Lords for seven days, when there was another scheme brought forward in opposition to it, which scheme, however, was unsuccessful. He could only remind the House that it was a very unusual course to oppose a Bill on the second reading except in such circumstances as these, and the fact of its having received a unanimous vote in the House of Lords was a strong reason why a Bill that time never be thrown out on the second reading. Such circumstances ought to be given to it by the Committee, before the House committed itself to the course of throwing it out. It seemed to him that the fact that the Bill should have been so thoroughly discussed was a reason why it should go to a Select Committee, and should not be disposed of in the summary way suggested by the honourable member for Dublin.

Mr. Lewis supported the second reading of the Bill. The honourable member for Dublin, he said, seemed to have forgotten that he had had the opportunity of pressing his objections on the House of Lords Committee, and this being the case he (Mr. Lewis) considered the objection almost was one that was very inconvenient to the House. Upon the second reading of a Bill—a preceding that was very rare—and one which, in the honourable member, he could not but think was a most unwise course. He was quite aware that the Bill had been before the House of Lords, also had had the Bill before them, and had conducted an investigation extending over several days. If this practice were adopted generally, the system of conducting private Bills through the House would become most inconvenient. If the honourable member thought he had a case, let him go before a Committee and state his objections to it. He would remind the opponents of the Bill were to state their objections to it.

Lord RANDOLPH CHURCHILL said that having had some acquaintance with the Water Supply of Dublin, he should support the honourable member in his motion for the rejection of the Bill. He had undertaken a very strong opinion that the Bill ought to be thrown out. The right honourable Mr. Balfour) had said that the Bill was before a Committee of the House for seven days several nothing but this—viz., the immense inconvenience of local local business being considered by Committees who had no practical acquaintance with the facts of the case. The facts were that the sanitary state of Dublin was about as bad as it could be, and that the United Kingdom, and various attempts had been made by the Corporation to remedy this state of affairs, but all of them with one thing which was decidedly needed in Dublin it was the supply of water, which might be said to be equal in quality to that of New York. The water-works were constructed at an immense cost about 30 or 40 years ago, but he believed constructed at an immense cost about 30 or 40 years ago, but he believed he was correct in saying that the mains passed through Rathmines and Rathgar. It was now proposed that the Rathmines people to have no authority whatever to supply water from another source, but to obtain their supply of water from the public work carried out by the Dublin Corporation seven years ago. But in no case could Rathmines obtain a better supply of water. The water which the Corporation offered to supply at a reasonable rate passed through Rathmines, and it was a strange thing that it was a case where the House of Commons should put its foot down and refuse to allow the Dublin Corporation to act in such a big-hearted manner.

The ATTORNEY-GENERAL for IRELAND thought that the course proposed by the honourable member for Dublin was exceedingly inconvenient. He could only repeat what had been said before—viz., that not only had the matter been thoroughly investigated by a Committee of the House of Lords, but it was also the subject of discussion by a most influential body the Rathmines Commissioners should not be permitted to supply themselves with water as they did with other necessaries. He had no wish to say against the protection of the supply of water to Dublin. Everybody said it was excellent, but this was no reason why Rathmines should not also obtain an excellent supply of water. There was no reason why the Dublin Corporation should have the privilege of selling water to the Rathmines Commissioners if the latter thought they could get better water elsewhere. In 1871 the Dublin Corporation expressly excluded the Rathmines Commissioners from their district, and they finished the people of the districts from coming and taking water, and therefore a claim of right was now made by Rathmines that no one excluded from the scheme of 1871 should be entitled to obtain water for themselves. He, therefore, thought that, on all grounds, to throw the present Bill out would be a very strong and unjustifiable proceeding.

Mr. A. M. SULLIVAN thought that the House should very carefully interfere with the passage of a private Bill in Committee, especially when the most exceptional circumstances existed such as a second reading. He knew very well, and pointed out that the honourable gentleman had reported that the so-called city of Dublin had formerly become so enlarged as to include a lot of districts, including that had grown up around the old Municipality of Dublin, and he would be most unwelcome if they allowed a number of these small, independent schemes for the supply of water to spring up, instead of having them all under one complete and central system of water supply. The noble lord (Lord R. Churchill), who was himself born with Dublin, was also personally acquainted with the Vartry water which was the finest he had ever tasted. The House would undoubtedly have cause to the future schemes of water supply which would constitute a group of petty districts, if it were allowed to pass. It was hoped the Bill would put a fork in it, and it was allowed to pass. It was hoped the Bill would put a fork in it, and it was allowed to pass. It was hoped the Bill would put a fork in it, and it was

TO CORRESPONDENTS.

T. W.—Thanks for information received. Must defer notice till next week.

H. V.—American newspaper accounts, such as that you send, are generally so "padded" with untruths and exaggerations as to make it impossible to rely upon them. We prefer, however, much more than you suppose, to be entirely guided by facts.

Secretary.—Paper on "Tarbrush" on Gas its Faults.—We have received the report, just published, of the meeting of the Society, held at Lille, on the 26th of June last year. It contains much of great interest to the gas profession, and we shall take early opportunity of referring, in detail, to many of the subjects presented to, and discussed at the meeting.

No notice can be taken of anonymous communications. Whatever is intended for insertion must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of good faith.

TO SUBSCRIBERS.

Subscribers who desire to avail themselves of the reduction in the subscription to the JOURNAL by paying in advance for the second half of the year 1880, are reminded that this can only be done during the present month.

Subscribers who have not paid their subscriptions for this, or for any previous year, are requested to remit the same forthwith to the Publisher, in order to prevent any interruption in the regular delivery of the JOURNAL.

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, JULY 13, 1880.

Circular to Gas Companies.

The disastrous explosion which took place in the neighbourhood of Tottenham Court Road on the evening of Monday, the 5th inst., with its sad results in the destruction of life and property, is of absorbing interest to the whole of the gas world. A full and exhaustive inquiry into the cause of the accident, and into all the circumstances attending it, will doubtless be held promptly; and we shall therefore confine ourselves this week, as far as possible, to a statement of the facts so far as they are known to us, reserving comment till we have heard the evidence which will be forthcoming.

It was a singular coincidence that at the time we were going to press with our last "Circular," containing as it did some remarks upon the liabilities of Gas Companies for damage caused by escapes of gas from street-mains, this unexampled illustration of the gravity of those responsibilities should have been just happening. Although this disaster is almost—and, in its terrible extent, quite—unexampled, yet it is of a class which is generally appreciated by gas engineers, and the avoidance of such accidents in the past is a tribute to the care with which their work has been done and its contingencies provided for. Continually, both in the streets and on the works, it is necessary to shut off lengths of working mains, and cut out portions, in order to make connections. It is impossible to completely exhaust the gas from the sections thus made dead, and a mixture with atmospheric air within the explosive limit is the result while the work is being done. In such cases not only would the application of a light to an open pipe, as in the recent accident, before valves have been opened or bags withdrawn, cause an explosion, but the same effect would be produced by the using of overheated lead in the running of a joint, inflaming the yarn used in caulking. These are dangers which have been known to exist, and we repeat that the avoidance of harm from them says much for the care and watchfulness of those engaged in such work. The accident of last week resulted not from want of knowledge as to how to deal with dangerous conditions, but from absolute ignorance of the existence and presence of such conditions at the time.

The facts are, we believe, as follows:—The Chartered Gas Company have been making preparations this spring for supplementing the supply in their western and west central districts, by a direct connection with the main from their Beckton works. This was to be effected by laying a 36-inch pipe from Goswell Road, where it would be joined on to, and obtain its supply from the 48-inch (Beckton) main, through Bloomsbury to a point in Howland Street, a little westward of Tottenham Court Road. There it connected an existing 36-inch pipe, which, we presume, is at present the principal supply main in that neighbourhood from the western stations of the Company. The total length of this connecting-link main was rather over two miles. For the purpose probably of expediting the work, it was laid in two sections by separate gangs of men, but both in the employment of the same contractors. One of these sections extended from Goswell Road to the east side of Tottenham Court Road in Bayley Street; the other, that in which the explosion took place, from Howland Street, down Charlotte Street, through Percy Street, and across Tottenham Court Road, to meet the first section. Our readers unacquainted with the district will be helped in following the direction of this main by reference to the sketch which we give elsewhere; and we will, if possible, furnish a more detailed plan with our next issue. The eastern section, that from Goswell Road, is about a mile and a half long; the other rather less than half a mile. Early in March last, the working main in Howland Street was cut, and a T-branch put in, the outlet looking down Charlotte Street. On to this outlet, which was flanged for the purpose, was bolted a 36-inch valve, made by Messrs. Westwood and Wrights. A few lengths of pipe were then laid from the valve, so as to carry the excavation clear of Howland Street, and avoid again interfering with its traffic, and the short length so laid was capped up and left. The laying of the main itself was then commenced from the Tottenham Court Road, under which thoroughfare it was carried at a depth, we believe, of about nine feet, so as to clear the pipes already in position, and also a pneumatic tube used by the Post Office authorities. By about the middle of May the laying of this section was completed, and a connection was then made on to the short length already referred to, so opening up the whole main to the valve which severed it from that which was charged with gas. When this connection was made it is said that the air in the short length was pure, showing no sign of the presence of gas, thus confirming the Company's Chief Inspector in his confidence in the soundness of the valve. It will thus be seen that for nearly two months this section had been finished; it was capped up at its eastern end, the paving of the streets was made good, and no doubt was entertained that the valve which had shut out the gas from the short length would do so equally securely from the longer one. Meantime the section from Goswell Road was being laid, and a few days before the accident it was completed ready for connecting. No junction had been made with a live main in this case, and when the work was tested the length was closed at each end by a cap. If we are rightly informed that a pressure of over twenty inches was put within this main, and that it was maintained for twenty-four hours with no appreciable loss, there could be no better testimony to the care and accuracy with which the work had been carr' d out. The western section was tested on the day of the accident by pumping air into it through a two-inch pipe at the Bayley Street end. We have not heard what the result was, but we assume that it was satisfactory, because the two lengths were to be joined on the following day. This is a question of much importance, as we shall point out further on.

Parliamentary Intelligence.

[From the "London Journal of Gas Lighting."]

Seventeenth Annual Meeting of the British Association of Gas Managers.

INAUGURAL ADDRESS OF THE ACTING PRESIDENT, CHARLES HUNT, ESQ., OF BIRMINGHAM.—DIFFERED THROUGH ILLNESS FROM A YEAR AGO.

Gentlemen:—The circumstances under which I have to ask for more than the usual measure of that indulgence and support which have been so freely accorded to every former occupier of this chair are fully known to you. It has unfortunately happened that the President of your choice has been compelled by persistent ill health, in the midst of his term of office, to retire into your hands the dignity conferred upon him. Our regret at the necessity for such a step remains profound; and I am sure that you will wish me to convey thus publicly to Mr. Douglass the assurance of your sympathy, and of your earnest wishes for his speedy and complete recovery and future prosperity.

As you are doubtless also aware, our esteemed Secretary, Mr. Bennett, has during the last few months been laid prostrate by a serious illness, from which he is happily to a considerable extent restored. While congratulating him upon his recovery thus far, we have it in our power to testify, in the most practical manner possible, to our regard for one to whose exertions the Association is so greatly indebted, by assisting in the work of this meeting when assistance would be of service, and by the exercise of as much forbearance as possible during the continuance of it.

During the past year we, as an Association, have lost through death five of our number. These are—Mr. George Berry, formerly and for many years Manager of the Ashford Gas Works, in Kent; Mr. A. F. Livesay, formerly part proprietor of and otherwise officially connected with the Ventnor Gas Works, Isle of Wight; Mr. R. W. Brothers, late Manager of the Chorley Gas Works; Mr. H. S. Pierson, formerly Inspector of Mains, in the service of the Chartered Gas Company; and Mr. Claudio Gil, of the Gas Works, Barcelona; all of them most worthy representatives of the profession to which they belonged.

It is fitting here to record also the death of one who, although not a member of the Association, yet took a warm interest in its welfare, as in everything connected with the gas industry. It was only last year that we had to lament the loss of the familiar reporter of our proceedings, and now the keen yet kindly critic has gone from among us. Mr. T. W. Fewtrell, F.C.S., whose death we now deplore, took for several years an active part in the management of the *Journal of Gas Lighting*, succeeding, in a great measure, the late Mr. T. G. Barlow. His intimate knowledge of chemistry rendered his criticisms upon the subject of gas manufacture of especial value; although his name will probably be held in remembrance chiefly as co-editor of Mr. Newbigging of "King's Treatise on Coal Gas," the most valuable and comprehensive work of the kind yet attempted.

If the present total number of members be compared with that for the year 1870, when it was 314, it will be seen that the Association has constantly more than doubled during the past ten years, proving it to be possessed of an amount of vitality greatly in excess even of that with which the manufacture of gas is ordinarily credited. Nor will it be found upon examination that its augmented membership suffers in comparison with this great accession to its numbers. Year after year fresh fields for investigation have been opened up, new problems have been presented for solution, until there is hardly a detail, intimate or remote, of the complex art of gas manufacture that has not been made the subject of free, exhaustive, and instructive criticism. Our discussions have made of individual knowledge common stock; our published transactions will be found to be a faithful relief of, almost without exception, the most advanced opinions upon all technical matters relating to gas.

These annual gatherings afford to the gas manager more and more favorable opportunities for throwing off that crust of isolation by which he is apt to be enveloped, and for freeing himself of crudities that are so often engendered by a life of comparative self-dependence. It is not necessary that his voice should have been heard at those meetings; he may have been a mute participator in our proceedings; yet if he has not returned to his work improved by contact with his professional brethren, quickened in his desire to do the best that he can both in and for his calling, he will have proved himself to be insensible to one of the most powerful appeals that could be addressed to him. Such, in brief, has been the work of the Association, and such may it long continue to be.

My object, however, in thus referring to it is not one of laudation merely; there is, as may be readily imagined, a reverse side to this pleasing picture, which I conceive it to be equally my duty to place before you. Some there are among us who do not feel entire satisfaction at the past career of the Association, and who desire to mould its future more in accordance with their views of an enlarged sphere of usefulness. With these it is impossible not to feel a certain amount of sympathy. There can be but few who, looking back along the road they have traveled, have not to recall some opportunities disregarded, some aspirations unfulfilled. As with the individual, so it may also be with the Association.

It is objected that its aims have been metropolitan rather than cosmopolitan; its actions mechanical rather than progressive. Toward the satisfying of a grievous feeling on the part of members for more frequent opportunities of discussing matters of immediate importance, it has made no effort; and hence the formation of district associations; of sections, bound to it indeed by the strongest ties of sympathy, but owing to it no other allegiance than that which is secured to it by the force of superior numbers, position, and influence. In the conduct of its affairs it has adhered, without sensible variation, to its original programmes; our annual volume, while increasing in bulk and, let me add, in value also, remaining what it was at the commencement—a report solely of the proceedings of two or at most three days in every year. There seems to be no good reason why, except perhaps on the ground of expense, this should not be made of still greater value to us all. Following the example of similar associations, it might, through the instrumentality of a Committee of Publication, be constituted a complete record of the progress of gas manufacture in all parts of the world. This would be accomplished by the selection, and translation where necessary, of such extracts from both British and foreign journals as might, in the opinion of the Committee, possess a permanent interest in relation to gas. In this way we should be kept informed semi-annually or oftener if found desirable, of the advances made in connection with gas lighting abroad, and at the same time be building up for ourselves an epitome, for reference, of the most valuable and comprehensive kind.

In another direction also it seems possible that we might with advantage imitate the practice of kindred societies—namely, in the encouragement and promotion of original research. I am not unmindful of the fact that the Association has in its gift at least one medal, besides premiums at will, and that in the bestowal of these it is unlikely that the claims of the meritorious investigator could be overlooked; yet do we not fall somewhat in our aims by not giving, to a certain extent at least, point and direction to the labors of the latter, and by abstaining, in our collective capacity, from all attempts at elucidating some of the apparent mysteries of gas manufacture? Such, at any rate, are among the suggestions that occur for extending the usefulness of the Association; and I venture to hope they may not be deemed unworthy of your consideration.

Whatever of truth there may be in the saying that "London is not England," certain it is that its gas polity is reflected far and wide, possessing an interest extending beyond even the limits of the realm. Here was first rendered manifest the evil consequences of the failure of active competition when applied to gas undertakings; and here also, following within the space of a few brief years the rejection of this principle, was first accepted, in its most comprehensive sense, the very opposite one of amalgamation. It is not necessary to justify the combinations that have taken place, and of which we cannot yet have witnessed the last, by pointing to reductions of price that have followed, or are expected to follow; that advantage has been made apparent enough during the past few years by the disappearance from crowded neighborhoods of works that could not but be inconveniently and uneconomically conducted. The growing requirements of an overflowing population had, in fact, rendered amalgamation a necessity altogether apart from financial considerations; yet the concentration of manufacture in the most suitable localities thus made possible, must of itself, from its greater economy and the higher degree of skill that it admits of, have eventually secured great and lasting benefits to the consumer, had they only possessed what has been called the "magic of distance" to assist of fruition.

One legislation, however, like Parliament itself, seems destined every few years to undergo a more or less complete revision; and in the fulness of time, albeit precipitated by events that need not now be recalled, it was considered desirable to stimulate the action of the companies toward further reductions in the price of their gas. The introduction of the sliding scale of dividend is recognized as having been mainly the work of one of our past-presidents, and now an honorary member—Mr. George Livesay; and it is an achievement of which he may justly feel proud. Without of necessity indorsing every argument that was advanced in support of so great a change, it may be accepted, at this distance of time, as the first, as it remains the only attempt to apply to what, in the hands of companies, are essentially commercial undertakings, sound commercial principles; and for this reason if for no other any effort to disturb it would be a matter for regret. Nevertheless it is to be appreciated that the public will regard with increasing jealousy adjumentations of dividend for which only a bare justification can be shown to exist.

The permanence of the sliding scale as an institution depends, it may be said, upon its good behavior. It may be expected to continue in favor so long as it operates, or is believed to operate, more for the benefit of the consumer than the legislation it superseded; but it might quickly fall into

---

Kimberley Water-Works Company, Limited.—The Company was registered on the first inst. with a capital of £300,000, in 50,000 shares of £6 each. The object is the construction of water-works in the South African colonies.

MR. SUGG ON THE SCIENTIFIC USE OF GAS.

As already briefly noticed in our columns, Mr. Sugg, on Tuesday, the 20th inst., delivered a lecture, on "The Scientific Use of Coal Gas," before the Hull Literary and Philosophical Society. The lecture, which was abundantly illustrated by diagrams and experiments, was very well received; but with the exception of a portion of it our readers would be little interested, as it was a recital of experiments which they are, of course, familiar with, and known, in many cases, which deserve notice in our columns, and we take the opportunity to do so.

After alluding, in a popular kind of way, a description of how gas is produced and what are its constituent parts, the lecturer dwelt on the necessity of the properly proportioned burner fittings for burning gas, affecting the question of pressure. At this point he exhibited Zaslin's patent apparatus for accurately measuring the flow of gas by simple inspection. This apparatus, a description of which is appended, was fixed to one of the burners shown, and showed the flow of gas that passed through the burner on a very ingenious little apparatus, the invention of Mr. George Joslin, of Colchester. It is simply a taper glass tube, which is connected with the gas that supplies the burner. It may be placed on any convenient pipe conveying the gas. The taper tube is fixed to the burner. Within the glass tube is a small tube of mica, of such a diameter that when it falls to the bottom of the tube it fits closely to the sides. When I turn on the gas the mica disc is forced up the tube to a height at a point at which the quantity of gas required by the burner can escape from under it by the space between its edge and the sides of the tube. As the tube is taper, it is clear that the higher it goes the greater the space will be between the circumference of the disc and the sides of the tube, and consequently it is necessary to refer to know at a glance how much gas is passing. I have only to read the figures or degrees marked up the outside of the tube. These have been verified by trials with an experimental meter.

The lecturer then passed on to the question of the use of burners with and without governors to the effect of actinism, and the value of each on the eyesight. On this latter point he dwelt somewhat at length, his remarks being as follows:—

I have now to bring before you a subject of the greatest possible interest in relation to the use of artificial light. It is indisputable fact that there is not the present day a large proportion of a number of young men and women, and even children, who are obliged to work by artificial light. France and Germany, as well as in England, this subject has attracted the attention of scientific men, and it is one which must not be allowed to drop until every reasonable actinic condition is fulfilled. Many of the dull of eyesight, which compels young boys and girls, and also young men and women, to work, a great deal of their time, is due to their work by the aid of candles, others by factory; but the great number employ gas. The light is, however, mostly insufficient and of a very unsatisfactory kind. Most of the evil complaint arises in relation to artificial lighting—it is the quality of the light, regarded from a chemical point of view. Sir light, as we are aware, is composed of rays, light rays, heat rays, and chemical rays, which on a ray of light is made to divide itself, or split up, by being passed through a prism, into the seven colors composed of the colors—red, orange, green, green, blue, indigo, violet. This is called its spectrum. The red is the heat ray, and this rays on the spectrum are the longest, and this changes into the green, then becomes less, and finally ends in violet. The greatest heat is found to be beyond the red ray of the visible spectrum, while the greatest chemical effect of light is in the violet, or the visible spectrum on the other side. The chemical or "actinic" rays are the most powerful in relation to producing the greatest effect upon a photographer's sensitive plate, and without this ray we could not obtain a satisfactory photographic portrait.* But there is a certain condition of the eye in a state of daylight with respect to the chemical property diffused in the day. At early dawn there is light almost without actinism, or chemical ray; but as soon approaches the light of day increases in actinic power, and in the afternoon rapidly declines, till at evening no actinic ray is present. Now, this chemical actinic property, in the shape of the actinic ray, or chemical ray as it is usually called, to distinguish it from the other component parts of light, is the most important ingredient in photo plate, so is acts upon that most portion of all photographic apparatus, the human eye.

Light which contains a great quantity of actinism injures the optic nerve, and renders it insensitive, exactly as a photographic plate is rendered insensitive by the same agency if it is over-exposed to it. Therefore, it is most natural thing that occurs to all human beings is to get out of the blinding glare of light, and to shut our eyes or shield them from it when there is light with too little actinism. The great diminution of this chemical property of light towards the close of day is the reason why clearly that the eye must not be exposed for too great a length of time to the action of the actinic rays. Consequently, it seems to me that what we want as an artificial light is that kind of light, as opposite to natural light, we have on summer evenings—white and diffusive, but almost devoid of actinism.

Now, if we read by the light of a candle placed too far from us, the pupil of the eye is abnormally dilated, and the consequence is that it is opened to its widest extent; so it is on all the rays of light possible. This is a arrangement, which is quite suitable to the construction of a cat's eye, is altogether unsuitable to the human eye. The delicate nerves are overstrained, and, in time, become permanently injured. If we use the candle at a proper, or the greatest amount of the sharp-pencil of light falls on the eye, so that we can see from seeing so distinctly the object we are looking at. The greater and more intense the light, the less the pupil of the eye is dilated. The extreme is reached when we place the unshaded gaslight directly in front of the eye, and in close proximity to it. All the disagreeable and hurtful effect of strong daylight is produced upon the eye, without its immense diffusion and perfect steadiness. Sharp bright rays are darted into the eye when we look up, and a strong glare is produced as symbols of the downcast eyes. The flicker of the light keeps the diaphragm of the eye constantly trying to adjust itself to

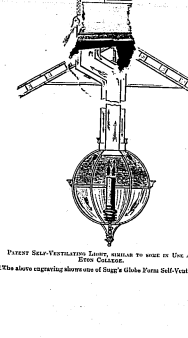
* Cecelia Abergy, of South Kensington, has demonstrated that the red ray as well as the violet rays can be photographed.

variable light, causing great fatigue. In addition to this, the heat of the lamp is thrown full on the front part of the head. Nothing is more contrary to the wise provisions of nature than the position we have to take to "shade" our eyes from it. But this is the condition of things in relation to the art; just light which is used by our young men and women who are engaged in work. In fit, then, to be wondered at that the eye become prematurely old and insensitive—less their brightness and all the fine nerves of vision waste away, and form with which nature originally endowed them? Is it wonderful to argue that there are instances of persons who have studied for years that they can read by gaslight, and still have good eyesight. Instances can be easily be found of persons who have done everything they possibly could to destroy their eyesight, but have not succeeded; but by far one person who has not impaired his sight by the injudicious use of artificial light in pursuing his studies, through the light which we have done on education to your children, and they impair their eyesight in a high-class establishments of the great advantages and their high education, and are heavily handicapped in the race of life by the fact of their being obliged to wear spectacles. This is entirely possible was the case before the introduction of artificial light, and is greatly owing the course of their lives.

But you will naturally ask me, How can we alter this state of things? I reply, a very simple and easy one, and yet well worthy the aid of a candle, let it be a good one, and provide yourself with a proper shade for candle, candles, not opaque, but slightly translucent, so that the candle may be visible inside, so that a red colour light falls on the eye. It is a large thing, and, therefore, not objectionable, but opaque shades—do not answer the lower edge of the shade, just a little curtain of pale rose paper or silk round the lower edge of the shade, so that the light falls on the eye. Green shades or other coloured non-conductors of heat should be interposed between the hand and the light, so that a current of air may not be created to the eye. The reason for it is that the actinic rays of light are stopped by glass is an impediment to heat, and also to a great extent. Green glass is the best light for drawing, writing, or reading by, therefore, in my opinion, the Argand burner should, in the manner I have indicated, with a screen of ruby glass, be placed between the eyes and the artificial light, and the same. This is one of the non-actinic reading lights. [Lampshown and explained.] Although, as I have said, I prefer the ordinary light equal to 20 candles, I find by experiment that a burner of that light equal unsafe from weakness of sight to read by any artificial light. Even a 10-candle burner has been said to be so without fatigue. But for myself I can only say such a light equal to 16 candles or so will be found best.

It is a common error to think that Argand burners are the most powerful, though even powerful in that Argand burners are the most powerful, though even powerful in that Argand burners are the most powerful in light-giving properties with the consumption of gas than fishtail or flat-flame burners, and this is the reason why Argand burners are more suitable for producing a soft and non-actinic light than the latter. Thus, for example, a flat-flame burner giving a light equal to 16 candles, with, say, proper reduction, attached to a reading lamp, is pernicious to the eyesight; an Argand burner, equal to 100 candles, requires nearly the same time to consume the same quantity of gas. The inference, therefore, is that the Argand burner with the chimney lessens only half the actinic power of the open flat-flame burner; and it is the actinic power or the ratio of the light to the chemical property diffused by the outdoor daylight is diminished to more than one-half by the opposition of the glass in the windows to the entrance of the actinic rays.

The lecturer then called attention to the complaints made about the heat and the consequent injurious effects on the eyes of the products of the combustion of gas on pictures, libraries, and museums. In connection with the question of drawing of a light, he referred to the new picture gallery, at Bristol. The light given by each set arms or sunlight, picture gallery, at Bristol. The light given by each set arms or sunlight, picture gallery, at Bristol. 1000 candles, and the products of combustion are to be equal to from 100 to of fresh air to the gallery per minute. The ventilation and the supply were in which the light is given placed, a in connection with the Grand Club in London. It was, the two of these lights, each light equal to 300 candles, and the two of these lights, each increased in the heat. ture of the room was not



PATENT SELF-VENTILATING LIGHT, SIMILAR TO THOSE IN USE AT ETON COLLEGE.

(The above engraving shows one of Sugg's Globe Form Self-Ventilating

Lights for 100 or 200 candle burner. The lantern is of clear glass below, and white glass in the upper part, the two being divided by a copper moveable ring, similar to that immediately above the globe, and surrounding the inlet and outlet tubes. The ring, or inlet flue—the outlet being contained within it—may, of course, be connected with any required currents of air to both directions as indicated by arrows.

The lecture concluded by a reference to the use of gas in engines for obtaining motive power in the place of heating purposes; and, in connection therewith, the means of electrically lighting railway carriages.

JOSLIN'S APPARATUS FOR ASCERTAINING THE HOURLY RATE OF GAS CONSUMED BY BURNERS.

This ingenious little instrument, referred to in the above lecture, is the subject of a patent dated June 15, 1872 (No. 2126), the inventor being Mr. George Joslin, of Colchester.

The object of the apparatus is to provide the means of ascertaining the hourly rate of the consumption of gas by any burner—as, the rate of consumption at the time of inspection calculated at the quantity that would pass in the course of an hour—by allowing in a glass or metal tube or cavity of a disc supported by the gas at a height corresponding to the rate of gas being consumed.

The apparatus consists of a taper tube of glass, metal, or other material, of round or other form in its horizontal section, and increasing upwards in area. Into this taper tube is a thin disc or discs of tube, aluminium, or other material, and of the same form as the horizontal section of the taper tube. If one disc is used, it is maintained in a central position by a piece of metal or other material attached to it, or two or more discs may be connected together. The taper tube is connected with the burner or burners, and the gas is admitted at the bottom of the taper tube connected to the wall it arrives at the figure which corresponds with the hourly rate of the gas passing. After the gas has passed the disc it flows from the upper part of the taper tube to the burners. The taper tube may be enclosed in a tube, the diameter of which is greater than the disc, or other means may be used to indicate by figures upon a graduated scale the hourly rate of consumption; or the indicator and figures may be placed outside the tube or case before mentioned, and projected by a lens, or otherwise, upon a screen or surface, or upon a fixed sectional elevation of one form of the apparatus: A being a brass tube, B a taper glass tube, and C a cap to allow the position of the mica glass, D, to be noted. It is a glass tube, slightly conical, the lower part of which is open, while B is the burner in position to be tested. The glass tube, B, is graduated so that it indicates the hourly consumption of gas.

EFFECT OF TEMPERATURE IN THE G. AIR SUPPLY UPON SOME ILLUMINATING P GAS-FLAMES.

By Mr. R. H. PATTERSON, F.S.S.

SECOND PART.

The only reasonable motive that there can be for A when supplied to a burner is, that this preliminary enable the gas-flame to acquire a higher temperature, combustion, and consequently burn with greater bril can be no doubt that an advantage is obtainable ordinary fuel in grates or furnaces. But there is difference between that case and the use of gas for purposes; because ordinary fuels, such as coal, presents resistance to ignition. A feuller match, for example, or of them, may wholly fail to ignite it; heat or flame in strength or mass is required before ignition is effected; course is the same thing dynamically, a small flame mus to coal for some length of time before combustion is prod then, is something to be saved or economized. Eith amount of heat, or a shorter application of it, will suffi fuel which has been heated. Also, in a grate or furn always some part of the fuel not actually ignited; and so i is the case it is obvious that the higher the temperature of th portion, the less heat will be absorbed from the burning produce combustion in the rest.

Still more clearly is it of advantage to heat fuel which is *added* to a fire or burning furnace; for the first effect of duction of cold fuel is necessarily to reduce the temp combustion—indeed, *any* addition of fuel which is not burning must operate in this disadvantageous manner. A lies the greatest defect in the present system of gas-making four or six hours the retort is emptied of its mass of high more by the charge of fresh coal; so that no sooner is the temperature attained than it is suddenly pulled down to point to allow of the distillation being effectively carried way of remedying this (although there are serious practical in applying it) would be to heat the retort steadily in it mense of small-sized coal in a hopper, and the other is t coal which is about to be supplied to the retort. But to ha any considerable extent means also to vaporize a port combustible and illuminating substance; and unless the vapours thus discharged from the coal by heat are pres utilized, more damage may be done to gas-making than is sated by the intenser combustion produced by this heating the retort.

But the obvious advantages obtainable from heating fuel ignition and combustion, are not paralleled when the same is applied to gas. The more sluggish any combustible ma the other words, the more slowly combustion extends from part—the more valuable is the effect of prior heating; i the whole mass springs into a blaze the moment the requisi tature is applied, to any part of it, it is hard to see what a

* "Gas-Works Statistics, 1880;" and "The Gas and Water Manual Directory, 1880." London: C. W. Hastings.

prior heating can confer. No one thinks of heating gunpowder in order to intensify its combustion; and coal gas, when employed in jets for illuminating purposes, burns for all practical purposes with not less instantaneousness and spontaneity. It is true that in some of the thicker gas-flames there is a tiny core of *gas not burning*; but this is not owing (as in coal) to what we may call sluggishness of combustion, or resistance to ignition, but merely because that part of the gas is for the moment excluded from the air. When first spread out and in contact with air, coal gas, owing to the exceeding minuteness of its combustible particles, burns with almost instantaneously; and, as is well known, even when gas is in bulk an intermixture of air sufficient to explode it, the mere touch or impact of a lighted lucifer match—even the smallest spark of fire—sets any of gas, or the whole hundred jets of the Wigham burner, instantaneously into full combustion, and at as high a temperature as the gas-flame can develop. Thus, in a word of flame, the gas is raised from the ordinary temperature of 60° or 70° Fahr. to about 3000° Fahr. What difference, therefore, can it make whether the unlighted gas has a temperature of 60° or 600° Fahr.?

And such a temperature—viz., of 600° Fahr.—will be found, by any one who makes the experiment, an exceedingly troublesome one to produce in gas. Moreover, as is well known, if coal gas be raised to this temperature—at least, by any means hitherto employed —there will be found some deposit of carbon upon the surface of the burning burner. The same experiment will prove an ordinarily high temperature unless the tubes or chambers in which it is contained are filled by a mass or network of conducting material—such, *for instance*, as wire gauze—which conveys the heat from the outer surface of the pipe or chamber. This is quite the case of the gas-stream; and, whatever the material thus employed for conducting the heat, and incidentally applying it to the gas, it will be found coated with carbon when the temperature of the gas rises to 600° Fahr., or even less. The gas, in short, begins to suffer from "dissociation," some of the richer hydrocarbon compounds being broken up, with a deposit of carbon, which is the illuminating substance.

Upon these various grounds, it seems to me that the result which I obtained from the experiments in 1871—viz., that the heating of the gas added nothing to the illuminating power of the gas-flame—is an inference not unreasonably drawn. And this is my opinion on the question as it at present stands; but no one will be more ready to change it than myself were he, or any other experiments should point to an opposite conclusion. Also these experiments show the necessity for the heat being applied close to the burner, otherwise the gain will return to its ordinary level before it reaches the point of ignition.

Temperature of the Burner.

But there is another phase of the question to be considered; and it is entirely distinct from that of heating the gas, although practically it becomes mixed up with it. Although there may be no advantage to be gained by heating the gas, it is manifestly of importance that there should be no withdrawal of heat from the gas-flame. Now such an abstraction is always taking place, more or less, and I have already spoken of the air supply, the heating of which undoubtedly lessens the withdrawal of heat from the flame, or enables the flame to attain a higher state of combustion; and I need not speak further of the cooling effect of the atmospheric surroundings of the flame. But there is another source of heat-absorption—viz., the burner itself. That every gas-burner absorbs heat from the flame is demonstrated to the touch. The burner quickly becomes so hot that it cannot be touched. This is especially the case with the Argand, in which the mass of the burner, and notably the surface in direct contact with the base of the flame, is much larger than in flat burners, both bat's-wings and fishtails. When Mr. Sugg was constructing his new Argands, with the small separate supply-tubes fitted into the bottom of the burner, he found that if the burner was made of metal (brass or the like) it would burn over until the very part that the "soft metal" employed in soldering-on the small tubes was melted; and yet, if the burner was made of glass, by making the body or gallery of his Argand of steatite was to obviate this difficulty. Even the steatite burners become so hot that they cannot be touched. Even the steatite Argands so hot that it is easy to handle them while the gas is burning; and metal Argands become so hot that Mr. Sugg alone their temperature at from 500° to 600° Fahr.

This heat, of course, is entirely obtained from the gas-flame. But this absorption of heat by the burner is somewhat different in character from the other form in which a withdrawal of heat from the flame takes place—viz., by ordinary radiation into the surrounding atmosphere. Air is a bad conductor of heat, whereas metal, like brass or iron, is one of the best conductors; accordingly, relatively to the extent of radiating surface of the flame exposed to these rival absorbents of heat, more heat will be withdrawn by the metal than by the air. On the other hand, the heat absorbed by the air is more completely or suddenly lost, than that absorbed by the metal burner; because the former is dissipated at once, carried off instantly into the general atmosphere, whereas the burner contains a portion of the heat which it absorbs. Nevertheless, the burner is constantly parting with its heat to the air; and this radiation prevents the heat accumulating in the burner beyond a certain point; but this accumulated temperature—say 500° Fahr.—is only maintained by the constant absorption of heat from the flame commensurate with the heat which the burner is constantly giving off into the air.

Now, were it possible to keep a burner hot, irrespective of the flame, the heatness of the burner would be of some advantage; and if the burner could in this manner (*i.e.*, by independent means) be kept so hot as altogether to stop its absorbing heat from the flame (in which case the burner would require to be as hot as the flame itself), there would be a considerable advantage. But the case is different when the hotness of the burner is produced by an abstraction of heat from the flame itself. Obviously, it would be better if the heat remained in the flame, instead of passing into the burner. Further, what happens is not merely a transference of heat, but also a loss of it. Were it possible for the burner to retain all the heat which it absorbs from the flame, this abstraction would be of merely momentary disadvantage; for the burner would quickly acquire its highest possible temperature, after which the abstraction of heat from the flame would cease. But, as needs hardly be said, this is not the case; for although the burner becomes hot, it is constantly losing a part of its heat by radiation, and this last heat is being constantly made up by an equal absorption of heat from the flame.

Thus the advantage which Leslie and others thought was obtained by the burner becoming hot is an illusion. Undoubtedly, *per se*, the hotter the burner the better, but not when the heat is obtained from the gas-flame itself, and under circumstances where the burner is parting with its heat almost as quickly as it is abstracting it from the flame.

These considerations help—perhaps suffice—to explain what, *prima facie*, is a mystery. It has been found that steatite Argands give a higher light than metal Argands identical in structure. This seems certainly a very puzzling phenomenon. Mr. Sugg made the reasonable conjecture that this was owing to the coolness of the gas as it issued from the burner. The steatite being comparatively a non-conductor of heat, the gas in the cylinder of a steatite Argand must ungoverningly be cool, at least compared with what it is in a metal Argand. And, in fact, this was, at first sight, the only apparent difference; and therefore it was a natural inference that it was the coolness of the gas which gave to it its higher illuminating power when compared in a steatite burner.

Effect of Non-Conducting Burners on Illuminating Power.

It is important to observe at the outset how this matter stands. There is no question that the cooler the gas the smaller is its volume; and therefore the heavier it is, containing a larger amount of illuminating substance. But this consideration must be here excluded, because in the experiments in question the gas has the same temperature as it passes through the meter and the governor of the gas as it issued from the burner. The steatite being comparatively a non-conductor of heat, the gas in the cylinder of a steatite Argand must ungoverningly be cool, at least compared with what it is in a metal Argand. And, in fact, this was, at first sight, the only apparent difference; and therefore it was a natural inference that it was the coolness of the gas which gave to it its higher illuminating power when compared in a steatite burner.

We notice that Mr. Frederick Colyer, M. Inst. C.E., having retired from the firm of Messrs. G. Waller and Co., gas and water engineers, with whom he was so long connected, announces that he intends practising in all matters connected with gas and water works will be continued there in all matters connected with gas, gas and water engineer, Westminster.

We understand that the Rudiman and General Iron Company (Messrs. James Cowan and Samuel Segenworth) have been awarded in them for "anti-corrosion Exhibition that a gold medal has been awarded to them for "anti-corrosion tubes and fittings," treated by Professor Barff's rustless process. They have already supplied goods to fifty or sixty of the leading gas and water companies, and have had numerous repeat orders.

The Provincial Economic Gas Company, Limited—Among the new companies recently registered is one with the above title. The Company proposes to acquire certain terms of an agreement of the 6th ult. between [illegible] and Co., of Leeds, and Mr. Thomas Hall, of Leeds, for the sole use of the latter's process for the manufacture of gas from petroleum and other hydrocarbons, and to erect works for the manufacture of such gas in the district of Leeds. The nominal capital is £50,000, in 5,000 shares of £10 each. The subscription list will be opened on the 20th inst.

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, JUNE 29, 1880.

Circular to Gas Companies.

The Liverpool Lighting Act of last year is no longer, of its kind, a solitary legislative phenomenon, and the Corporation of Liverpool have ceased to stand alone in the possession of the powers which that Act conferred. The Bill lately before Parliament and the Preston Improvement Bill have respectively been passed by Committees of the House of Commons, and may be considered certain now to obtain the full sanction of the Legislature. These Bills are in effect identical with the Liverpool Act, and there are now consequently three Municipal Corporations enjoying parliamentary sanction and right to expend the money of the ratepayers upon experiments in electric lighting. We say "experiments" advisedly, because in each case it is admitted that the work proposed to be done is partial and tentative, and the Corporations are refused permission to reap a profit as the reward of their labours and expenditure. It is reasonable to suppose that Parliament has now done enough for the encouragement of scientific inquiry in this matter; and we are entitled to expect that some really instructive and practical demonstration will be made before further powers of this character are sought for, or granted to other Municipalities. It is unusual, and we think the practice in several ways open to very grave objection, for each Corporation to have authority given them to spend money in speculative investigations. In this country, at any rate in recent years, there has been no lack of private enterprise or capital to examine, develop, and apply inventions or processes of a novel character which have given any promise of commercial success. The electric light is no longer a novelty; it has proved itself suitable to the work of illumination in several special applications, and its superiority over all others, where single centres of very great intensity are required, is generally accepted. We maintain, however, that this latter position of superiority is limited strictly to lighthouse purposes, and that for all others, lights of amply sufficient volume and power can be obtained from gas.

The success which has attended the introduction of several of the applications of electricity for lighting purposes, both on the Continent and in England, has been attributable to a great extent to the formation of more than one Electric Light Company, and a Municipal Corporation or any other body or person desiring to spend money upon further experiments, will find no lack of enthusiastic helpers. What is more to our purpose, however, such a Corporation would also, we believe, find no difficulty in obtaining definite tenders from several responsible firms or companies ready to undertake any such duty as the lighting of "streets, parks, or places of public resort," in the same manner as the Société Générale d'Electricité has contracted with the Metropolitan Board for the lighting of the Thames Embankment, and this would, in our judgment, be the more prudent and legitimate method of procedure. The House of Commons Committee of last year reported: "It is desirable" that Local Authorities should have power to give facilities "to companies or private persons to conduct experiments;" while they also reported that "if Corporations and other "Local Authorities have not power under existing statutes to "take up streets and lay wires for street lighting or other public "uses of the electric light, your Committee think that ample "power should be given them for this purpose." Yet the former quotation shows that it was rather with the view of enabling contractors to do the work for them than that the Corporations themselves should become traders in electric, as so many are, and so many others desire to be, in gas lighting.

We take this point for the reason that we do not regard with unmixed satisfaction the condition laid upon Corporations supplying the electric light, that they shall derive no profit from its sale. The effect of this limitation is that performs the new light must enter into competition with the old one at an unfair advantage, inasmuch as the comparison of expense will be between the first cost of the one and the commercial selling price of the other. We do not need to remind our readers how great is the difference between the two. In a town, for instance, where gas is being sold at 3s. 6d. per thousand cubic feet, not more than half that amount should be reckoned when making comparisons with the electric light under the conditions laid down for it at Hull and elsewhere; but this aspect of the question is persistently lost sight of by those who argue in favour of the economy of electric lighting. If the Corporations then had determined to grant concessions to private firms or companies to undertake the work as a matter of ordinary business, the public would have known what was a fair price for the new light comparatively with gas, because either the price charged would have been one sufficient to pay a fair profit to the contractors, or, if no profit resulted, it would be seen that the charge was too low. In any event, there would be no difficulty in arriving at a right conclusion as to what the price should be. As it is, the Gas Companies and their Engineers in the various towns where these experiments are being or are to be made, will do good service by watching closely, not only the experiments themselves, but also the figures that will be found in reference to them; and the duty seems to devolve upon them of protecting the public, not only of their own towns but generally, from being misled by either ignorant or interested statements.

These considerations apart, we are glad of any movement which promises to lift the question of electric lighting, as compared with gas lighting, nearer to the region of fact and competitive with gas lighting, nearer to the region of fact and demonstration, and away from that of mere talk, to which it has hitherto been so largely confined. Bearing in mind the character and position held by many of those who have been actively engaged in promoting electric lighting, and the many opportunities which have already been afforded for exhaustive

Water and Sanitary Notes.

THE Gas and Water Committee of the Corporation of the City of London, in obedience to the reference of the Court of Common Council, duly applied to the Home Secretary for an interview; but Mr. Cross declined to see them, on the ground that any action on the part of the Corporation at the present moment would only complicate matters. We may infer from this that the Home Secretary has settled in his own mind the plan he will adopt next session in dealing with the Metropolitan Water Question. When the reference to the Committee was made, we suggested that after Mr. Cross had pledged himself so strongly, both to the House of Commons and to the country, to take up the much-vexed question of the London Water Supply, it was a little indecorous on the part of the Corporation to interfere with his actions. The Common Council have received what we do not care to call a snub, but they have been told not to interfere in the matter until their advice is asked, and we know when that will be. As was pointed out in a recent number, it was possible that the conference of the Committee with the Home Secretary might resemble "interviewing" in the American sense of the word, he was about to pursue. The Home Secretary is a matter-of-fact man, and not a humourist, or he would have derived some fun from the Gas and Water Committee. We shall not endeavour to anticipate what course the Home Office will pursue. We read in a morning contemporary that the Parliamentary Draftsmen of the Treasury are busy in the preparation of a Bill which is to transfer the management of the Metropolitan Water Companies to a "Water Trust "of some kind or another, not probably that foreshadowed in a parliamentary notice which we commented upon last week. The source of our contemporary's information we do not know; but, as the organ of the beer and spirit trade, it is not likely, we fear, to be in the secrets of the Government respecting the Water Question. The matter, we believe, may be safely left in the hands of Mr. Cross. The Water Companies, too, are perfectly able to take care of their own interests.

The report of the Directors and the accounts of the Lambeth Water-Works Company have been issued in anticipation of the ordinary half-yearly meeting to be held this day. The occasion is not without importance. A crisis is impending in Metropolitan water affairs, and we are happy to see that the Lambeth Company are well prepared for whatever may happen. In the first place, the Company have faithfully fulfilled all their public duties. They supply water purified by long subsidence and perfect filtration, and they are quite willing to extend as rapidly as possible a constant supply with hydrants all over their limits. We are somewhat astonished to see that the Metropolitan Board of Works are at last moving in this matter. They have stood aloof so long as to fall into merited discredit. Now we may hope that hydrants and the constant supply system will be universal all over the Board's limits. But for this we shall not have to thank the like the Kent, the New River, the East London, and others, were endeavouring to carry out the provisions of the Metropolis Water Act of 1871, which it was the especial duty of the Metropolitan Board to promote. They are now roused, as we have said, into something like activity; but it is too late. We fancy that they will discover, in a very few months, that any pretensions to a control over the Metropolitan Water Supply will have vanished from their grasp. We cannot help thinking that the Act of 1871 afforded the Board an opportunity, but they shrank from incurring the odium which might have ensued from the carrying out of the regulations of the Board

[illegible] Company. The

[illegible] Companies, and does not take into consideration the amount and quality of [illegible] obtained, nor the consequences and inconveniences resulting from sel[illegible] many methods which are obviated in the Healy system.—*Springfield Republican.*

[Omissions of Gas Companies from Page 548.]

Statement of the Receipts and Expenditure of the Gas Companies in the Metropolitan District, and the Quantity of Gas Sold, during the Year ended the 31st December, 1878.

Name of Company.	Receipts for Gas.	Receipts for Residuals.	Total Receipts.	Expenditure.	Quantity of Gas sold.

Westminster	30,000	3,000	33,000	25,000	800,000,000
Woolwich	30,000	3,000	33,000	25,000	800,000,000

to yield an annual rental of £4117. A Company in this position are entitled to much consideration from the Government. We will not say more consideration than any other of the Metropolitan Water Companies, who have equally well fulfilled their duties to the public, and have, as the Directors of the Lambeth Company put it in their report, in all cases sought to levy rates, under their parliamentary powers, in a reasonable and equitable manner.

It is impossible to refer to all the various reports of sewerage difficulties which are brought under our notice. We may mention, however, East and West Looe, situated in a remote district in Cornwall, where the sanitary conditions under which the inhabitants live are as bad as they can possibly be. Dirty narrow streets, with the houses imperfectly furnished with water or closets, or any other decent conveniences, are thickly inhabited by people who carry out their refuse after twilight, and throw it into the sea. This is not a matter for us to comment upon; but looking over, as we do, the whole of the country, we feel bound to say that the drainage of East and West Looe requires the attention of the Local Board, and the interference of the Central Authority. Such matters as these should be settled by the Local Authorities concerned, without the smallest difficulty or trouble; but they will not settle them, and until influence is brought to bear upon them by some Central Authority, they will go on and act exactly as they please, always looking at the rate, but never at the comfort and convenience of the ratepayers. Now, we are the firmest friends of local self-government, but we may say, once and for all, that the proceedings of these wretched Vestries and Local Boards are not to be tolerated. We have pointed out over and over again, that nothing effective would be done for the drainage and water supply of England, until the whole country was mapped out into drainage and watershed areas. If this had been done in Cornwall, and the work had been carried out by a strong Central Authority, all the disorders which now pervade the district, when water supply and drainage schemes are discussed, would long ago have ceased. There is one thing that can be done, and that is for six responsible ratepayers to make application to the Local Government Board, and bring down an Inspector, whose instructions must be fully carried out. Local self-government is, in many cases, a simple blunder. The people who are benefit into authority are commonly the most ignorant and selfish in the locality, and the sole thing which brings them into power is the wealth which they have amassed by their selfishness. Let us have, for the regulation of sanitary matters, an honest despotism; but, in any other case, we must leave such people as constitute the Local Authority of East and West Looe to do what they can.

GAS LEGISLATION FOR 1879.

(*Continued from p. 732.*)

THE *following Acts*, for the most part, authorize the purchase of gas undertakings by local authorities, or confer further powers upon local bodies already in possession of gas undertakings. It will be seen that some Acts are introduced in this section which do not properly come into our classification, but the omission is unavoidable.

The *Birmingham Gas (Nechells and Yardley) Act* scarcely comes within the scope of the Acts with which we are now dealing. It is simply to repeal a section in the Birmingham Gas Act, 1875, carried over from the Birmingham and Staffordshire Gas Act, 1864, which allowed a differential charge for gas to be made in the Northfield, Yardley, and Solihull districts, of 1s. per thousand feet beyond that charged in the borough.

The *Blackburn Improvement Act* extends the limits of the Corporation, so as to include a portion of the township of Lower Darwen and that portion of Little Harwood which was not until now included in the district of the borough. The Corporation have power to borrow £30,000 for the improvement and extension of their gas-works, and the sum is to be paid off in the usual manner by means of a sinking-fund, the customary returns being made to the Local Government Board.

The *Blackpool Improvement Act* is to extend the borough so as to include some surrounding townships. It further empowers the Corporation to borrow £36,000 for extending and improving their gas-works, and also to employ the electric light for the illumination of the promenade and other places of public resort, but for no other purpose, for a period of five years. The expenses of the light are to be chargeable to the district-rate, and whatever profit may be derived is to be carried to the credit of that rate. The Act gives the Corpora-

Abstract and Summary Notes.

The Gas and Water Committee of the City of London, in reference to the recommendation of the Common Council duly applied to the Home Secretary for an instructor; but he declined to do so. The Committee have, however, succeeded in obtaining the services of Mr. Bunnett, who has had considerable experience in the laying and working of gas and water mains, and who will act as instructor to the Committee's men. Mr. Bunnett has already entered upon his duties, and will shortly commence a course of lectures to the Committee's men, which will be followed by practical instruction in the trenches.

[Official Report.—Continued from page 154.]

Tenth Annual Meeting of the New England Association of Gas Engineers.

Held at Boston, Feb. 18th, 1880.

[Concluded.]

Mr. Stiness—I was at the Corliss Engine Works about three weeks ago, and in conversation with Mr. Corliss he claimed that with the very best results they have never been able to get below 2¼ pounds of coal per horse power per hour. In addition to that, I think Col. Armington remembers that when we visited the Conant Thread Works, they stated that for a year's work with a 1000-horse power engine their result was 2¼ pounds of coal per horse power per hour. Mr. Corliss questioned that any engine could run with less than 2¼ pounds of coal per horse power per hour, and you put your figures at 2 pounds.

Mr. Vanderpool—I would say that I do not know of any engine that does that work right along. Now I refer to first-class condition, and with new boilers, and all the conditions favorable, these figures may perhaps be reached for a limited time; but I doubt very much whether any engine, working year in and year out, can do it.

Mr. Stiness—The results at the Conant Thread Works were 2¼ pounds of coal per horse power per hour for a year's work, and Mr. Corliss questions whether it can be done with less than 2½ pounds. Of course, that makes your figures so much better.

Mr. Vanderpool—A very great advance in the utilization of power may come from the better utilization of fuel under the boiler. There has been a great improvement in boilers in the last year or two, so that there is a great saving in boilers' fuel by gas furnaces. They are bringing it down so that instead of getting an evaporation of 7 or 8 pounds per pound of coal, they get 10 or 11, which will make a great difference in the power.

Mr. Scott—I have here the result of some experiments with a Corliss compound pumping engine. We made four experiments. The result was 1.88 pounds of coal the first day, 1.78 the second, 1.68 the third, and 1.66 the fourth. I would state that Mr. Corliss has a contract for one of his engines guaranteed to run 48 hours two to four pounds per horse power per hour.

Mr. Goodwin—There is one other remark that I would like to make, and that is in relation to the variation in the quality of coal gas—that is to say, in illuminating and heating power—examples of which I have here. For instance, gas of 26 candles, for illuminating purposes, is 76 per cent. better than ordinary 16-candle gas. Experiments show, however, that for heating purposes it is but 23 per cent. better.

Mr. Vanderpool—Upon that point I would say that that comes in the weight. That is taken by weight, not by volume. Taken by volume, it would be 2 to 1. That is, supposing the specific gravity to be 500, it would give about 1200 heat units per cubic foot; whereas 16 candles would give about 600, and 32 candles would give about 684, both by calculation and experiment. It makes a difference which way you take it. We do not sell gas by specific gravity, but by the cubic foot.

Mr. Goodwin—I merely want to put it into candle power; 33-candle gas is 120 per cent. better than 15-candle gas for illuminating purposes, but only 50 per cent. better for heating purposes.

I would like to make one other remark, in reference to a little incident that happened in reference to gas cooking stoves. Two ladies called at our office some time ago, and wanted to know if we had any gas stoves. They wanted to use one in a school for cooking that they were about to start in Philadelphia. They said, "We are from Boston, and we have ordered a range from there [I don't remember the name of it, but it was a very elegant looking one] that beats anything in the world." I said, "Ladies, I propose to beat your Boston range."

"You can't beat anything that comes from Boston."

"Will you give me an opportunity to try?"

"Certainly, sir."

I had a No. 9 stove put up, and I didn't go near it until one day a certain gentleman called, the forepart of whose name is "Major," and who conducts a gas light journal; but it went on to call my names here. He called at my office, and I went with him and introduced him to these Boston ladies, and asked them to say anything they could against that stove; and I appeal to the Major if they did not say, "Mr. Goodwin, there is a loaf of bread cooked in that stove, and any man or woman who wants to eat a better loaf of bread than that don't deserve to have any"—or words to that effect. I did not go near them again until the other day I took a gentleman there and asked them to say the worst they could against the stove, and their reply was, "We could not get along without it; we cannot say a word against it."

Mr. Thomas—The matter of the introduction of gas stoves as a means of increasing the consumption of gas, has been worked up pretty carefully in the city of Brooklyn by a course of lectures given there by a lady who may have been imported by Mr. Goodwin; but I don't say she was. (Laughter.) The stove that was used during the lecture was, at my rate, Mr. Goodwin's, and was a No. 9 stove. There was not a good opportunity for getting gas there without bringing it down from the side lights; but we a hole in the floor and made a connection under the floor with an ordinary ¾-pipe. When the lady first came in the room I noticed the stove was lighted, but after heating some water and showing how quickly it could be done, the gas was turned off for a short time. There was some considerable description of the stove before she commenced her lessons on cookery, showing how the gas was turned on and off, and how the stove was operated. Then she commenced making different things and cooking them on the stove. She cooked some three or four different dishes and handed them to the audience to let them see how they liked them. The lecture occupied about an hour. After she was through the stove was kept lighted for, I suppose, half an hour longer, and the consumption for the entire time, as near as we could fix it on the meter, was about 100 feet.

Now I think it is a great mistake (and I found it so myself) to attach an ordinary gas stove used by a family to one of the side burners. I had a little one in my house, and I just ran a ¾-pipe from the cellar and brought it up to the gas stove, and I never had a particle of trouble. In fact it was such a pleasure to my wife to use it that I was afraid I would be cooked out. (Laughter.) As far as the things that were cooked on it were concerned, especially meats, as Mr. Goodwin says, if a man has never eaten a steak cooked on a gas stove he don't know what good steak is. The loss in cooking is brought down as low as 10 per cent., I think. I am confident the loss will not, in my event, exceed 12 per cent., while the loss on articles cooked over a fire is at least 30 per cent.

These stoves are very readily managed, and are very economical. All you have to do when you want heat is to turn the gas on, and you have it. When I first introduced the stove at my home, I found that my wife had too many burners on it, and it made the oven too hot; but since that time we have had no trouble whatever. It is a stove that I got a number of years ago. I was on one occasion invited to a dinner where all the preparations were made with that stove. The party consisted of eighteen persons, and the cost of cooking was 25 cents. You can do the ordinary family cooking for at least 15 or 16 cents. The ladies were perfectly delighted with this stove and its operation, and a great many inquiries are made of my wife every day; and I have no doubt but that there will be a large trade in gas stoves in the future.

Mr. Neal—Has your stove a funnel leading into the chimney?

Mr. Thomas—No, sir; it just sets out in the laundry.

Mr. Neal—Has it a water-back?

Mr. Thomas—It has a water-slide on one end.

Mr. Neal—Can you heat water for bathing purposes?

Mr. Thomas—No, it does not heat enough water for that. It heats enough for cooking purposes, but not for bathing purposes.

The President—We have disposed of our order of business, and it is now for the Association to determine whether the present session shall be longer continued.

Mr. Neal—There is no other business upon the Secretary's table.

Mr. Harbison—Before we adjourn I would like to ask if there is any gentlemen present who will state what their experience has been in the use of scrubbers in place of condensers? The impression is that everybody knows all about it; but I am so unfortunate as to know very little about it.

The President—That would open a large field for discussion, and the time for adjournment is very near.

Mr. Neal—I would state that there are several of the members who are anxious to get away, and to try the sense of the meeting I move that we adjourn *sine die* at a quarter past twelve to-day.

Carried.

The President—Before we adjourn I would again urge on the members of the Association the desirability of bringing to our next meeting as exact statements as possible. Keep them in some portable shape, put them in your pockets and bring them along. Our friend Mr. Cabot has set us an example in this respect which I hope we will all follow. When we refer to our experiments, it is certainly much more satisfactory, both to ourselves and the Association, to be able to give exact information, than it is merely to make a general statement from memory. Such a statement does not carry with it the weight that a direct reference to our figures does. I hope you will all try, in your experiments this year, to keep an exact record of the results, and give us those exact records, and not a statement from general recollection; and I think we shall all be pleased with the enhanced interest that such a course, if adopted, will give to our meetings in the future. (Applause.)

Mr. Wood—There is one little matter that has occurred to me that I would like to speak of before we separate, which perhaps may be of some

[From London "Journal of Gas Lighting."]

Experiments in Improved Street Lighting at Birmingham.

On Wednesday last, at the invitation of Mr. Charles Hunt, Engineer of the Birmingham Corporation Gas Department, a number of gas engineers, principally from the Midland Counties, and others interested in the subject of improved street lighting by means of gas, assembled at the Winsley Street works of the Corporation, for the purpose of viewing a collection of lanterns and burners of large power which had been got together by Mr. Hunt for the purposes of comparative trials of their efficiency. Among those who were present were Messrs. J. Annan, Wolverhampton; T. Arnold, Borough Surveyor's Office, Birmingham; J. C. Bent, Birmingham; G. Bray, Leeds; T. Collett, Dudley; W. Cross, Leamington; W. Davis, Hereford; J. Denkes, Worcester; A. Dougall, Kidderminster; H. Hack, Saltley; T. Jackson, Birmingham; Wm. King, Liverpool; T. Layton, Redditch; J. Mealie, Burton-on-Trent; W. North, Stourbridge; G. Parker, Oakengates; R. O. Paterson, Cheltenham; J. Peaty, Burslem; H. S. Pike, Hinckley; T. Proud, Birmingham; J. S. Reeves, Bilston; J. Reid, Derby; T. Roberts, Sheffield; P. Simpson, Rugby; S. T. Stonebridge, Saltley; J. Slocombe, Birmingham; E. Smith, Secretary of the Corporation Gas Department; J. Stone, Stafford; W. Sugg, London; C. Taylor, Derby; J. Tindall, Walsall; W. Whatoley, Newcastle-under-Lyne; H. Woodall, Leeds; J. Wright, Birmingham, etc., etc.

The burners and lanterns were arranged in different parts of the works, the more important ones being placed at distances of about sixty yards from one another on a large tract of unoccupied land to be eventually used for extensions. By this means the effectiveness of the burners was easy of comparison, and much satisfaction was expressed at the completeness of the trials. Appended is a list of the burners and lanterns used, showing the consumption of gas by each burner, the illuminating power afforded (when tested in the photometer room) and the illuminating power obtained per foot of gas consumed.

After a long inspection of the various lanterns and burners, tests were made by a shadow meter between Sugg's 200-candle Argand (No. 9) Bray's 200-candle Quadruple Batswing (No. 10), and the burner and lantern as used by the Paris Gas Company in the Rue du Quatre Septembre (No. 12), with the results shown on the diagram. These appear to agree pretty nearly with the photometrical results obtained from each burner, as shown in the preceding table.

On Thursday evening another trial was made between the burners Nos. 9 and 10 on the diagram. The consumption of gas in each was raised to exactly 46.75 feet per hour; and the lights were shown to be equal when the shadow meter was 73 ft. 2 in. from Bray's Quadruple Batswing, and 76 ft. 10 in. from Sugg's Argand.

It should here be mentioned that the Superintendent of the works, Mr. Alfred Colson, rendered very efficient service in conducting these tests; in fact, to his able assistance Mr. Hunt is considerably indebted for the success which has attended the experiments all through.

The lamp-columns adopted by the Gas Committee to be erected in various parts of the town, which have been specially designed and made for the Corporation by Messrs. Hart, Son, and Peard, of London and Birmingham, were much admired for their substantial yet ornamental and effective appearance.

At the close of the inspection refreshments were served, after which

Mr. Henry Woodall proposed a vote of thanks to Mr. Hunt for affording those present an opportunity of witnessing the interesting experiments that had been carried through so successfully, remarking on the careful and judicious arrangements that had been made for a fair and equitable comparison to be instituted between the various systems for public gas illumination now before the public.

Mr. R. O. Paterson seconded the proposal, which was carried by acclamation.

Mr. Hunt, in returning thanks, expressed the pleasure he felt at seeing so many present. It might, he said, be desirable that he should offer a word or two of explanation as to the circumstances under which the exhibition had been brought about. These experiments were initiated some fourteen months ago by the Chairman of the Gas Committee (Alderman Chamberlain, M. P.), who was desirous of showing in Birmingham what could be done with gas in the way of street lighting, as compared with electricity. His (Mr. Hunt's) instructions were comprehensive and, he might say, liberal. He was to procure not only the most suitable burner, but also a lantern capable of diffusing the light to the greatest possible extent, and, at the same time, one that should, with the column, contribute rather to the ornamentation of the street than otherwise. As they all knew, the question of the burner involved considerations apart from the illuminating power obtained; but his experience was that the proper form of lantern was a far more difficult matter. He might take this opportunity of acknowledging his obligation to the Gas Committee for the indulgence they had shown him with regard to the length of time the experiments had taken. It was not contemplated by anyone that they would last so long; but he felt, with the Committee, that they should, as far as possible under the circumstances, impress the character of permanence upon their work. How far they had succeeded in their aims was seen that night; but their experiments, at all events, proved one thing—that gas could hold its own for effectiveness with the electric or any other light.

The London *Metropolitan* comments as follows upon the results given below:

It would certainly appear from these figures that Mr. Sugg comes off first. We are informed that the tests of the 200 candle burners of the two manu-

Alfred Clough, tendered very efficient service in conducting these tests; in fact, to his able assistance Mr. Hunt is continually indebted for the success which has attended the experiments all through.

The lamp-chimneys adopted by the Gas Committee to be erected in various parts of the town, should have been specially designed and made for the purpose, as those at present in use are quite unsuitable.

From Lecture—Journal of the Institution of Mechanical Engineers.

Experiments in Improved Street Lighting at Birmingham.

On Wednesday last, at the invitation of Mr. Charles Hunt, Manager of the Metropolitan Corporation Gas Department, a number of gas engineers and others interested in the question of street lighting assembled at the Corporation Testing Station, Aston Park, to witness a series of experiments which had been arranged for the purpose of testing the comparative merits of the ordinary fish-tail burner and the Sugg "London" burner, when consuming the same quantity of gas per hour. The experiments were conducted in the presence of Mr. Alderman Avery, Mr. Councillor Martineau, Mr. Councillor Cook, Mr. Councillor Hawkes, Mr. Councillor Hill, Mr. Councillor Hughes, Mr. Councillor Pumfrey, Mr. Councillor Wilkes, Mr. Councillor Wilkinson, Mr. Councillor Yeomans, Mr. Councillor Yeomans, jun., Mr. Councillor Yeomans, jun., Mr. Councillor Yeomans, jun.,

of the inhabitants. He thought it was too much to give the whole of the balance for public improvements.

Bailie M'Gown said it was quite clear that if they adopted the Chairman's suggestion, they would never have any more public improvements at Paisley. The framers of the Corporation Act of 1859 and Provost Murray, who was a shrewd and sagacious man, would surely not have put in a clause such as the last one, which had been quoted, unless they had some expectation of a limit being set for public improvements. It was unreasonable to speak of giving the £1500 to pay off a portion of the late extension of the works that had an interest to capital. In the year 1869, for instance, there was a surplus from the Gas Trust of £2576, which was positively more than they now spoke about. The interest forward was £23,000, as against £15,000 in 1875, and in 1871 the interest was £19,000, and the price was raised to the same tune. It was said that large consumers of gas were paying for the public improvements. He submitted that this was not the case. He found that generations past had paid very high prices for gas, and it was one of the prizes thus paid that the works were in such a splendid condition. The price now was 3s. 2d. per 1000 feet, and he submitted that they were able to sell at that price in any community in Scotland. He found in Dundee the price was 3s. 6d., in Edinburgh 4s. 6d., Aberdeen and Greenock 3s. 9d. each, Stirling, 4s. 5d., and Kilmarnock, 4s. 7d. The only town where it was 3d. less than they were was Dalkeith, but that gas was only equal to 22 or 23 candles, which was not to be compared to theirs.

Treasurer Russell: There is one other point.

Bailie M'Ewen: Gladstone; but the successors are for its services-pages from the Company's mains. He had no sympathy with the Chairman's views. He thought they were in danger as servants of discovering in the mind that the gas undertaking was the best property connected with the Corporation. Assuming that the £1500 paid for gas-works as a recess session £150,000, while it was admitted that their own works would be worth about annually now not £1000 to redeem the debt, they gave cheap gas at the same time, it seemed to him in accordance with the Corporation Act of 1859, which said that they might supply some of the profits for public purposes. The clause was put by Bailie Clark no doubt said that extensive public improvements were to be carried out for that; but he felt that there was spirit in an Act as well as letter, and he felt that there was spirit in the Act was clearly that if the works were kept up in a thoroughly efficient and if the gas was cheap, they could use the surpluses to some extent for public purposes. In these circumstances he moved that they should carry out the Act of 1859, forward.

Treasurer Russell said the Chairman had raised the price of gas as well as the surplus £1000. He had not told them the facts of the case that the consumers of gas had paid which had gone for the extension of the works and the redemption of stock. Under the joint management, from 1845 to 1870, 598,900 tons of coal were consumers of gas, which went to increase the works and to redeem the debt. Since 1870, when the Corporation obtained the management of the works, they had paid over £17,726, which was made in all £417,626, for interest, and redemption of stock and loans of that interest; and he thought the public ought to know the basis of that interest. If they gave gas at 3s. 2d. per 1000 feet, they would have a surplus of £4000 on that gas at 3s. 2d. per 1000 feet, they would it? He had no objection to the Chairman's proposal, but what were they going to do with moved, but he wished it taken off the charge of gas, thus making it the 6½d. Supposing they did this, they would still have a surplus at the end of the year, which would make £3500; if they did not touch at £1500 towards paying off the debt, they would have still £3000 of a surplus, and he was of opinion that the £1500 be added to it.

Bailie Steven supported Treasurer Russell, as he did not see why they should not give the consumers the benefit of cheap gas.

Mr. Robertson thought the first thing was to say what was to be the price of gas in the future, and then whether there was to be with the present surplus of £1500. He considered the whole amount of the surplus should go back to part payment of the other parties of the works for the time, and finally to surplus went the way indicated. He thought they should not do anything for posterity. Finally, he strongly supported the resolution moved by Bailie M'Ewen, that the £1500 should not be voted for the reduction of the debt incurred in connection with the past extension of the works, but should be set aside. He intended afterwards to give notice of motion that £150 of the surplus be allocated to extinguish the debt on the Feuls Part.

In reply to a question,

The Chairman said his motion was that the £1500 be applied for paying off the debts incurred in extension and maintaining the works as required by section 2 of section 85 of the Corporation's Act of 1859, while Bailie M'Gown's amendment was that the surplus be not dealt with in the meantime.

A motion to delay the further consideration of the matter was then agreed to, Treasurer Russell saying he would, on the debtor balance reduced,

OLDHAM CORPORATION GAS SUPPLY.

From the last annual report of Mr. Herbert Andrew, the Superintendent of the Oldham Corporation Gas Department, it appears that during the twelve months ending March 25, the expenditure on capital account was as follows:—

Higginshaw gas station	£4292 11 7
Hollinwood "	177 9 10
Gas-mains "	1970 15 11
	£6442 0 4

The amount of gross profits was £25,869 19s. 10d., and after paying thereon the annuities, the interest on investments, and £3219 to the sinking-funds, there remained a net profit of £16,650 19s. 7d. From this surplus it has been resolved to pay the sum of £15,000 to the borough fund, leaving a balance of £651 12s. 7d. for disposal.

The price charged for gas was 3s. 2d. per 1000 feet, with discounts, as in Bolton, varying with the consumption "within the meaning of the borough," and "beyond the municipal borough, but within the limits of supply," and "beyond the limits of supply" respectively.

The quantity of gas manufactured was as follows:—

Oldham gas station	125,869,000 cubic feet.
Higginshaw "	10,167,000 "
Hollinwood "	10,190,000 "
Royton "	37,114,000 "
Total	183,335,000 cubic feet.

Against 167,631,000 cubic feet in the preceding year; and the quantity of coal and cannel carbonised in its manufacture was 48,510 tons, the latter being an increase during the year of 1427 tons 12 cwt. The average quantity of gas made per ton of cannel and coal carbonised was 9571 cubic feet. The quantity sold during the period was 157,061,000 cubic feet, against 143,630,000 cubic feet in the previous year, or an increase of 4·707 per cent. The loss from leakage and unaccounted for was 27,170,000 cubic feet, or 7·851 per cent. of the quantity delivered. The maximum quantity delivered in 24 hours was 2,250,000 cubic feet on Dec. 22, and the greatest pressure was 2·875,000 cubic feet. The average illuminating power of the gas was equal to 16·35 candles, the standard in the Corporation Act being 14 candles.

During the past year 1731 new meters were fixed and 1248 consumers' meters were removed, leaving a net increase of 483 meters, and the number of consumers is 30,921. The length of gas-mains, and the number of engagements, and removals was 19,950 yards, and 1000 in extension; and 1,000 yards of public lamps within the district of supply is now 5296, being an increase for the year of 82. There are now 3000 public lamps within the municipal borough, and 771 in the out-townships.

The total amount of capital borrowed on the 25th of March was £230,550, with unexhausted power to borrow £19,450; while £16,950 has been redeemed from the sinking-funds since the Corporation Act of 1853 was passed.

The capital account shows that the sum of £190,000 is debited as the cost of the transfer of the old Company's undertaking on the 31st of July, 1851—viz., the value of the mains, meters, and pipes, as per the Company's books at the time of purchase, £99,153 10s. 8d., and amount paid for goodwill to the Company, on estimating the annuities at 27 years' purchase, £90,901 7s. 4d. To this there has been expended, at the Corporation valuation of the 25th of the 31st, mentioned above, £3219 12s. 8d., £1,000 out of the revenue account was as follows:—

Manufacture Account.

Manufacture of gas—*Extract from Account for the Year ending March 25, 1880.*		
Cannel and coal, including carriage, unloading, &c.	£12,802 17 2	
Lighting and stoking retorts	2,403 19 0	
Repairs of retorts and settings	1,021 13 4	
Rent of retort-house	262 2 6	
Salaries of Manager and indoor-staff of station	87 0 0	
Wages (carbonising)	1,284 7 0	
Oxides and purchase of waste and of gas, &c.	3,096 3 7	
	7,294 3 1	
Distribution of gas—		£25,953 12
Salaries and wages of Officers and Rental Clerks	£1,421 11 7	
Repairs, renewals, and removal of mains and of service-pipes (less old material sold, £302 10s. 10d.)	1,142 12 10	
Inspection of meters	1,241 17 8	
Services, meters, &c.	2,591 17 7	
	6,397 19	
Rents, rates, and taxes		3,371 2
Management—		2,455 1
Salary, Superintendent and Clerks	£707 1	
Do., Collectors	1,000 0	
Proportion of Town Clerk's and Treasurer's salaries	391 2 6	
Stationery, printing, advertising, and stamps	229 17 6	
General establishment charges and incidentals	126 9 4	
	2,454 10 4	
Less expenses, coal-gauge, &c.	1,251 7 9	
Bad debts	1 11 0	
	2,253 1 1	
Balance carried to profit and loss account	27,349 10 10	
	£59,581 7 7	

Gas—Revenue Account.

Sale of gas—		
Gas per meter to private consumers	£56,586 11 3	
Gas for public lamps	1,993 15 11	
	£58,580 7 11	
Less discount	1,000 0 0	
	£57,580 7 11	
Residual products—		£57,580 7 11
Coke (less labour, £727 10s. 6d.)	£1,650 2 11	
Tar and farm sales	511 17 1	
Ammoniacal liquor	3,151 9 1	
	5,313 9 1	
Rent of meters	19,585 3 10	
Fittings, repairs, &c.	1,000 0 0	
Services, rentals, &c.	201 6 11	
	3,877 13 10	
	£29,781 7 7	

In the appendices to the accounts, interesting information is given as to the number of new consumers added, and the sizes of meters fixed, in the different months of the past year; as to the mains laid and taken up during the same period; as to the gas manufactured and consumed from July 31, 1855, to March 25, 1880; and as to the gross profit made, and the sums of its appropriation, from 1855 to the present year.

A Corporation Official convicted of Embezzlement.—At the Manchester Summer Assizes last week, Frederic Hopton, aged 40, late chief clerk and cashier in the Water-Works Department of the Manchester Corporation, was charged with embezzling the sum of £1 10s. 6d., and other sums, various amounts, the money amounting in all to nearly £1000, the property of his employers. After a protracted trial, he was found guilty, and sentenced to ten years penal servitude.

but it is at least final and comprehensive, and we are fast becoming strangers to the multitudinous and very shallow devices in taxation with which our Continental neighbours are yet afflicted. A complex organisation such as a gas undertaking offers a ready field, in the multiplicity of its belongings, for experiments in that kind of taxation which is akin to the method of raising money known to the impecunious as "kite-flying;" but as long as Governments have to provide for vast expenditures without daring to ask the taxpayer openly for the revenue they require, we must expect to see continued manifestations of this peculiar description of misapplied ingenuity.

The Silvertown magistrates have recently had occasion to clear up a doubt which seems to have prevailed in that neighbourhood respecting the liability of carts loaded with refuse gas lime to pay toll on passing over turnpike roads. As it was not disputed that manure of any kind is transit for use in agriculture is exempt, it is difficult to see how such a well-known manure as foul lime could have been considered subject to toll by any one other than an over-officious gatekeeper. An effect was, however, made to show, in defence, that as lime is not always exempted from toll, the particular compound in question lay at least in debatable ground; but this ingenious contention was overruled on the broad commonsense principle that the material was in fact manure, and was only intended for use as such. Therefore the toll-gate keeper will interfere no more with the free transit of farmer's carts as they remove the rejected material of the purifiers of the Silvertown Gas-Works.

The Sutton Town Council have been charged more than once of late with reckless extravagance in respect of certain proceedings to which they have committed themselves, notably in connection with the enclosure of open spaces, making new roads, and similar works, for which, as alleged, they are rendering the present generation of ratepayers fat for the prospective benefit of their descendants. So deeply has the sense of their excessive generosity in those matters sunk into the popular mind, if the local press may be credited, that at the next municipal elections will probably be returned a new set of candidates pledged to "economy and retrenchment." The growing discontent has already found expression in the choice few of the present Councillors to return to trim their sails to this rising gale. Hence, the speaking depu on themselves no little public odium Town Councillors hope to turn at least a portion of their prospective unpopularity to account. The gas undertaking—and endeavour to show, in connection with it, that the present instance the chance of making economy soon revealed itself. The Sutton gas over a district of forty square miles ill-provided with means of conveyance prising that the Engineer, who was a personal supervision over this extens down to his assumed his duties, the ex "and trap." This, however, was denie proving rather costly, the Gas Committ him an allowance for travelling expen choice of conveyance. This is the outlay the economic sensibilities of a few sad Council. An undertaking returning a pr amount to operations conducted over a it is said, leer an expenditure such as t by a parish doctor. And the moment exhibition of cheese-paring is the cause reduction in the price of gas, still leaving anticipated increased profit. And the un endeavoured to show some appreciation o man who is officially responsible for keepi its legs, is to put him on full pay, making

The statistics of the Oldham Corporat which we publish some extracts in anot good margin of profit on the past year's w while if the disposable balance, or a n having been added to the respectable t taken from the gas profits and applied i Much detailed information of a general ch the various accounts and tabular statemen report; but, as is too many compilations form which fails to give them the inter comparison with results obtained elsewh have been secured with very little ext methods of analysis practised by Mr. Fle the accounts of the Metropolitan Gas Co Loss, or even the more exhaustive redu

The members of the Société Technique de l'Industrie du Gaz en France—the French equivalent for our Gas Institute—Association of Gas Managers—have just had their "Congress," which was opened with a very interesting address by the President. M. Jordan, as stated by himself, is connected with the iron industry quite as deeply as with that gas, and by virtue of his semi-independent position he claimed the right of being heard as an unprejudiced observer on the question in view of the competition which at this time, more than ever, is forced upon it by its many rivals. The address, indeed, was chiefly concerned with this important subject, upon which the President's judgment was eminently calculated to reassure his hearers. But besides the vindication of those concerned in the manufacture of gas from the charges which the advocates of rival systems of lighting level against them, in France as elsewhere, there were portions of his address which offer much food for reflection to sympathising and interested outsiders. For instance, in the allusions made to the various devices by which gas undertakings in France we obtain instruction illustrative of the extraordinary propensity of the French bureaucracy for raising, by indirect and roundabout means, money which, by the way, they appear just as willing to expend in a similar manner, if we may judge from the latest proposal to subsidize French steamship owners, with the ulterior object of fostering a native merchant service. It gives one an impression that in following out this general idea of taxation, the French authorities hold the belief that money so raised comes into existence by some special creation, instead of out of the pockets of the people, and that they think the long-suffering trader is in ignorance of the extent to which he is victimized by his rulers, just because he cannot precisely tell how and where the money goes. We are seldom at a loss to comments upon a proposal for levying a tax upon gaslighters, at the rate of 20 centimes per cubic metre consumption, irrespective of the tax payable on the gross value of all plant and utensils, and a separate rate on all mains and pipes which are laid under any public highway. Our own system of valuation for the relief of the poor is frequently oppressive, inefficient in many respects, and obstructive of improvements; but it is not to be compared with the French system, which is based upon the principle that the more a man spends in improving his property the more he shall be taxed for the privilege of doing so. Of course, the proposal is not likely to be carried out in its entirety, but the fact that it has been made at all is significant of the tendency of French financial ideas.

M. Jordan, as stated by himself, is connected with the iron industry quite as deeply as with that gas, and by virtue of his semi-independent position he claimed the right of being heard as an unprejudiced observer on the question in view of the competition which at this time, more than ever, is forced upon it by its many rivals. The address, indeed, was chiefly concerned with this important subject, upon which the President's judgment was eminently calculated to reassure his hearers. But besides the vindication of those concerned in the manufacture of gas from the charges which the advocates of rival systems of lighting level against them, in France as elsewhere, there were portions of his address which offer much food for reflection to sympathising and interested outsiders. For instance, in the allusions made to the various devices by which gas undertakings in France we obtain instruction illustrative of the extraordinary propensity of the French bureaucracy for raising, by indirect and roundabout means, money which, by the way, they appear just as willing to expend in a similar manner, if we may judge from the latest proposal to subsidize French steamship owners, with the ulterior object of fostering a native merchant service. It gives one an impression that in following out this general idea of taxation, the French authorities hold the belief that money so raised comes into existence by some special creation, instead of out of the pockets of the people, and that they think the long-suffering trader is in ignorance of the extent to which he is victimized by his rulers, just because he cannot precisely tell how and where the money goes. We are seldom at a loss to comments upon a proposal for levying a tax upon gaslighters, at the rate of 20 centimes per cubic metre consumption, irrespective of the tax payable on the gross value of all plant and utensils, and a separate rate on all mains and pipes which are laid under any public highway. Our own system of valuation for the relief of the poor is frequently oppressive, inefficient in many respects, and obstructive of improvements; but it is not to be compared with the French system, which is based upon the principle that the more a man spends in improving his property the more he shall be taxed for the privilege of doing so. Of course, the proposal is not likely to be carried out in its entirety, but the fact that it has been made at all is significant of the tendency of French financial ideas.

facts into ratios and abstract data, as may be observed in many of the papers of Continental Gas Companies which we publish from time to time, were more generally copied by the accountants who prepare for publication the reports of our important provincial gas-works, a great benefit would be conferred on the members of the profession at large.

It is with surprise that we learn from some of the American papers that Mr. Edison's incandescent lamps, the wonderful carbon burners of which we have heard so much, have actually been improved upon by another inventor—Mr. John H. Guest, of Brooklyn. There appears to be no room for doubt respecting the reality or value of the improvement, which consists in sealing the connecting wires in mercury at the point where they pass into the exhausted interior of the lamp, and so surmounting the difficulty which has troubled Mr. Edison, of air leaking in through crevices in the glass and destroying the vacuum. This is very satisfactory so far, but how comes it that such a simple expedient was left to an outsider to introduce? This improvement, it is true, is not of such a character as to place the horseshoe lamp at once and for ever on the pinnacle of practical success, to do which, indeed, would require alterations of far greater sweep; but that an improvement, however small, should be possible upon anything emanating from Menlo Park, is another melancholy proof of human imperfection. The lesson is but an old one to us, but it is necessary to be reminded of its truth, after the repeated efforts of newspaper correspondents and other (dis)interested witnesses to demonstrate that it did not apply to the case of the great inventor.

According to Mr. J. S. Sloane, M.I.C.E.I., late Engineer to the Commissioners of Irish Lights, the introduction of gas for the use of lighthouses is seriously hampered by the great disadvantage that has been imposed on them by the authorities who are charged with lighting our coast line of dwelling to burn gas at some of their most important stations, they would have taken care to supplement the special burners constructed for that purpose with suitable lenses, in order that no part of the available illuminating power should be misdirected or lost; but it appears that this was not done, and, as a consequence, Mr. Sloane is of opinion that gas has not in this connection received full justice. No one, however, will be surprised to hear from the same authority that the electric light, when tried for lighthouse purposes, has had every encouragement that science and art can give to make it practically successful, although, after all, Mr. Sloane has only qualified praise to give to it. On the different grounds of reliability, clearness in foggy weather, steadiness, and economy, he contends that gas is infinitely preferable to the electric light for lighthouses, even with the unequal conditions under which the two systems have hitherto existed, while expressing himself as unable to imagine what would be the effect of the largest and most perfect gas-burners, if fitted with properly-prepared lenses. That such observations as these should be possible is anything but creditable to the authorities in question; and we may be absolved from the charge of contending for the interests of gas alone in expressing the hope that in all cases, whatever system may be employed in lighthouses, suitable apparatus for enabling the light to do its duty to the full may not be lacking. Mr. Sloane has described the principle on which he would construct lenses for gas-burners, the possibility of making appliances of this kind to meet any requirements is not disputed; so that, now the evil which has arisen from a perhaps inadvertent application of ellipsoidal lenses to Mr. Wigham's burners has been publicly exposed, we may expect to see it remedied.

Ever since the development of the various manufacturing processes involved in the production of wrought iron, which resulted in the application of that material to the multitudinous uses with which it has been associated in modern times, efforts have been constantly made to remove one of the greatest practical drawbacks to its continuance in strength, utility, and beauty—namely, its tendency to rust. It is too well known that wrought iron is no sooner turned out of the manufacturer's hands than it begins to decay from this cause, and nothing hitherto discovered, by way of preventive treatment, during manufacture or after, has availed to thoroughly preserve it in its pristine state. Galvanising with zinc has for long been a favourite device for protecting a certain class of wrought-iron goods; but its application is limited, it is costly, and not always desirable. Platinising has also been warmly advocated as far preferable to galvanising for the same class of articles. And now the latest device, although one not particularly novel in principle, is that of coating iron with a film of its own magnetic oxide, which has been brought under general notice by Professor Barff and Mr. George Bower, of St. Neots. Although the same end is arrived at by the two systems followed by Professor Barff and Mr. Bower respectively, the means adopted in each are quite different. Barff's may be described in brief as a steam process, the oxidizing agent employed to produce the peculiar action before mentioned on the surface of the iron being superheated steam; while Bower's process consists in subjecting the iron to be coated to carbonic oxide flame, with an excess of hot air. In both cases the result is the formation of a thin film of magnetic oxide of iron, adherent to the wrought-iron articles subjected to treatment, and this film is not susceptible of deterioration or further change in presence of influences which would speedily destroy ordinary metallic coats. With the relative advantages of the two processes named we need not at present concern ourselves, for if the principle can be constantly secured with extended success, the survival of the fittest will be observed in this as in every other contest, and the system which is most reliable and the cheapest will be most successful. We may, however, state a few considerations on the general subject. In the first place, it will be observed that, as with galvanizing, there exists a great class of subjects to which the oxidizing process will not apply. Nothing, in short, that cannot be put into an oven can be treated by either a steam or a dry method of oxidation. The plates and bars for large iron structures may, indeed, be so treated, wherever there is no subsequent manipulation—such as hammering, welding, rivetting, and the like—to be gone through. When any rough usage of this kind is necessary, no method of precious surface treatment will avert rusting. Hence for gasholders, &c., it is to be feared that the paint-brush must still remain the great preserver. But, of course, there is an enormous scope for the peroxide process, even if the hitherto subjects are excluded from its range, and in its proper field it may be found to yield results equal to the highest expectations of its friends.

EXAMINATIONS IN "GAS MANUFACTURE."

The list of the successful candidates in the examinations held throughout the country last May, under the auspices of the City and Guilds of London Institute for the Advancement of Technical Education, has just been published. The following table, in reference to the examination in the "Gas Manufacture" section, is compiled from the pass list:—

	Class of Certificate.	Prizes.	Previous Successes.
Honours Grade.			
Blair, Thomas . . . . . London	First.	First Prize, a Silver Medal and £5 . .	1879. Advanced First, with First Prize of £7.
McIlwaine, Neill . . . . . Houghton-le-Spring	First.	Third Prize, a Bronze Medal	1878. Elementary First, with First Prize of £5.
Hulse, William W. . . . . Burslem	Second.		
Marquis, William Thomas. . Rochester	Second.		
M'Gillivray, Hugh . . . . . Edinburgh	Second.		
Advanced Grade.			
Hall, John Ferguson . . . . Liverpool	First.	First Prize, a Silver Medal and £3 . .	1873. Elementary First.
Heath, William Robert . . . London	First.	Second Prize, a Bronze Medal and £1.	1879. Elementary First.
Hogg, John . . . . . London	First.	Third Prize, a Bronze Medal	1877. Elementary First, with First Prize of £5.
Akroyd, Benjamin . . . . . Halifax	First.		
Axon, Samuel Taylor. . . . Leicester	Second.		
Baines, William T. . . . . London	Second.		
Dransfield, John . . . . . Oldham	Second.		
Plumbe, Hilary E. . . . . London	Second.		
Shellabear, Charles . . . . Houghton-le-Spring	Second.	. . . . .	1879. Elementary Second.
Sheard, John Tomlinson . . . Batley	Second.		
Elementary Grade.			
Lewis, Benjamin A. . . . . London	First.	Second Prize, a Bronze Medal and £3.	
Dempster, Alexander. . . . . Halifax	First.	Third Prize, a Bronze Medal.	
Davies, Francis James . . . . Bilton	Second.		
Jones, Richard Rees . . . . Wolverton	Second.		
Lovatt, George Thomas . . . Wolverton	Second.		
Mellor, John . . . . . Oldham	Second.		
Morris, William Walter . . . Jarrow-on-Tyne . .	Second.		
Plant, Joseph. . . . . Wolverton	Second.	. . . . .	1879. Elementary Second.
Wilkinson, Harry . . . . . London	Second.		

YEOVIL GAS COMPANY.—The annual general meeting of this Company was held yesterday, when the Directors reported that the works were maintained in good order. The profit for the year ended June 30 amounted to £1097, which allowed of a dividend being paid of 10 per cent. This would absorb £1462, leaving £365 to carry forward. During the past year the Company have carbonized 2121 tons of coal and cannel, making 21319 lbs. 2d., and produced 10,841,00 feet of gas, of which 1,247,000 feet were supplied for private lighting, and 1,380,000 for public lighting.

THE GLOBE.—Mr. Walter Morris, "Special Correspondent" of the *Globe*, writing from Sheffield, Warren County, Penn., U.S., says: "The most wonderful part of Sheffield is a natural gas well. The gas from this well is used in the furnaces of the tannery of Horton, Crary, and Co., and runs the machinery; it also lights all the houses in the town, being brought in iron pipes 3 miles from the well. It was discovered in boring for petroleum. Escape-pipes have been run up to a height of some 50 feet, and the huge flames from these pipes flare away day and night, and have done so for the last five years. The daily amount given off is estimated at 3 millions feet. The gas was found at a depth of 1500 feet, and blew all the boring machinery out of the well. The pressure is so great when turned full on that the gas blows itself out. But it is not like the ordinary coal gas, but more like petroleum. There is little doubt that put into use the edge of the whole field, and probably, all the land near is underlaid with oil. The amount has not been found to lessen, nor the pressure diminish in the whole five years. It seems rash waste to see these six or eight escape-pipes flaming away day and night, as they have done for the last five years. How long they will go on no one can tell, but at present it looks as if for ever. At present they have no purchasers, as not utilizes the gas except on the spot. There is, however, a well just successfully sunk at Clifton, 7 miles from Sheffield, and there is little doubt but that others will be found in the neighbourhood."

EXHIBITION OF GAS AND ELECTRICITY.

ARRANGEMENTS are in progress under the auspices of the Philosophical Society of Glasgow, for holding in that city an exhibition of a very interesting character during the four weeks commencing 28th September. In many respects it will be like the Exhibitions of Gas Apparatus that have been held in many towns throughout the kingdom during the past three or four years, but it will be of a much more comprehensive character, inasmuch as it promotes, amongst other things, aim at bringing together in one building thus illustrations of all the most recent developments in the use of electricity as well as of gas for lighting and other purposes, in order that there may be made a most thorough comparison in respect of the efficiency and economy of those two agents, and of the various electrical systems with each other. The Exhibition will be held in a large drill hall and grounds on one of the main tramway lines, and, if necessary, annexes will be erected. The range of subjects to be illustrated by the Exhibition will include apparatus, appliances, models, or drawings that relate to, or illustrate any of the following, namely:—

Coal Gas.—The manufacture, purification, storage, distribution, regulation, measurement, and measurement. Its utilisation in lighting, heating, cooking, ventilating, and as a motive power. Photometrical testing of gas or other sources of light. Residual products of gas manufacture, coke, tar, benzole, aniline dyes, ammonia salts, &c.

II. *Oils, Oil-gases, Candles.*—Their manufacture and use for lighting, heating, cooling, and motive power.

III. *Electricity.*—Its generation and application for lighting, telegraphy, motive power, &c.

IV. *Hydraulic Appliances.*—Meters suitable for comparison with gas-meters, and apparatus for the measurement and regulation of the flow and pressure of water.

V. *Architectural Appliances.*—More especially those which relate to lighting, ventilation, heating, and lightning conduction; and architectural brasswork and sanitary appliances, such as can be exhibited in the open grounds.

VI. *Miscellaneous Appliances.*—Gas-lighted buoys, fog-horns, miners' safety lamps, fire-damp indicators, and apparatus for lighthouse illumination, ventilation of mines, &c.

Awards for merit are to be given in such classes of the Exhibition as the committee and exhibitors may arrange to be tested, and other exhibits as may possess very special merit. There will be a supply of gas and water provided by the committee for the Exhibition through the co-operation of the Corporation gas and water commissioners. The gas has an average illuminating power of twenty-six standard candles, and the water pressure will probably be 56 lb. It is intended to supply sufficient motive power by the gas and other engines that are exhibited in action. Amongst our readers there are doubtless many who may take an interest in this exhibition, the offices of which are at 154, St. Vincent Street, Glasgow.

WESTMORELAND COAL ENRICHED WITH ALBERITE, NEW HAVEN, 1869.

Hydrogen	42.47
Marsh gas	46.16
Carbonic oxide	5.09
Carbonic acid	—

Hydrogen	43.15
Marsh gas	42.97
Carbonic oxide	6.06
Carbonic acid	0.36
Oxygen	0.12
Nitrogen	2.05
Hydrocarbons	5.29

In addition to these ingredients, obscure compounds of sulphur with hydrogen, sulphids of carbon and ammonia salts are found in the gas, and may, in large quantities prove highly objectionable and mischievous. Illuminating gas is therefore composed, first, of a series of non-illuminating but highly combustible gases, which together form a burning fluid whose sole office is the supply of heat; second, a group of hydrocarbon gases, yielding upon combustion more or less light; third, diluents whose influence is deleterious directly proportional to the percentage present; fourth, impurities.

The first group consists of hydrogen, marsh gas, and carbonic oxide, and upon the proportions of these bodies present in the gas depend some important features. They regulate the degree of heat which the gas attains in burning, and they determine its density in a great measure. Hydrogen is the lightest gas known possesses the highest calorific power, and while assists the buoyancy and vitality of the gas, produces upon combustion high temperature which, as we subsequently see, is not favorable to a pure and whitest light. Its gravity compared with air is 0.693, its calorific power 34,462 units, its calorific intensity is 2,746°C., the latter falling as much below the former, since hydrogen in burning unites with the oxygen of the air, which supports its combustion and forms aqueous vapor, and a certain amount of heat is abstracted from the sum total of heat generated in order to raise the temperature of the water produced.

Hydrogen from its calorific power is pre-eminently valuable in gas, and its percentage in normal coal gas should exceed that of any other ingredient. Not that it may not predominate so as to virtually destroy or effectively diminish the luminosity of the gas, but that within reasonable limits it enables the production of illuminating material in the best way possible. The principle underlying this is the much-discussed, some time discredited and recently rehabilitated doctrine of photogeny propounded by Sir Humphrey Davy. This philosopher insisted that the luminosity of a gas flame was due to the presence in infinite numbers, confined to the luminous zone, of solid points of carbon which become incandescent at high heats. So long as gas flames are concerned this is unquestionably true, and the appearance of soot upon a cold object pressed into a flame, the opacity of the flame itself, at least of its light-giving portions, and the ease with which a small luminous flame can be made luminous by the introduction into it of such solid point, and, so far as it is a practical question, establishes the reality of this theory. Granting this position, there is very evidently a proper proportion to be maintained between the heat produced by combustion of a gas flame and the number of carbon points to be raised to whiteness by that heat. This heat may be obtained by the intimate mixture of oxygen with the flame, and by a large proportion of hydrogen and highly heating bodies which upon burning produce the necessary temperature. The significant conclusions to be drawn from this will be shown further on. It only here indicates the indispensable services rendered by hydrogen in the economy of lighting.

Hydrogen, while it thus, *par excellence*, renders the flame a hot one, imparts lightness to the gas, which permits the ingression to use a reduced pressure for its distribution. Hydrogen, as the lightest body known, diffuses with great rapidity, and a change in the constitution of the gas may take place in long transits from its escape through exotics and minute apertures although they suffer transformation, do so in relatively smaller volumes as the density is greater. The well known experiments of Dubereiner and Graham upon the diffusion of gases showed that through the finest cracks in the walls of a vessel, even though pressure was exerted by the confined gas, the gas will escape and air from without penetrate in its turn within the vessel. The injurious dilution of coal gas by atmospheric air may occur in this way in the works, or out of them in the mains, the lightest elements of the coal gas effecting their escape first and with the greatest rapidity.

Although this consideration has a theoretical value, practically it is not of frequent importance, as leakage of gas from mains, etc., is generally a process of effusion, whereby the gas pours out in an almost homogeneous mass. Marsh gas is the second member of the heating gases; its gravity is 0.557, its calorific power 13,053 units, its calorific intensity 2,630°C. It thus presents a marked contrast to its companion, although it is a non luminous gas excepting a few candles of light claimed for it, and assists in raising the temperature similarly as hydrogen. It is, however, its gravity which renders its presence useful in the coal gas type of gases. It gives body to the gas, a definite weight and texture. It is true we could have a gas in which the burning fluid was wholly hydrogen, and the necessary gravity supplied by increased proportions of hydrocarbons, which would likewise overcome its high heating power, but in the actual economy of coal gas manufacture, hydrocarbons are not abundant, and the marsh gas protects them from a too sudden and complete destruction in so hot a flame as we would have were hydrogen substituted for it, while it makes the gas more manageable to the engineers and more serviceable to the consumer. Marsh gas should not exceed the hydrogen, and should, in fact, be regarded rather as a preservative element than a directly useful one in the gas, where, if its presence is excessive, it raises the gravity of the gas, which in turn necessitates increased pressure, and that reduced luminosity unless compensated for by more or richer hydrocarbons. Neither is it desirable to have it sink below thirty per cent, as in the average percentage of hydrocarbons, its replacement by hydrogen would seriously affect the proper combustion of the latter, as well as inducing costly and needless expenditure of gas by the consumer.

Carbonic oxide concludes the list of heating gases. Its gravity is 0.967, its calorific power 2,400 units, and its calorific intensity 1,970°C. It is a heavy and a highly heating gas. Carbonic oxide may be considered as the latest member of coal gas constituents, and essentially is of no service. It is rather a necessary accident of gas making than a desideratum. The engineer must endeavor to reduce its percentages as low as possible, replacing it with hydrocarbons or hydrogen. Were marsh gas absent carbonic oxide would serve its purpose, securing by its gravity just that stability for the gas which it is the office of marsh gas to supply. Further, it skirts the heating power of the hydrogen, and it thus enables the engineer to increase the hydrocarbons and obtain a higher candle power for his gas.

The water gas is actually plays the same part in coal gas as does coke, and the former marsh gas may be regarded as an accidental and undesirable element, just as the presence of carbonic oxide is an undesired deficiency. Its poisonous properties are well understood, and on sanitary grounds its presence is obnoxious. In reality it is the only organic poison in coal gas, the other gases permitting inhalation, though of course detrimental.

In experiments made by the writer upon a gas containing small quantities of carbonic oxide, and upon a fully charged with that body, the result, 10,000 to 10,205. This body, which is virtually pure carbon, added to a hydrogen flame makes the latter luminous, and exactly similar conditions in the flame from which it was abstracted force us to conclude it was the cause of the brilliancy of the latter. In true coal gas the clelant gas exceeds the other hydrocarbons. But heavy tar vapors exist in well purified coal gas along with the hydrocarbon gases in almost imperceptible quantities, but to an extent sufficient under some circumstances to be annoying by their settling and aggregation in meters, elbows, etc. Naphthalin, a solid hydrocarbon, may be extracted from almost any gas by passage through a glass tube under ice, stuffed with thin discs of tin perforated by a sieve of fine holes. Gas which previously may not have been suspected of containing this crystalline substance yields it upon such treatment. The writer has obtained large deposits of naphthalin crystals resembling the holes made in the tin discs. The presence of solid or semi-solid bodies in gas, as a rule, is objectionable; they burn slowly, are indeed apt to fill through the flame, escape incomplete ignition, and they absorb heat, while they disturb the economics of the flame in their sparkling transit; and in one case known to the writer, irritated weak lungs breathing the air they filled. These hydrocarbons are not supposed to be all contained in the coal of distillation, or at least not to remain unchanged. For instance, [illegible] are formed and exist temporarily at moderate heats, but are decomposed at high heats within the retort chamber. Thus [illegible] found in the Paris gas:

Benzine (in vapor), acetylene, ethylene, propylene, allylene, butylene, crotonylene, terene, and their pyrenes, all of which he regards as formed from the four fundamental hydrocarbons, acetylene, ethylene, dimethyl, and marsh gas, mixing with hydrogen.

Hours after Commencement. Specific Gravity.

	1	2	3	4	5	6
Enilmann	0.6	0.52	0.43	0.37	0.37	0.3
Kombaluit	0.416	0.697	0.353	0.292	0.24	

The second group of gases into which we divide coal gas is that of the hydrocarbons, those high compounds of hydrogen and carbon which impart light to the gas flame when properly burnt, viz., not over or under burnt. These gases are olefiant gas, C_2H_4, propylene, C_3H_6, butylene, C_4H_8, acetylene, C_2H_2, allylene, C_3H_4, benzine vapor, C_6H_6. The principle involved in their supply of light is similar to that in the process by which carbon is deposited in the retorts. At a high temperature these carbons become disassisted, they fall apart into marsh gas and vapor of carbon, and this latter forming a veil of minute points as raised to incandescence on a lower heat by the combustion of the other gases and emit light until destroyed and burnt up into carbonic acid.

The necessity indicated above for a high temperature is shown here, first, because it rapidly decomposes the hydrocarbons, and from certain theoretical considerations probably produces a vapor whose carbon particles are more minute than would result from disassociation at a lower temperature; and, secondly, because the intense heat as rapidly brings them into incandescence. A subsidiary benefit is also gained, since the marsh gas which results from the falling apart of the hydrocarbons, as is well known, if withdrawn from air, decomposes into hydrogen and carbon, and this may also partially take place within the gas flame. It is obvious that were a gas so highly charged with hydrocarbons that the flame became overcrowded with carbon vapor so that the heat would be insufficient to raise it to whiteness, then the light would in consequence become orange or red. The importance of this consideration, as to the high heat required in a gas flame for its best and most satisfactory appearance, is based then upon, first, the belief that the light arises from incandescent particles of carbon; second, that high heat more instantly and, so to speak, more diffusely, splits up the hydrocarbons into simpler elements. As a corollary from this last hypothesis we say the illuminating power of two flames is proportional to the number of their radiant particles at a high heat. In other words, light results from collected masses and velocity; the slower supply one, the temperature the other.

Although the reality of this explanation of the luminosity of flames in general has been called in question, not altogether without reason, yet there seems little cause to doubt that in the case of the gas flame it is entirely just. Carbon is certainly separated, and although in a gas flame the soot deposited on a cold surface is not absolutely pure graphite, practically it is so. That collected by Mr. Evans, when a silver vessel sank two to three millimeters, in the flame of a silk burner, gave a trace of a solid yellow body when treated with benzole, while alcohol and alcoholic chloride and diluted sulphuric acid extracted nothing. This soot when washed gave—

Carbon	95.444
Hydrogen	1.021
Ash	3.527
Oxygen	1.038

The oxygen is supposed to arise from water yet clinging to it, removing which, and disregarding the ash, we may very safely call the composition 95.625, 11 0.205. This body, which is virtually pure carbon, added to a hydrogen flame makes the latter luminous, and exactly similar conditions in the flame from which it was abstracted force us to conclude it was the cause of the brilliancy of the latter. In true coal gas the clelant gas exceeds the other hydrocarbons. But heavy tar vapors exist in well purified coal gas along with the hydrocarbon gases in almost imperceptible quantities, but to an extent sufficient under some circumstances to be annoying by their settling and aggregation in meters, elbows, etc. Naphthalin, a solid hydrocarbon, may be extracted from almost any gas by passage through a glass tube under ice, stuffed with thin discs of tin perforated by a sieve of fine holes. Gas which previously may not have been suspected of containing this crystalline substance yields it upon such treatment. The writer has obtained large deposits of naphthalin crystals resembling the holes made in the tin discs. The presence of solid or semi-solid bodies in gas, as a rule, is objectionable; they burn slowly, are indeed apt to fill through the flame, escape incomplete ignition, and they absorb heat, while they disturb the economics of the flame in their sparkling transit; and in one case known to the writer, irritated weak lungs breathing the air they filled. These hydrocarbons are not supposed to be all contained in the coal of distillation, or at least not to remain unchanged. For instance, [illegible] are formed and exist temporarily at moderate heats, but are decomposed at high heats within the retort chamber. Thus [illegible] found in the Paris gas:

Benzine (in vapor), acetylene, ethylene, propylene, allylene, butylene, crotonylene, terene, and their pyrenes, all of which he regards as formed from the four fundamental hydrocarbons, acetylene, ethylene, dimethyl, and marsh gas, mixing with hydrogen.

Gas and Gas Making.

By L. P. Gratacap, Ph.B.

THE PROBLEM.

Making gas is a mixture of gases whose separate percentages in the retort by the material used, and the degree of perfection to which the process is chemically incline. We are considering gas made by the destructive distillation of coal, and no modification of this process, as coal gas with oil gas, or any novel practice, as water gas. These are reserved for separate treatment.

The ordinary constituents of coal gas and their quantitative relations are given in the following selected analyses.

Fisher's theoretical composition:

Hydrogen	44 to 48
Marsh gas	34 " 38
Carbonic oxide	6 " 7
Carbonic acid	1 " 3
Air	1 " 3
Vapor, temperature 40° to 60°F.	1 " 3
Hydrocarbons	6 " 10

GASWORKS, CHELSEA.

	Manchester Gas.	Rochdale Gas.	London Gas.
Hydrogen	45.58	53.44	50.94
Marsh gas	34.90	29.87	41.99
Carbonic oxide	6.51	6.89	10.27
Carbonic acid	3.07	—	1.10
Air	—	—	—
Nitrogen	2.46	—	—
Hydrocarbons	6.46	10.83	10.81
Sulphuretted hydrogen	0.29	—	—

BIRMINGHAM, GRACE STREET.

	Manchester Gas.	London Gas.
Hydrogen	48.05	51.35
Marsh gas	32.87	35.38
Carbonic oxide	12.93	7.49
Carbonic acid	0.32	0.38
Oxygen	—	—
Nitrogen	—	—
Hydrocarbons	3.37	3.56

Hydrogen (96.625), 0.205, 3.170.

The second group of gases into which we divide coal gas is that of the hydrocarbons, those high compounds of hydrogen and carbon which impart light to the gas flame when properly burnt, viz., not over or under burnt. These gases are olefiant gas, C_2H_4, propylene, C_3H_6, butylene, C_4H_8, acetylene, C_2H_2, allylene, C_3H_4, benzine vapor, C_6H_6. The principle involved in their supply of light is similar to that in the process by which carbon is deposited in the retorts. At a high temperature these carbons become disassisted, they fall apart into marsh gas and vapor of carbon, and this latter forming a veil of minute points as raised to incandescence on a lower heat by the combustion of the other gases and emit light until destroyed and burnt up into carbonic acid.

The necessity indicated above for a high temperature is shown here, first, because it rapidly decomposes the hydrocarbons, and from certain theoretical considerations probably produces a vapor whose carbon particles are more minute than would result from disassociation at a lower temperature; and, secondly, because the intense heat as rapidly brings them into incandescence. A subsidiary benefit is also gained, since the marsh gas which results from the falling apart of the hydrocarbons, as is well known, if withdrawn from air, decomposes into hydrogen and carbon, and this may also partially take place within the gas flame. It is obvious that were a gas so highly charged with hydrocarbons that the flame became overcrowded with carbon vapor so that the heat would be insufficient to raise it to whiteness, then the light would in consequence become orange or red. The importance of this consideration, as to the high heat required in a gas flame for its best and most satisfactory appearance, is based then upon, first, the belief that the light arises from incandescent particles of carbon; second, that high heat more instantly and, so to speak, more diffusely, splits up the hydrocarbons into simpler elements. As a corollary from this last hypothesis we say the illuminating power of two flames is proportional to the number of their radiant particles at a high heat. In other words, light results from collected masses and velocity; the slower supply one, the temperature the other.

Although the reality of this explanation of the luminosity of flames in general has been called in question, not altogether without reason, yet there seems little cause to doubt that in the case of the gas flame it is entirely just. Carbon is certainly separated, and although in a gas flame the soot deposited on a cold surface is not absolutely pure graphite, practically it is so. That collected by Mr. Evans, when a silver vessel sank two to three millimeters, in the flame of a silk burner, gave a trace of a solid yellow body when treated with benzole, while alcohol and alcoholic chloride and diluted sulphuric acid extracted nothing. This soot when washed gave—

Carbon	95.444
Hydrogen	1.021
Ash	3.527
Oxygen	1.038

The oxygen is supposed to arise from water yet clinging to it, removing which, and disregarding the ash, we may very safely call the composition 95.625, 11 0.205. This body, which is virtually pure carbon, added to a hydrogen flame makes the latter luminous, and exactly similar conditions in the flame from which it was abstracted force us to conclude it was the cause of the brilliancy of the latter. In true coal gas the clelant gas exceeds the other hydrocarbons. But heavy tar vapors exist in well purified coal gas along with the hydrocarbon gases in almost imperceptible quantities, but to an extent sufficient under some circumstances to be annoying by their settling and aggregation in meters, elbows, etc. Naphthalin, a solid hydrocarbon, may be extracted from almost any gas by passage through a glass tube under ice, stuffed with thin discs of tin perforated by a sieve of fine holes. Gas which previously may not have been suspected of containing this crystalline substance yields it upon such treatment. The writer has obtained large deposits of naphthalin crystals resembling the holes made in the tin discs. The presence of solid or semi-solid bodies in gas, as a rule, is objectionable; they burn slowly, are indeed apt to fill through the flame, escape incomplete ignition, and they absorb heat, while they disturb the economics of the flame in their sparkling transit; and in one case known to the writer, irritated weak lungs breathing the air they filled. These hydrocarbons are not supposed to be all contained in the coal of distillation, or at least not to remain unchanged. For instance, [illegible] are formed and exist temporarily at moderate heats, but are decomposed at high heats within the retort chamber. Thus [illegible] found in the Paris gas:

Benzine (in vapor), acetylene, ethylene, propylene, allylene, butylene, crotonylene, terene, and their pyrenes, all of which he regards as formed from the four fundamental hydrocarbons, acetylene, ethylene, dimethyl, and marsh gas, mixing with hydrogen.

BURNLEY CORPORATION GAS SUPPLY.

The statement of accounts of the Gas Department of the Burnley Corporation for the nine months ended March 31 last, just issued, shows that there was expended during that time, on capital account, a sum of £8319 7s. 9d., making the total to date £129,179 7s. 10d., and leaving a balance of capital in hand of £3995 17s. 2d. The following is a summary by the following "general data," prepared by the Gas Engineer (Mr. Samuel Patty Leather):—

Gas made	143,251,700 cub. ft. = 6215 cub. ft. per ton.
Gas sold	127,497,300 " = 5530 " "
Gas unaccounted for	15,754,400 cub. ft. = 683 cub. ft. per ton, or 11·71 per cent.
Average illuminating power during the nine months	17·23 candles.
Coal and cannel used in the nine months	11,511 0 tons.
Coke made per ton of coal used	1·21 lbs.
Coke used as fuel per ton of coal used	0·22 "
	or 22 p. ct. of coke made.
Tar made per ton	121 lbs.
Ammoniacal liquor made per ton	19 gals.

	Per Ton of Coal Used.	Per 1000 Cubic Feet Sold.
Cost of coal and cannel	16s. 1·05d.	5s. 1·27d.
Value of residuals	7s. 7·08d.	2s. 4·25d.
Net cost of coals, &c.	8s. 11·97d.	2s. 9·02d.
Net working expenses	11s. 8·74d.	3s. 7·15d.
Expenditure for gas	15s. 0·71d.	5s. 7·17d.
Interest and sinking-fund	3s. 10·93d.	0s. 9·16d.
Total cost of gas	18s. 11·64d.	5s. 9·33d.

Dr.—*Revenue Account, for the Nine Months ending March 31, 1886.*

No exact expression for the leakage of the main can be obtained from these data, owing to the small number of observations, and the uncertainty how much of the air escaped to escape through leaks in the main into the soil at the atmospheric pressure, and how much passed through

STRONG'S WATER GAS SYSTEM.

By Mr. Gunson S. Dewar.

[A recommendation—indeed boldness, perhaps, even to the Engineering fact of the following paper.]

Some two years since, the representatives of the Strong process publicly announced that it was possible to convert the best anthracite coal to a gas, which should possess a greater heating value than the fuel from which it was derived, for practical purposes. The objection was at once raised that here was an absurd attempt to extract from a given weight of carbon more heat than it contained! The answer was that it is upon the materials really used that the number of the CO burden the expenditure of a proportion of its heat, and hence the new process is not open to the absolute charge from the old.

Prompt answer was made, admitting this but fact, but explaining that the objection was theoretic and not practical—that the conspicuous moment the between the potential energy of a fuel and that of its gaseous products of combustion was not the measure of the value thereof as thermo-metrical agent. It was shown that the calorific intensity of coals are determined by delicate laboratory methods, which, however correct and valuable, are utterly unattainable by ordinary practice; that the standmakers of Sheffield utilize only 5 per cent. of the value so ascertained; consumers in the domestic industries not over 10 per cent.; while the most economical use of fuel ever attained—namely, in the largest and best-managed gas-works—was but about 15 per cent. The latter result claimed for some boilers was but a fraction of the proportion, on the apparently just ground that, as the generation of steam depended upon the driving of engines, the efficiency of heat should be judged by the power developed rather than the weight of water evaporated, and that, so judged, the loss is as great as in other fuel applications.

Evidence was then offered that in the combustion of the Strong gas it is possible to utilize within 10 to 12 per cent. of its full theoretic value, and

It remained only to make a comparison of results, which was done substantially in the following manner:—One pound of anthracite possesses a potential energy of 14,500 units of heat, of which the actual energy—namely, that realized in practical operations—is, as we have already seen, from 8 to 12 per cent. Therefore, 1 lb. of anthracite is equivalent to the energy of 1740 units. The average product of 1 lb. of anthracite by the Strong system at that time was 22·05 cubic feet × weight 0·03116 = 0·6873 lbs., possessing a potential energy of 0·6873 × 4726 = 3021 units of heat, and an actual energy of from 88 to 90 per cent. thereof, or 2721 to 2690 units.

Assuming for simplicity what is, perhaps, not an unfair assumption, that the labour cost of conversion is compensated by collateral advantages in the reduced labour of using gas fuels, the economist was left to consider the question which, within term of set he would realize the greater number of heat units.

This answer on the parts of the advocates of the new system seemed intelligent and correct; at all events it has never been controverted. Admitting it to be so, we must acknowledge also that the new method of converting carbon into superheated steam, instead of atmospheric air, represents an important advance in the art of combustion.

The practical value of the Strong process, as developed by further experience with the Sheffield furnaces, seems perfectly conceived. The opinion that a great variety of fuels could be utilized by it has been justified by the results, and the startling fact established that all yield nearly identical gases, the variation being not in quality but in volume, which is considerably in proportion to the amount of moisture contained in the fuel. The special excellence of this system in rendering available the heat of bituminous coals is also established. Such coals, when used as suggested, such as cannel, coals, and peat coal, and which were employed in the proportion of 3 lbs. to 1 lb. of the better grade, is now ascertained to have a more important significance than the utilization of clamp material, important as that is.

The facts now to be stated will certainly revive the original objection, that the method is claiming to get more out of the fuel than it contains. But the explanation is found in the following manner. In the ascertainment of the relative values of the above-named materials, as already explained, by a comparison between the theoretic results of the street, it being similarly the potential energies of the fuel and the gas were related in 9092 is to 13,500; that is, that the loss by conversion was 5408 units of heat, equivalent to about 40 per cent. of the theoretical calorific value of the fuel.

Now, it is claimed that this percentage of loss has, by greater skill and experience in applying the principle been actually reduced, till, in some cases, to about 20 per centgrave. In other words, the difference between the crude facts and their gaseous products, as therefore determined by scientists, are approaching so closely as to indicate that the Strong system will yet develop what is now understood to be the maximum theoretical energy of the fuel in the gas. Here are the facts:—

1 lb. of Boghead coal is known in a red heat upon the grate of the Strong furnace, and the heat of the resulting products of combustion is stored in a regenerator. Subsequently, when the ashes and superheated a proper quantum of steam, and this latter is passed directly back to the coal, is be ascertained that the largest yield of gas from the volatile is 27·7 cubic feet.

The potential energy of this gas is as follows:—

27·7 cubic feet × 0·03116 = 0·86 lbs. × 9705 = 9,316 units.

The potential energy of the 1 lb. coke is . . = 12,250 .

This, it will be observed, is 91 per cent. upon the earlier results of 1874 units of heat per pound of fuel, and the loss by conversion is so reduced in 91 per cent. of the potential energy.

If 1 lb. of Boghead coke is treated as before, but the superheated steam is interrupted before coming in contact with the incandescent coke in the lower part of the body of fuel, it is possible to convert a larger weight in that form, and the yield in gas, proportionately to the purity of the dust fuel (free of percentage of carbon), will be greatly increased. Take peat powder of the following composition :—

Water	17·00 %
Combustible gas	39·15
Non-combustible gas	20·05
Carbon	23·97
Ash	10·80
	99·97

When 3 lbs. of this material are used, the total gas product is 101·26 cubic feet. Deducting from this volume the 57·60 cubic feet, which, as already shown, are obtainable from the 2·4 lbs. of carbon per each pound of peat derived from the peat, or 23·85 cubic feet or gas for each pound of peat used.

The total gas product possesses the following potential energy :—

101·26 × 0·03116 = 3·156 × 8798 = 26,916 units. The potential energy of the fuels from which it was derived is :—

3 lbs. peat × 7851 =	23,553
1 lb. coke × =	12,250
	37,112

Showing a loss of potential energy of 124 units of heat only. This is equivalent to a loss of about 19 units of heats for each pound of fuel, as against 1874 when the coke was taken without dust carbon.

If the calorific value of the peat is compared directly and separately with that of its own gas, we meet a surprising result namely:—

7917 cubic feet × 0·03116 = 0·2467 × 8798 = 27,046 units.

1 lb. peat = 7851 units.

Here the gas is found related to the fuel as 7·17 to 1, equivalent to a gain of 3019 units of heat, or 17 per cent. even upon the basis of potential energies! What loudness of title for of loss in conversion? It is not disturbed, but most strikingly illustrated. The seemingly impossible result is not beyond an explanation, and one which appears sufficient a theory advanced by the advocates of the new system, and yet to be generally admitted—namely, that in the conversion of the energy of the fuel sold to the gaseous state there is a temporary increase of the potential energy of the fuel, which is not permanent, but is productive of no other effect, and which has never entered into the balance sheet calculations of values. In other words, that the ultimate maximum potential energy of carbon is greater than the accepted estimate.

Take as example the conversion of the peat just calculated. The heat essential to the act was furnished entirely by the coke, which communicated to the molten of the steam, and hence the carbon of the peat vessel directly and momentarily with the steam, and hence the carbon of the water to form and volumizing 3021 units of heat per pound. When the analyst accepts to determine the calorific energy of the peat, he obtained 7851 units only. The difference of 1170 units, or a considerable proportion thereof, we must infer was expended in the gasification of the crude fuel, which, according to this theory, is not merely a question of reduction, but a principle of it. This theory is based upon the proposition that only the gases contained in fuel materials are combustible, and that the carbon of the fuel during the processes of nature, expended in their substitution from their original gaseous form, must be repaid to restore it and render them available in combustion.

Let us for the moment regard heat units as a merchantable article, like any other commodity of purchase and sale, and, regarding the above facts, consider the commercial bearings, as in what market, or in what shape, we can most advantageously buy them.

Assume that lump anthracite coal or coke is selling at 4 dols. per ton of 2240 lbs., and that dust or peat at 1 dol. per ton is available, and that we have 1 dol. to spend for practical heat units—that is, for such as we actually get the value of in combustion. See accompanying table. It will be noted that the figures are not theoretic precept in case we, but that the relative values are practical ones, and consequently the prices, of course, represent the natural cost of manufacturing an available fuel, but they indicate that the gas maker has a margin for liberal profit without using marmosettes. Naturally the gas purchaser will always determine for himself, as in any other transaction, whether the price charged is in excess of the advantages gained, but will calculate many collateral items as to the convenience, comfort, and reduced labour attending the use of gas fuels, must enter. And he will always have the alternative to his return to crude fuels, if the gas manufacturer becomes exorbitant in his demands :—

	Heat Units.	Cost per Ton of Fuel.	Per Cost, Dollars per Million.
1. If we pay 1 dol. for lump coal, applied as in Sheffield steel-making, we obtain	223,800	0·00110	5
2. The same sum as applied in domestic use gives	756,000	0·00132	30
3. The same in the most perfect blast furnace	5,716,100	0·00095	36
4. One dollar's worth of lump coal converted by the Siemens gas-producer, will yield gas representing theoretically	2,651,971	0·00039	33
5. One dollar for lump coal or coke, converted to water gas, as explained, and heated with 20 per cent. of fuel	1,756,451	0·00021	65
6. The same sum expended for one fourth the lump coal or coke and three-fourths peat, and converted by Strong's system, as explained, yields after allowing 10 per cent. loss	10,633,633	0·00038	95

asked a question as to how much of the available surplus the passenger reductio- of 1Bd. per 1000 cubic feet would absorb. He understood that there was a proposal to reduce the debt on the gas-works with the surplus, to which he objected, on the ground that the present generation, and not future generations, should have the benefit of the immediate profits. Mr. Hay replied that there was a sum of £7000 available for whatever purpose they liked to appropriate it. The Lord Provost said that in reducing the price to 4s. 6d. per 1000 feet—from 5s. 6d. to 4—after which there would still be a surplus of £500. After some discussion it was agreed to remit the matter to the Gas and Water Committee to consider and report upon. While speaking of Inverness gas affairs, it is proper to make a correction in last week's "Notes." The quantity of gas sold in that town during the last financial year should have been stated at 22,000,000 cubic feet, instead of 2,200,000, as still very handsome, if correct; but if last week's figures are right, the business must have increased been 25 per cent. But though it is still up at 10 per cent. it was about 11 per cent. higher some years ago, when the present Manager entered upon his duties.

The following are some of the figures connected with the lighting department under the Glasgow Public Authorities during the year ending 31st May last:—The number of public and private lamps there was extended the sum of 210,997 by the addition of 2,000 and upwards, exclusive of the Corporation and various other items the total amount was £30,390 7s. 6d.; and the receipts to be deducted from that amount for broken lamps, for sundries sold, and for private lamps, &c., amounted to £3076 14s. 5d. In connection with the lighting of common stairs there was incurred a total expenditure of £22,548 5s. 6d., including wages of stair lighters, cost of gas, and oil

THE CHALLENGE

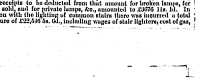
Gas Regulator,

For Economizing the Use of Gas.

POSITIVELY FROM

20 TO 30 PER CENT. SAVED IN GAS

Without any Reduction in Light.



It has a Self-Acting Valve, Adjusted Exactly to the Velocity with which the Gas Moves.

(Room 4,)

NEW YORK.

ASSOCIATION OF GAS MANAGERS.—The Engineer from the presidential address of Mr. J. Robb to the North British Association of Gas Managers shows that some gentlemen connected with gas works view the electric light in the right way. He says:—"In looking over our transactions for several years past, I am astonished at the number of so-called inventions and improvements in gas manufacture, and machinery connected therewith, which have been offered for our acceptance, and been urged upon us with much eloquence and many weighty reasons, and yet you all know that few, if any, of them are ever heard of afterwards. Whether this arises from apathy to the interests of our profession, or from that intrinsic faculty which it is said we Scotchmen possess in a remarkable degree—I will not say of "seeing through a millstone," but rather of seeing at a glance the real value of anything that is placed before us, I will leave someone else to determine. There is one thing, however, which we cannot set aside, and that is the bold flight of our modern gas engineers in an upward direction. We have seen scrubbers towering above all other buildings in gasworks, and we shall shortly have an opportunity of beholding a gasholder, when filled with gas, rising to the amazing height of 160 feet. We may well ask—What next? Some one will say, "The electric light;" but, gentlemen, I think we are far from seeing the realisation of the hopes of those persons who have embarked their fortunes in the production thereof. Yet we need not shut our eyes to the fact that an intense and brilliant light can be produced, which may be used to great advantage in some situations; and although I believe that the time is far distant when it will take the place of coal gas in domestic illumination, yet I am convinced that when the necessity arises for its adoption, science will be able to overcome the difficulties with which the subject is now surrounded. Within the past two or three years it has struck me forcibly that, as gas managers, we have been losing sight of the primary object of our profession, viz., the production of illuminating gas, and have been drifting away in the direction of becoming manufacturers of the secondary or residual products thereof. I am led to this conclusion from the prominence which is given to this subject at all the meetings of our Associations, and from the multiplicity of machinery which has of late years been patented for the purpose of enabling us to enter into the trade. Almost daily we have our attention called to some washer or scrubber newer and more efficient than any other which has preceded it, and if the benefits resulting from the use of these improved appliances are really as great as they are represented to be I do not see how anyone can reasonably delay their adoption. Ammonia is becoming such a valuable article of commerce it may become a question with gas managers how far the amount of this substance contained in a coal should enter into their calculations when making a contract for their yearly supply. The quantity of ammoniacal liquor and its strength have not hitherto formed items in the results obtained from a ton of coal in the analyses sent to us (with the exception of a very few), but I expect it will take a more prominent place in all future analyses. My only fear is that coal merchants will not be slow to take advantage of the additional value conferred on the article in which they deal, and add to the price of the coal according to the quantity of ammonia contained therein. As showing the difference in the quantity of ammoniacal liquor contained in a ton of coal the following is a sample:—Muirkirk 14·00 gallons, Stanrig 9·00 gallons, Foulshiels 29·12 gallons, Shotts 9·00 gallons, Pondegh 31·00 gallons. Allow me to apologise, gentlemen, for trespassing so much on your time and patience. It only now remains for me to call your attention to the very interesting list of papers and communications the titles of which you will find in the programme."

This report was presented to the Chemical Section, and referred to the best means for the development of light from coal-gas. The report pointed out that great fluctuations of pressure occurred in the mains, and that being so it was necessary to have complete control over the pressure of gas supplied to the burners, in order that burners might be used to the best advantage. It suggested that the pressure so supplied to the burners could be regulated by the taps in the burners or at the meter, but in many situations where the pressure altered much in the course of a single night this was very troublesome to attend to, and in most cases would be neglected. The Committee therefore [illegible] which choose to leave [illegible] which acted automatically to the pressure of the gas.

Science in Elementary Education.

Dr. Gladstone brought up the report on this question. The committee nominated at Sheffield for the purpose of considering whether it is important that her Majesty's Inspectors of Science and Art Schools should be appointed with reference to their scientific acquirements, and whether candidates of the said establishments for inspectorships have received a considerable amount of evidence upon the subject, and beg to report as follows:—

"1. It has come to their knowledge that the teaching of the scientific specific subjects is materially discouraged by the incapacity of many of her Majesty's inspectors to examine in them. This incapacity is explained by the fact that the inspectors are not generally acquainted with the subjects which they are required to examine in, and as on account of their high attainments, on through political patronage. 2. In the opinion of the committee there might be no examinable duty for her Majesty's inspectors composed of those of the most experienced of the present Science Inspective Association, with a few members of the Council of the Association, added for the occasion. 3. The committee would be thereby upon the examinatory teachers, and the candidates ought to be tested in the practical work of examination in one of the central laboratory schools in London. 4. The committee believe that the opening of the inspectorship to the Science Association generally would tend to the improvement of many of the professions and improve the character of both inspector and teacher. 5. The committee are further of opinion that while a University degree may be accepted as a test of scholarship, it is not a test of the particular scientific knowledge required of inspectors, and is not sufficient in itself to guarantee the holder thereof a worthy the position of inspector. There appears to be no means why experienced laborers should be made an indispensable condition of appointment. 6. The committee recommend that a memorial be presented to the Lords of the Committee of Privy Council on Education, embodying the above conclusions."

In presenting the report Dr. Gladstone spoke of the necessity of the Legislature with reference to the teaching of the rudiments of science in elementary schools. The new code of this year extends the facilities for teaching science as a class subject, but still limits the choice of the teacher to two class subjects. Lord Norton obtained a majority in the House of Commons against the proposal to remove the restriction that the instruction must generally were opposed to it; but both the last and the present Educational Blue-book showed that, while some would positively discourage science teaching, many favoured object lessons and the knowledge of common things, while others would even extend the present schedule.

A long and animated discussion followed the reading of the report, and ultimately the committee was reappointed.

English Mechanic Sept. 3 1880

THE IMPURITIES IN GAS, AND THE MEANS OF ELIMINATING THEM.

It would be idle in me to occupy even the least portion of your valuable time in apologies for the introduction of a subject which must be to you, as it is to me, a matter of grave concern to all of us. We are known as gas engineers and we have to deal with a manufacture of illuminating gas, which, in its commercial distribution, is only equalled by the amount of interest which is now being largely felt by a considerable portion of the intelligent public and by consumers. May we not be permitted to approach our subject by way of the suggestion that these inquiries were likely existence in our gas to (1) the use of indifferent or ill-adapted material; (2) defective plant in the manufactory; (3) unskilful or careless management; or (4) all these causes?

I do not know that we may arrive at a proper estimate of the difficulties which would be involved in any attempt at the supply of "pure gas," even if this were desirable, we may profitably pay some little preliminary attention to the material which we use in its manufacture. And here we must be at once struck with the number and various qualities of the coals presented to our notice when a good average gas coal, however, we may be allowed to state in opposition as follows:—

Carbon	. . . 76·0	Coal gas	31·57
Hydrogen	. . . 5·2	Ammoniacal water	
Nitrogen	. . . 1·6	Tar	6·73
Sulphur	. . . 0·7	Coke	
Water	. . . 11·3		
Ash	. . . 2·2		

I believe you fervently take it, that the best gas coal is that which, while yielding the highest percentage of illuminating gas, gives best sulphur and tar.

I have a predeterm fear of overweighing you with details in a paper which is necessarily of a discursive character; but nothing is more enlightening than the numerous diversities in the qualities, and hence in the nature of the products of distillation, of these "gas coals." I append a table to which you will find examples illustrating this in a extraordinary degree.

Let us now consider the general products of distillation, and may conveniently classify them as follows:—1. Illuminating gas. 2. Tar. 3. Ammoniacal liquor. 4. Coke.

1. Illuminating gas, consisting of

a. Light - yielding constituents	Gases, e.g.	Acetylene	} Hydrocarbons
		Ethyl	
	Vapours	Benzol	
		Naphthaline	
b. Light heaters		Hydrogen.	
		Carbon dioxide.	
		Carbonic dioxide.	
c. Impurities.		Ammonia.	
		Glycerine, and its sulphates.	
		Carbon disulphide.	
		Carbon disulphide.	
		Unpolymerised hydrocarbons.	
		Nitrogen.	

2. Tar, consisting of

a. Hydrocarbons which are liquid, as	Benzol,	
	Cumol.	
	Butyl.	
" " solid, as	Naphthaline.	
	Anthracene.	
	Pyren.	
b. Acids	Carbolic.	
	Cresylic (cresol).	
	Benzic.	
	Creosote.	
c. Bases	Aniline.	
	Picoline.	
	Lyridine.	
Asphaltine compounds.	Anthracene.	
	Pyridine.	
	Carbon.

" sulphocyanide.	

4. Coke, consisting of . . . . Carbon . . 95 . . 95
Iron salts . 11 . . 4
Ash . . . 4

This table will exhibit the variety of the by-products with which the gas engineer has to deal, and which are to be found in the paper.

The carbonaceous matter is now seen as forming over 95 per cent. of the product of distillation is partly pre-existent in the coal, and is partly formed by syntheses in the process. The ammoniacal liquor is mainly a combination of this water with the nitrogenous and other volatile compounds. The numerous hydrocarbons alike form the tar, and these, together with the water, are supposed to be essential from the gas by the condensers; for with the highly-fatty condensations or lutrepuration can possibly take place in the lighter and more valuable hydrocarbons.

The condenser is too well known to require any description. Its forms are numerous; but the principleand object of all is the lowering of the temperature of the crude gas as it passes from the hydraulic main, so that it may have deposit much of its watery matters. It is probable that too much has been made here made of the importance of this process. It is certainly not the only one in connection it must then hold effected by thorough condensation. And this is not the case, as the results are as follows:—The gas passing from the retorts has a temperature of about 60° to 80° C.; when however the fundamentals may be effected, it should never be carried beyond a temperature of 10° to 15° C. When this is the case, either by accident or design, the gas is deprived of certain variable quantities of valuable hydrocarbons, and its illuminating power suffers in the same ratio. Besides, these hydrocarbons, so deposited, are a constant source of trouble and annoyance. Not only should the temperature be maintained as low as possible, but the gas should be constantly forced through as rapidly as possible, and a liberal allowance of area in the condensers will always more most economical. The writer has recently found this area as low as 10 square feet of tube-surface allowed for 1000 cubic feet gas passing. It is believed this should never be under 20 to 100 square feet per 1000 feet of gas.

Coal naphtha is obtained by the distillation of coal tar. The tabulation has shown that the naphthaline is present in the gas. Its illuminating power of our gas, while a disappearance of the liquid hydrocarbon takes place—in fact, 0·25 grammes of naphtha used in carburetting gas has given an increase of illuminating power equal to from 18 to 20 per cent.; but free and rapid condensation removes the greater part of this vapour, and the richest gas suffers most in this way.

It is not deemed necessary that we should pause in consideration of the acids and bases of coal tar, which may be said to comprise all their ascertained purification can effect.

With the purifiers we have the first stage of chemical purification; and this purification may be dealt with under two main heads—viz., that effected by "lime," and that effected by "oxide of iron." The ordinary arrangements for purification by these reagents are familiar. The useful and extent, however, to which they do their work is probably less well known. Lime, as we all know, removes carbonic acid, sulphuretted hydrogen, and carbonic acid; and hence, while the purifiers are in efficient working order, we should have no trace of these impurities present in the gas. But this extent of purification is rarely obtained, as will be seen from the tables appended. Oxide of iron then steps in to perform a function for which the lime is not adapted; and hence arises the advantage of the two purifying materials. Oxide of iron removes the last traces of sulphuretted hydrogen, and it also removes cyanogen.

The action appears to be something like the following:—The gas having deposited much of its tar and ammoniacal waters in the condensers, scrubbers, and wells, comes into very intimate contact with the lime, when the carbonic dioxide unites with the lime, forming calcic carbonate. The sulphuretted is similar fashion becomes broken up by the affinity of the sulphur and the lime for each other, and a formation of calcium sulphide is the result. But it is found that this calcic sulphide has a strong affinity for the carbon disulphide and other sulphur compounds. The ammoniacal hydrocarbons represent all cyanic sulphide, therefore, passes on, only to be intercepted by the ferric oxide. Hose for and to what an extent this is daily effected will always depend on the state of efficiency and the attention paid to the purifiers and their action. The appended tables are very instructive in this regard.

It may be of interest here to give a tabulated analysis of spent oxide; which will further indicate the direction in which it acts, also exhibits some unusual features:—

Water	12·2
Sulphur	53·3
Aluminous and siliceous matters	9·1
Organic matters and tar	17·1
	100·0

The sulphur particulars of coal gas has an importance which cannot easily be over-estimated; and the question has been so recently investigated and reported upon by the Chemical Section of London as to require little further notice here.

It must, however, be borne in mind that although we may obtain high photometric results, we may also have gas of still very low quality; and that it frequently happens that we have a large excess of sulphur in the illuminating power. It is within the knowledge of the writer that, in consequence of the failure of the supply of a certain coal to a gas-works of considerable capacity, another coal was to be used. Gas of a satisfactory character, other things over 25 grains of sulphur per 100 cubic feet (1). If this were possible, it would not be difficult to absorb the claim of a large and influential "chairman" that he—personally—had, by sundry means, original to himself, increased the income from ammonia sulphate sales by some thousands of pounds. Is it possible that the gas had also benefited by the change? Is it possible that the consumers had benefited? Is it not more consumers likely by desire that a change which may have been from the supply of the gas by so much the purer and more wholesome? We might be pardoned if we were to suggest that a similar improvement—only to a greater extent—would be likely to accrue by a purification of the gas from 25 grains to say 12 grains, which is the result even of "ancient" management.

TABLE No. 1.—*Selected Results of Analyses of Gas Coals.*

Description.	Specific Gravity.	Coke.	Ash.	Sulphur.	Sulphur per Ton.	Ammoniacal Liquor.	Gas per Ton.	Illuminating Power.	Gas per Ton.
		Per Cent.	Per Cent.	Per Cent.	Pounds.	Per Cent.	Cubic Feet.	Candles.	Cubic Feet.

these machines may be in use, and at number three not more than two or three of them. In all cases, however, the smoothness and regularity with which the engine works is noticeable, there being no sensible diminution or acceleration of speed as the different machines are put in or out of action.

The attendance required is very slight.

The engine can be started in a minute's time, and the lubricating being done by an ingenious self-acting arrangement, no further attention is needed till the engine requires to be stopped, which is done instantly by slanting off the gas. The only other labor needed is to examine the slide valves once a week to see that the passages to the cylinder are clear, and this does not take more than from 15 to 20 minutes.

There is a water cistern in connection with the cylinder jacket, for keeping the cylinder cool, but I have found that the amount of water required after the first filling of the cistern is practically *nil*, as the temperature of the water has never risen so much as to require a stream of fresh water run in; the rest during meal hours and at night being sufficient for cooling the water down to the atmospheric temperature. Were the engine working continuously, however, as in driving an exhauster, a small stream of water would be necessary, and would have to be taken into account in estimating the expense of an engine for such a purpose.

The cost of the engine for the year from May 15, 1879, to May 15, 1880, working 37 hours per week, has been—

Gas for engine and slide lights, 19,000 c. ft., at 3s. 2d. per 1000 feet	£29	12	6
16 gallons of sperm oil for lubrication, at 2s. 6d. per gallon	2	16	0
Attendance, estimated at 1 hour per day, at 1d. per hour	5	4	0
Making total of working expenses	£38	12	6
The first cost of engine and cistern complete was £170, and the annual wear and tear may be taken at the rate of 7½ per cent., equal to	£11	18	0
Depreciation, the same	11	18	0
Making together	£23	16	0
Add to this working expenses as above	38	12	6
The total charge for year will be	£62	8	6

The amount of the working expenses would necessarily vary with the varying price of gas in different localities. What is given above was the selling price in Edinburgh and Leith last year, but of course the actual expense, where it is used in a gas works, will be not the selling, but the cost price of the gas. With regard to the percentages charged for wear and tear and depreciation, these are, I am sure, ample, looking to the well finished and substantial style in which these engines are got up, the absence of complicated working parts, and the large bearing surfaces of the parts liable to be worn out.

The amount of power derived from the above expenditure has been on the average at least two-horse power. As explained before, the use of wet coal of the machines is intermittent, but it takes about 1½-horse power to drive those that are constantly in use, and the addition of 4-horse power to the average, for those that are used occasionally (including as they do a circular saw of large size and a heavy screw-cutting lathe) is a very moderate estimate. This works out to an expenditure of about seventeen cubic feet of gas per indicated horse power per hour, which is much below what is stated to be used when the engine is worked with a full load, and seems to bear out what was stated by Mr. Carr in his paper last year, that, contrary to what might be expected at first sight, the engine works more economically when not used up to its full power.

The cost of a steam engine and boiler of three and a half nominal horse power, and equal in respect to workmanship to the Otto gas engine, would be about £210; and the usual allowances for wear and tear and for depreciation would be 10 per cent. per annum for each on an engine and boiler of this size. This, relatively to 7½ for the gas engine, is not at all excessive, as of course the boiler involves more wear and tear and depreciation.

The working expenses would be—

To fuel, at 8s. per week for 52 weeks	£20	16	0
Wages of attendant, at 12s. per week	31	4	0
Oil for lubrication (same as gas engine)	2	16	0
Water supply for boiler	2	10	0
Making total working expenses	£57	6	0
Add for wear and tear, 10 per cent. on cost	11	0	0
And depreciation, 10 per cent. on cost	11	0	0
Making total charge for year	£79	6	0

It will be borne in mind that the cost of fuel will be more or less than that given above, according to locality; but it is a fair estimate, checked by actual experience of the working of a small steam engine and boiler in our works, and in comparison with what it costs various users of similar engines in the neighborhood. The wages of an attendant I have taken at 16s. per week, and I have allowed 4s. off that, on the supposition (which in many cases, however, could not be realized) that the man could devote so much of his time to other work.

The general results, then, are as follows:

Working expenses of gas engine	£38	12	6
Working expenses of steam engine	57	6	0

And, taking wear and tear and depreciation into account, the total annual charge would be—

For gas engine	£62	8	6
For steam engine	79	6	0

The advantage is therefore largely in favor of the gas engine, and I venture to think that if I have erred at all in the comparison it is in under, not over, estimating the cost of the steam engine. I have also to point out that our engine is constantly going during working hours. There are, however, an infinite number of cases where power is needed only at intervals, and in such cases the comparison would be still more in favor of the gas engine.

In all cases where we have supplied gas for these engines the testimony of the users has been highly in their favor, and not long ago one gentleman gave me his experience as being that—"When he had a steam engine it cost him 18s. a week for wages to an attendant, and from 10s. to 12s. a week for fuel; but that now his cost was from 4s. to 5s. a week for gas, and no attendant needed."

In addition to the saving in cost, however, the gas engine has other advantages. It occupies small space; is always ready at a moment's notice; does away with the risk and danger of explosion, thereby reducing the cost of insurance to be effected in places where, with a steam engine and boiler, the companies would not undertake it. It also needs no special building, or chimney, and does not make the premises where it is used uncomfortable with heat, dust, and cinders.

One drawback it has, not as regards those who use it, but as giving trouble occasionally to gas managers, namely, that the action of the engine causes an oscillation of the lights taken from services immediately adjoining that of the engine, when the main pipe is small—say under 4 inches diameter. The supply should therefore always be taken from a large main where practicable, at any rate, where the main is less than 4 inches diameter no other service should be taken off in close proximity to that for the engine.

I had lately a correspondence with Messrs. Crossley about this, and they promised to send me a governor which is used on the Continent to prevent this oscillation, but it has not yet come to hand.

I may also note that the pressure in the main must be at least equal to that of seven-tenths of an inch of water.

That gas engines will ere long come into extensive use I think certain; not only as supplanters to some extent of steam engines, but also as affording a cheap and efficient motive power in a great number of places where the use of steam is difficult or impossible.

over

Dr. Anthony Nesbit has fed rabbits for weeks together upon food contain-
ing most of the dyes I have mentioned to-night, and, strange to say, if one
may judge from their appetite and condition, their general health was not
in to least impaired. It is true that some pigments—that is, paints, not
dyes—like cuprimol and emerald green, contain large quantities of arsenic.
Orpiment should never be used, as it gradually fades, and the deplorable
way in which Sir Joshua Reynolds's pictures have deteriorated is partly due
to the use of orpiment and carmine; this last color, although perfectly
harmless, becoming grey in the course of time.

Future of Gas Fire.—Permit me, in conclusion, to s a few words on
the Future of Coal Tar. It may confidently be said it : some of the pro-
ducts of eat tar are useless. A well-known chemist, sev al years ago, in a
work which in many respects showed great cleverness, w s unwise enough
to reproach chemists for the enormous labor which they had bestowed on
what he called so useless a substance as aniline. He, however, lived to see
it become one of the most valuable substances in existence. It is true that
the benzoline and pyridine series have not as yet been utilized ; but to doubt
that they would one day yield valuable derivatives would be to neglect all
the teachings of our glorious science. Nothing exists in vain, and the
chemists who, for the sake of pure science, study the physical and chemical
properties of new and as yet useless substances are preparing the way for
the practical men, who will one day be thankful for those pioneers who
have smoothed the road, and made the advance into new realms comparatively
lively easy. Although the benzoline series have not yet been utilized, I
found a quarter of a century ago that its isomer, toluene, by alternate treat-
ment with iodine of methyl and oxide or sulphate of silver, yielded superb
colored rosanilines, and doubtless, by suitable processes, the benzoline series
will be made to afford valuable products.

I found also that dimaline, treated with iodide of amyl, and then with
caustic alkaline, yielded the superb blue coloring matter cyanine. This
color, from its peculiar constitution, forms quite a new departure in organic
chemistry, and recent researches show it to be closely allied to our subject ;
as, from the observations of Dr. Dalla and Prescel, there seems to be little
doubt that chinoline st imes, and perhaps often, accompanies or replaces
benzoline in coal tar.

There are also many other substances which have not yet been utilized,
among which I may mention the solid hydrocarbons chrysene, retene, and
pyrene. It needs no prophetic eye to see that, with the substances already
known, there is room for a considerable development of new combinations,
and the Future of Coal Tar will be far more brilliant than the Past or the
Present.

To me gentlemen, coal tar, though "black," is "comely," and if I have
failed to impart to you some of my enthusiasm for it, the fault lies with
me, and not with the subject, which I feel is worthy of treatment by a
master-hand.

[From the "London Journal of Gas Lighting."]

Experiments on the Thermal Power of Gas Heating Apparatus.

By Mr. T. Thayne, of Cork.

Read at meeting of British Association of Gas Managers, June 8, 1880.

In a paper which I had the privilege of reading before you two years
since, your attention was called to the fact that gas cooking and heating
stoves did not, as a rule, give the full thermal effect practically available
from them. To us this is a matter of importance, as one of the points with
which we have to contend is to demonstrate the economy of gaseous fuel,
wherever circumstances will allow of its being consumed under the most
favorable conditions.

Manufacturers of gas cooking and heating apparatus are succeeding very
well in making them attractive to the eye. Both in style and finish they
render them more popular, attention must be paid to the mode of develop-
ment of the largest amount of heat from the smallest quantity of gas. What I
and it is that additional pressure be put on the stove makers, so as to ob-
able us to speak with more confidence to our consumers.

As a limited case in point, you are aware that some years ago gas burners
that is one did not give the same amount of light per foot of gas as we now
obtain. If the electric light did no other good than to arouse the burner
makers to the sense of injustice they were so long perpetrating on gas
lighting power, it has done good work. In like manner let us spur on
the stove manufacturers to that which will certainly prove to be of mutual
benefit.

In order to be able to recommend to the gas consumers of Cork the best
and most economical apparatus, I made, during last year, some experiments,
and from the results of these I think it will be seen that the apparatus in
general use are capable of such improvements as will lead to better results.

I am fully aware that the effect of any kind of fuel is much greater in
theory than in practice. I have therefore made the experiments on a
plain, practical method, such as may be applied to the doings of every-day
life.

Intimately connected with this subject is that of the thermal power of
gas of various qualities, and I commenced operations by making some tests
under this head. I noticed that the results as not quite in accordance
with some I have seen in the Journals. The apparatus with which I oper-
ated was capable of carrying 30 cwt. of coal per day. I was therefore
able to make a comparative calculation of the cost of the gas from coal of
various qualities. The coal was South coast, Newcastle coal, and coal
from South Wales. The points noted were—

The illuminating power.
The evaporating power of the gas.
The net cost of coal per 1,000 cubic feet.

Coal.	Illuminating Power.	Water Deposited.	Gas Consumed.
Newcastle.....	21.0 candles.	1 gallon.	18.50 cubic feet.
"	22.0 "	1 "	19.75 "
"	20.0 "	1 "	20.30 "
"	19.5 "	1 "	21.75 "
"	14.5 "	1 "	22.90 "
South Wales.....	19.5 "	1 "	22.50 "
South Wales and 20 per cent. caunel.....	14.0 "	1 "	28.00 "

On account of thermal theoretical efficiency of the various descriptions of gas is far greater than the results which are given above.

On the average it will be found by the experiments that 16 lbs. of water were evaporated by 1 lb. of gas. Newcastle coal gas, for example, of sp. gr. .420 has on ava.erating value equal to 2 times its weight. From the figures it will also be seen that the thermal power does not increase in the same ratio as the illuminating power, as some persons suppose. The calculations I have made of the net cost of coal per 1000 feet of gas proves that a very cheap gas of low illuminating power can be produced for heat-
ing purposes, provided we were able permanently to enrich it at the con-
sumers' meters when need for illuminating purposes was determined worthy of the attention of the inventive portion of the community.

Taking gas from Newcastle coal at 16 candles as a standard of the average gas at present supplied, and 750 as the thermal units per foot of gas, I make a series of experiments on the gas stoves from the various makers. I took the stoves as they are delivered in the usual way to purchasers.

No.		Thermal Units per Cubic Foot of Gas.
1.	Cooking stove fitted with a Bunsen burner formed by a ring of 14-inch wrought iron pipe with jet holes 1 inch apart, etc.....	244
2.	Boiling stove, consisting of single burner 9 inches diameter, made of 1-inch pipe, jets 1 inch apart.....	209
3.	Hot-plate, consisting of three rings, each 6 inches diameter, jets 1 inch apart.....	280
4.	Like the above, rings 4 inches diameter.....	310
5.	Cooker, formed of bars of 1-inch wrought iron pipe, jets 1 inch apart.....	338
6.	Cooker in the form of a double row of rings, one inside the other, 6 inches diameter.....	399
7.	Burner, same construction as above, but 4 inches diameter.....	408
8.	Solid flame burner.....	450
9.	Wallace's burner adapted for domestic purposes.....	580

To the construction of these burners does the higher return of work rises from the others. It is on the principle that jets of fluid escaping from an orifice travel on in their original direction of motion a certain distance before they disperse. In this burner the combustion is so long ere it is complete, and in doing so it communicates a sort of gaseous friction to the air. Both these move in the same direction, but with a retarded motion; thus they become mixed in a chamber, from which they escape through a wire gauze, and they burn at a point of exit in the shape of solid flame, varying in diameter according to the size of the burner. Here we have a very powerful con-
centrated heat, developing a very large percentage of the calorific efficiency of the gas.

It is important to ascertain the reason of this. You are aware that in combustion for the purpose of artificial light, we have a very interesting arrangement of matters. The combustion of oxygen with hydrogen causes powerful heat, and consequent expansion. Hence the particles or carbon are scattered freely through the heated hydrogen, and thus they remain for some time before their exit; and from their incandescent, diffused in all directions, we obtain beautiful light. But in the Bunsen burner the case is different. The oxygen is introduced in such quantities that there is not

[From the London "Journal of Gas Lighting."]

Explosive Mixtures of Coal Gas and Air.

By Mr. W. Foster, M.A., etc.

Professor of Chemistry at the Middlesex Hospital.

Numerous cases recently have been recently reported through the ignition
sive mixtures of coal gas and air have excited a considerable amount
sition, and have given rise to much unnecessary anxiety. As an ab-
proposition, the dangerous nature of a mixture of coal gas and air is
nally understood not only by those engaged in the manufacture and
ribution of gas, but by a large section of the educated public. The best
dent method of dealing with such mixtures and of preventing their for-
on is, however, a matter on which much misconception exists; and this
ly arises from an insufficient appreciation of the general properties of
ous bodies. A knowledge of the practical bearing of the laws of diffu-
of gases is not by any means so general as one could wish. The present
ebrus appears a fitting occasion for a few observations on a subject of
greatest importance to all concerned in the manufacture and use of coal

It may appear an idle statement to say that coal gas, in a confined
e, is perfectly harmless; but unfortunately one is continually meeting
persons in all grades of society who do not abuse such a simple opinion.
erefore often becomes a part of the gas manager's duty to instruct his
tomers with reference to the properties of the article which he manufac-

Coal gas, whether cannel or common, is a mixture of several gases with
apors of hydrocarbons of low boiling point. By far the greater portion
any given volume of common gas consists of hydrogen and marsh gas
CH_4), the sum total of these two component varying from 80 to 90 per cent.
the whole. In 1851, Dr. Frankland made an analysis of the common gas
plied by the Chartered Gas Company in London, and in 1876 the same
pany's common gas was analyzed by Mr. Hunyhlge. The results of
se two analysis, so far as the chief components are concerned, are given
the following table—

	1851	1876
Hydrogen.....	54.3	50.6
Marsh gas (CH_4).....	36.2	38.3
Carbonic oxide (CO).....	8.9	9.1
Other gases represented in their equiva-
lents of olefiant gas (C_2H_4).....	7.7	7.8

low each of these components when allowed to escape from a containing
ce into the external atmosphere can be ignited and consumed like any
or combustible material. The oxygen of the air is necessary to carry on
chemical action which is commenced by the application of the ignited
ch, and, in the case of the gases containing carbon, further supply is
cessary for the removal of the carbonic acid gas produced. The high
mperature required to start the combination of the gas is maintained by the
at from the total amount of heat which it may possess. The smallest
ch of brightly incandescent matter, whether solid or gaseous, is sufficient
ignite a jet of coal gas issuing in atmospheric air. An excellent illus-
ation of this phenomenon is afforded by the use of the electric spark. If
wo platinum wires be brought into the position shown in the accompanying
ure, so as to form a gap of about one-eighth of an inch between their ends,
n the hand on the conductor of an electrical machine, sparks may be
wn from his body during the time the machine is put in motion by a
ond individual. If a jet of coal gas be allowed to escape from a metallic
zzle within his reach, on his extending his other hand, and causing one
the sparks to issue from the burner from above, a spark will instantly pass
ith the burner, producing ignition of the gas. [It will be remembered that
is principle was advocated on a limited scale a few years ago when there
as a scarcity of a taper being required in the dwellings of the aristocracy
ingenious but cumbrous.]

the electric spark the particles of gas in the track of the spark are rap-
ly heated by incandescent; and although their mass must be extremely
all, yet they are capable of setting up a similar condition throughout the
ole gas jet. On the other hand, comparatively large masses of solids at
w temperatures are incapable of setting up a similar condition of things,
for instance, a coal cinder at a dull red heat, and devoid of flame, will not
e ignition of a jet of coal gas, nor will the dull red embers of a recently
tinguished deal wood match. It is clearly obvious, therefore, that heat as
ch is capable of being transferred in consequence of the phenomena of ig-
tion. The substance, whether solid or gaseous, must possess those quali-
which enable it to call into play multitudes of a certain order—those which
e particularly abundant at the more refrangible end of the spectrum pro-
uced by a source of white light.

If the composition of a sample of coal gas be given, the amount of oxygen
(and therefore of atmospheric air) required to effect its perfect combustion
is a matter of simple calculation, as the quantities of the gases afforded us by
Dr. Frankland's analysis. As every two volumes of hydrogen require one
volume of oxygen, the 51.8 volumes of hydrogen given in the sample re-
quire 25.9 of oxygen. Every two volumes of marsh gas require four volumes
of oxygen, and therefore 31.5 would require 63.0. Every two volumes of
of carbonic oxide require one of oxygen, and therefore 8.9 require 4.4.
Every two volumes of olefiant gas require six of oxygen, and therefore 7.7
require 23.1. The results of these four independent oxidations are ex-
pressed in chemical symbols, as follows :

$$2H_2 + O = 2H_2O$$
$$CH_4 + 2O = 2H_2O + CO_2$$
$$2CO + O = 2CO_2$$
$$C_2H_4 + 3O_2 = 2H_2O + 2CO_2$$

On adding together those several quantities of oxygen, we find that 100 vol-
umes of such common gas require 115.4 volumes of oxygen for their com-
plete combustion. As every five volumes of air contain one of oxygen, it
follows that the quantity of atmospheric air necessary to completely effect a
like result is 582 volumes. In other words, one volume of gas of the quality
under consideration requires nearly six volumes of air (5.8). I need hardly
say that, in practice, larger volumes of air are necessary to carry on the or-
dinary process of combustion in an efficient manner, the surplus air assist-
ing very materially in removing the products of oxidation from the points
where they are produced. When atmospheric air is mixed with coal gas in
the proportion of 21 volumes of the former to one of the latter, the mixture
can be ignited when issuing from an ordinary burner, and consumed in the
same way as the unmixed coal gas. The character of the flame, however,
differs from that produced by the pure coal gas in that it loses, in a very
marked degree, its light-giving properties. This phenomenon has given
rise to much misunderstanding, and in the result of several influences operating
somewhat differently. Their considerable is certainly one present question.
In the case of a mixture of 21 parts of air with 100 parts of coal gas, we find
that a considerable proportion of oxygen is needed for the complete
combustion of the gas. This additional quantity is derived from the exter-
nal air, as in ordinary cases. If we take 100 parts of gas and air in the
proportions needed for the complete combustion of the gas (and, in the case
of the particular quality we have already considered, we shall require 6 of
air to 1 of gas), and allow them to burn under circumstances
ind in *theoretically*, quite independent of any supply of oxygen from ex-
ternal sources. Such circumstances, for instance, that a
ntle foot of it be confined in a spherical vessel, and that a flame be applied
to a portion of the gaseous mass; rapid combustion of the mixture would
immediately follow with explosive violence. As it could not even sub-
stance the oxygen required to form the ultimate oxidation products, and as
these are gaseous, and produced at an extremely high temperature in-
stantly, they exert on the sides of the
containing vessel a very great. One speaks in general terms of such an ex-
plosion as being instantaneous. Such, however, is not absolutely the case
with the explosion of mixtures now under consideration, as they require a
certain definite time for the completion of the action which
has been commenced by the application of the lighted substance. In other
words, the flame applied to the mixture does not spread at the rate of
many thousand feet per second. The greatest velocity with
which the explosive wave can be propagated for the completion of the action
of the particular quality we have already considered, we shall require 6 of
air to 1 of gas, and therefore 7 volumes of the mixture
ind in *theoretically*, quite independent of any supply of oxygen from ex-
ternal sources. Such circumstances, for instance, that a
ntle foot of it be confined in a spherical vessel, and that a flame be applied
to a portion of the gaseous mass; rapid combustion of the mixture would
immediately follow with explosive violence. As it could not even sub-
stance the oxygen required to form the ultimate oxidation products, and as
these are gaseous, and produced at an extremely high temperature in-
stantly, they exert on the sides of the
containing vessel a very great. One speaks in general terms of such an ex-
plosion as being instantaneous. Such, however, is not absolutely the case
with the explosion of mixtures now under consideration, as they require a
certain definite time for the completion of the action which
has been commenced by the application of the lighted substance. In other
words, the flame applied to the mixture does not spread at the rate of
many thousand feet per second. The greatest velocity with
which the explosive wave can be propagated for the completion of the action
of the particular quality we have already considered, we shall require 6 of
air to 1 of gas, and therefore 7 volumes of the mixture

American Machinist Sept 11 1880

The Electrician states that the following process for utilizing old india-rubber, of which many hundred tons are thrown away as waste substances, has just been patented in Germany. The rubber waste is subjected to the distillation in an iron vessel over a free fire, with the aid of superheated steam. The lighter oils which come over first are rejected, and then the heavier products. The latter, when fildictered and rectified in the usual manner, are found to possess all the good qualities of first-class natural rubber. Sept 11 1880

Journal of Gas Lighting Communicated Article. Sept 11 1880

ON THE AMOUNT OF LIGHT YAIELDIA IN COAL TAR, AND ITS PRACTICAL ILLUMINATIVE VALUE TO THE GAS MANUFACTURER.

By Mr. H. LEICESTER GRUTELLE, F.C.S., &c., Chemist to the Commercial Gas Company.

(*Continued from* p. 325)

In my last article on this subject, a table was given showing the respective quantities of naphthalene in various samples of tar, taken from different portions of gas-works. The mean amount of light naphtha found in ordinary stock tar was, it will be remembered, 2·6 per cent. by volume. Now, if it is assumed that each ton of coal distilled yields 20 gallons of tar and 10,000 cubic feet of gas, the absolute quantity of light naphtha, which is available for transfer to the gas can be easily calculated. I have taken round numbers in expressing the respective yields of tar and gas, in order to facilitate the calculation, the numerical figures being sufficiently near the truth for the purpose in view. Now 2·6 per cent. by volume of naphtha on 10 gallons represents a bulk equal to that which would be occupied by 18,200 grains of water, which amount represents the quantity to be distilled over with each ton of coal gas. The amount of available naphtha per 100 cubic feet is therefore 182 grains measures, or 1·82 grains measure per cubic foot. The equivalent of this quantity in weight is 1·65 grains.

Having ascertained the absolute quantity of light naphtha capable of transfer from the tar to the gas, the next point to determine was the amount of increased light to be derived from the addition of the naphtha in the quantity stated. The following table shows the results obtained in some experiments in this branch of the subject:—

Number of Experiment.	1	2	3	4
Initial lighting power of gas	16·61	16·60	15·8	15·9
Naphtha added, grains per cubic foot	2·36	2·61	2·7	2·61
Lighting power of gas after addition of naphtha	17·86	19·00	17·1	17·2
Total lighting power in candles due to addition of naphtha	1·25	2·40	1·3	1·4

Mean quantity of light naphtha in grains weight required to raise the lighting power of the gas 1 candle . . 2·61
Mean quantity of grains to each cubic foot, 1·4 = 0·768

From the above figures can be calculated the equivalent lighting value of 120 grains of light naphtha as compared with spermaceti. As 2·4 grains of light naphtha were found to afford the light of 1 candle, 120 grains would be equal to 12·7 candles. The result is not widely different to the value assigned by Dr. Knublauch to pure benzole; it will be remembered that this value was 14·16 candles. I may state that the burner used in my experiments was the ordinary standard—viz., Sugg's "London" argand—and that the method I used for impregnating the gas with the light naphtha was by passing it through a small two-necked bottle containing the liquid under the burner. I at first experienced the same difficulty as Dr. Knublauch—viz., that the gas absorbed too large a quantity of light naphtha to be subsequently burned at the rate of 5 feet an hour. I therefore contrived a special apparatus for the purpose of limiting the quantity of light naphtha taken up by the gas, which may be briefly described as follows:—I procured a small bottle of blown glass, to serve as ordinary stock at the top and an outlet in the form of a tube blown

into the side of the bottle, and extending to the horizontal direction as shown in the annexed engraving. The neck of the bottle was fitted with a caoutchouc stopper, through which was passed a glass tube, the lower extremity of which was curved and drawn out so as to form a sort of nozzle. The curved part of the tube was turned in that the nozzle was brought opposite and near to the horizontal outlet. By this arrangement the gas bursting in a jet from the glass nozzle had a tendency to escape at once by the horizontal outlet, simply drawing with it a small quantity of the naphthalised atmosphere in the bottle. I found that with this apparatus I could easily limit the amount of naphtha absorbed by the gas to about 2·6 grains to the cubic foot. If it is desired to impart a larger quantity of naphtha to the gas, it is only necessary to lower the inlet-tube so that the nozzle discharges its jet of gas less in a line with the outlet-pipe; the gas then has an increased tendency to mix with the atmosphere of the bottle before flowing away, and an increased naphthalisation is the result. This apparatus worked well, and with a little care could be easily managed.

With regard to the lighting power which I have obtained from light naphtha, I think the figures may be taken as representing the *highest* obtainable illuminating value with ordinary gas consumed in the standard burner. My reason for forming this opinion is that with a liquid like naphtha, which consists of a mixture of hydrocarbons of different boiling points, those which possessed the lowest boiling points (benzole, &c.) would be the first to evaporate. It would, therefore, that any experiment in which gas was passed over by light naphtha, by the simple evaporation of that liquid at the ordinary temperature, are practically equivalent to carburetting with benzole, and do not fairly represent the lighting value which would be obtained from the bulk of the naphtha. The only method to ascertain the real lighting value of the naphtha by the direct addition of the liquid to gas in a holder, but the results varied considerably with varying quantities of naphtha, and were on the whole altogether inconsistatory. This might arise from two causes—viz., the imperfect volatilisation of the liquid in the holder, or the partial removal of naphtha during the subsequent passage of the gas to the burner, by the combined action of the friction of the gas and the contact with water in the meter. The results were invariably lower than those obtained where the naphtha was added to the gas close to the point of consumption.

Taking the lighting value which my experiments, under the most favourable conditions, may assign to the light naphtha, it was found that an addition of 1·65 grains to the cubic foot of gas produced an increase of illuminating power equal to one candle. As the available quantity of light naphtha derivable from the tar was in the proportion of 1·65 grains to each cubic foot of gas, it will be seen that this amount represents a little less than a candle of increased lighting power.

As the results which have been obtained in practice wherever the Aitken and Young process has been submitted to a fair trial differ materially from those indicated by my experiments, I think there is but one conclusion to form in order to reconcile that which at first sight appears an anomaly. The conclusion is this, that the large increase in the lighting power of the gas which is obtained by the use of the Aitken and Young process is not directly due to the retention of the light naphthas, but is due to naphthalene which is contained in the gas, being prevented from separating out in the solid crystalline form by the increased amount of naphtha vapour which is present. To account for the large increase in lighting power obtained by the use of the naphtha, I think it is not only necessary to assume that the naphthalene which would be normally present in the gas is permanently retained, but that the gas becomes charged with an increased quantity in its passage through the analyser, this increase also being retained permanently.

I am unable to state what amount of naphthalene is capable of retention in gas at ordinary temperatures by reason of the presence of a definite quantity of naphtha vapour. The experimental determination of such a question would be extremely difficult, but this much is known—viz., that naphthalene is a most valuable illuminating constituent of coal gas.

Journal of Gas Lighting Sept 11 1880

With regard to the actual lighting value of naphthalene, I made some experiments some time back with the Albo-Carbon light, from which some information may be derived. As my state briefly that the experiments consisted in burning gas, the lighting power of which was known, from a No. 1 Bray's flatted, attached to an apparatus by which the gas became highly charged with naphthaline vapour. It was necessary to use a burner with small holes, on account of the richness of the gas. The initial lighting power of the gas with the standard burner was 16 candles, and the lighting power with the naphthalising apparatus was 24·7 candles, with a gas consumption of 5·6 feet per hour, the consumption of naphthalene being at the rate of 102·6 grains per hour. As the initial lighting value of the gas was 16 candles, 6 feet consumption, the lighting power of 96 feet would be 96 candles. This gives 14·8 candles increase for a consumption of 102·6 grains of naphthalene, or 7 grains per candle. The light value of 120 grains of naphthalene would thus be 17·1 candles. This experiment does not admit of strict comparison with those made with the light naphtha, inasmuch as the burner used in the naphthalising apparatus was not the same as that used to determine the initial value of the gas; at the same time the burner used for the naphthalised gas was, no doubt, well fitted to develop the lighting power from gas of such high illuminating value.

That the use of the Aitken and Young process tends to retain naphthaline in the gas is shown by the letter from Mr. Bell, which appeared in the JOURNAL for Sept. 8, 1870, and that gentleman also testifies to the increase of lighting power obtained by the use of the analyzer, as well as to the increase in the make of gas per ton of coal. With regard to Mr. Bell's figures, however, I quite concur in the remarks made by Mr. Paterson in the last of his series of valuable articles on "The Effects of the Contact of Tar with Coal Gas," published some time back in the JOURNAL. Mr. Paterson says that inasmuch as Mr. Bell introduced an exhauster about the same time that he adopted the Aitken and Young process, it is impossible to say what proportion of the improved results which he obtained were due to the exhauster, and what proportion to the analyzer. More definite testimony as to the effects of the analyzer on the quality and quantity of the gas obtained per ton of coal is to be found in the results of the experiments made by the West of Scotland Association of Gas Managers. Taking a mean of their experiments, the lighting power of the gas was increased by 0·27 candles, the amount of light naphtha transferred to the gas being represented by 2 per cent. on the tar. The increase in the make of gas was in one case 20 cubic feet per ton of coal. What amount of tar was produced from each ton of the coal used is not given, but if taken at 12 gallons, this amount of quantity of light naphtha transferred to the gas may be taken at 10,800 grains measure, and as the make amounted to 7,020 cubic feet, the proportion of naphtha to each cubic foot of gas was 1·64 grains. As particularly with varying quantities of tar, it is obvious that if a given quantity of light naphtha transferred to the gas may be taken at 10,800 grains measure, and as the make amounted to 7,020 cubic feet, the naphtha per cubic foot which I have shown as the available quantity, at ordinary temperatures, can be no less than 0·76 candles, a very considerable amount.

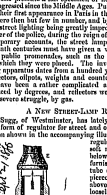
I will conclude with a few general remarks on the separation of tar from gas. If it is admitted that it is desirable to retain all the available light hydrocarbons in the gas, it seems by no means an economical plan to use such means of separating the tar, that a large proportion of light hydrocarbons are also separated at the same time, involving the subsequent treatment of the tar to effect their return to the gas. It is gradually becoming recognised that cooling is not the only agency by which tar can be separated from crude gas; but, on the contrary, cooling alone is not altogether efficient. I look upon it as quite within the bounds of possibility that by the employment of large vessels in which the reduced velocity of the gas would allow time for the heavier particles of tar to settle, and by the subsequent use of some system of straining through a series of sieves of successively fine meshes, the tar will be completely separated, at the same time that the temperature of the gas will be maintained sufficiently high to permit of the almost complete retention of light hydrocarbons. A similar process has already been recommended by Mr. Aitken, and if any mechanical system could be introduced for the separation of tar on the same lines, it would, I believe, be far more perfect than the present method, and altogether more desirable for the purpose of retaining the light hydrocarbons in the gas.

The Lighting of Paris.

The Municipal Authorities of Paris, in unison with the Gas and Lighting Companies, are, says *Builgeonis*, studying all sorts of plans for improving the illuminations of the city. Large contracts are being signed for candelabras in cast-iron and bronze, for *lustres-lampions* (as the clusters of lamps on the street refuges are euphoniously called) and all their appurtenances; and very shortly, no doubt, Paris will be, if it is not already, the best-lighted city in the world. The history of street illumination in the French metropolis presents a fair specimen of how that type of civilization has progressed since the Middle Ages. Public street lamps or lanterns made their first appearance in Paris in the sixteenth century, though they were then but few in number, and by no means perfect in themselves, street lighting being greatly improved by Messrs. Delabrigade, an officer of the police, during the reign of Louis XIV. To judge from contemporary accounts, the street lamps of the seventeenth and eighteenth centuries must have given a very picturesque appearance to the public promenades, such as the Champs-Elysées and quays, along which they were placed. The invention of *réverbères* or reflecting apparatus dates from a hundred years or so back, and with its reflectors, objects, weights and counterweights the first *réverbère* must have been a rather complicated affair. Improvements were introduced by degrees, and reflectors were only dethroned at last, after a severe struggle, by gas.

A New Street-Lamp Regulator.

Mr. Sugg, of Westminster, has lately perfected a compact and simple kind of regulator for street and other gas-lamps, of the same description shown in the accompanying illustration. The body of the regulator, A, is made in brass or steel metal. Gas entering from below enters the chamber, B, furnished at the top with a small tube open at its upper end, and pierced with a small hole just below the bell. The bell, B, is loosely into its seat, and is covered with a metal cap, C, of similar shape, with two holes in the side of it, through which gas is closed at the top. The whole is covered with a glass shade, D, from which a tube, E, leads to the burner. The exact flow of the rents of gas is shown by the screws in the governor, and the steatite bell, which is not liable to stick, is kept in place, as is weighted to the required measure, and when this is exceeded it rises, and so acts as a valve to cut off the outlet tube in the burner. The regulators are of substantial construction, and never vary their purpose minimately at any inlet pressure from 5-10ths to 6 inches, while they are much less costly



because than the diagram street-lamp governors in common use.

Railway Carriage Lighting in Germany.

From reports recently obtained from the various German railway authorities it appears that the present state of the lighting of carriages is as follows:—For lighting material, mineral oil, gas, and, to a considerable extent, even candles, are used. Of some 10,188 carriages adapted for illumination, 10,068 (or 97·6 per cent.) are lit with rape-seed oil, 253 (or 2·47 per cent.) with gas, and 2217 (or 1·6 per cent.) with candles. The gas employed has been in most cases made on some lines with the so-called Möhring oil, which is a mixture of petroleum and rape-seed oil. The gas is partly made in works belonging to the railway, from fat, partially, petroleum, gas oil, or coal tar oil, partly obtained from gas-works. The holders, in which gas can be compressed to 5½ or 6 atmospheres, are fixed under the carriages, and connected with the burners by means of tubes with pressure regulators and valves. The filling of the holders is accomplished either direct from the gas-works by means of caoutchouc tubes, or through transportable reservoirs, which can be filled with 5 or 6 cubic meters of gas pressed to 10 atmospheres, or from small vessels. A single filling of a holder suffices for 20, 30, or even 60 hours burning. The average cost given by the authorities, per frame and hour of burning, varies in the case of gas between 2 and 2·27 pfennige; in the case of oil, between 0·67 and 7·5 pfennige; and in the case of candles, between 1·8 and 6 pfennige.

ashing with gas. They may also give some practical demonstrations of smoke or anti-pollute chemistry.

In another direction the gas companies and water-trusters will form an attractive feature of the Exhibition, as they always do when on view. Some of the best will be engaged in providing for the thorough ventilation of it. Hoff Bell—a matter which is given much notice by Mr. Hermite and his fellow-members of Committee.

Amongst the less attractive but more practical matters will be the Gas Exhibits and such as is now held at Brussels, Paris, and Amsterdam, and which will be represented by Messrs. Clamond, Delmard, &c. There will be urged with all force the claims of the Exhibition to be a success. There will be some dazzling and surprising novelties in electric lighting, without doubt, and more especially that sent by Messrs. Clamon Bros. and Co., Birmingham; and Messrs. Siemens will likewise be represented in a very similar fashion to "Gazelle" of 1876, and a "Jenny" of 1880—together with "Siemens" dynamo machine, and other electrical appliances. The Exhibition is certainly going to be a popular one, and the way to do it is to go to it.

Altogether the Exhibition promises to be an exceedingly important, interesting, and deserving of success.

ON A SYSTEM OF HOT CONDENSATION.

By Mons. C. Jouaust, Engineer.

Paper read at the Meeting of the Société Technique de l'Industrie du Gaz en France, held in Paris, June 18th, 1880.

(*Translated from the Journal des Usines à Gaz.*)

Gentlemen,—Hydraulic condensation has for a long time been very properly held in a system of condensation, having for its object to increase the illuminating power of the gas. This system is, in fact, the most simple and the most generally adopted in the use. The application of this system was not built two years ago in a paper read before a meeting of gas managers in Carlsruh, and published in the *Journal des Usines à Gaz* (Vol. XXIV., p. 305). I was the more struck with the system, because, without being new, it had not, in my opinion, received the attention which it was entitled to from gas engineers. I had, in fact, the double conception of the system, and the practical application; and besides this, in view of the possible competition of the future, I felt that it was to my interest to communicate to my colleagues as soon as it was possible, the results which I had obtained in increasing the illuminating power of gas until by the best response of dividers for or balancing, and therefore I, myself, was obliged to delay to make it so complete as possible.

I will begin by defining its theory, which, it seems to me, has not always been sufficiently elucidated. It rests entirely upon the fact, that when the gas is brought into contact with the water, it takes up from it a certain quantity of vapour, which, in its turn, on leaving the water, is carried off by the gas, and which is in a condition of saturation. This vapour

At the meeting of the Associated Science Association, held in Hudderfield, the latter part of August, Professor Roscoe of the Owens Examiner for New College, read a paper on "The Illuminating Gas of New York City." In the course of it he gave the Professor spoke of the different processes by which gas is manufactured in that place. He noticed a change, the Coal Gas Company had made in their process of purifying, which had considerable interest. In my first letter to the Times, I made some remarks on the value of this Company's gas, derived from ordinary cannel coal; later on they added water gas to their product. Now the water gas has the quality that made from coal, and thereby the better material will be displaced when necessary. According to the figures given by Professor Roscoe it appears that the Company pay 4 cents 25-32 (nearly) per gallon for the cannel coal, and 2 cents 1-32 per gallon for the oil used in the carburetting process. Some of the most valuable additions to the illuminating qualities were made by the Company for the first six months of this year, 1880, during which time was first manufactured in September of that year, the average was 17·26 candles, as far as my memory serves me, per 100 cubic foot. The percentage of carbonic oxide in the gas in 1879, which augments the proportion in the atmosphere by about 1 part in 2,000, was 4·5 by the meeting at which Professor Love's paper was read. Mr. Giles, of Bradford, presented a communication on the "Electric Light," which was applied to Mr. Lorenz's machine. This gentleman has devised a plan for the storage of energy derived from the motion of the earth's surface, and the problem of economically developing this energy. The two processes by which coal can be converted into light are by the manufacture of ordinary coal gas and by electricity. Mr. Elliot stated that, in the case of large towns, electricity is more economical than gas. Electric lighting he considered into three kinds—first, by the voltaic arc, in which the light is concentrated; second, by the heating of a solid body, known as the electric candle; and the third, a modification of the second, which the most results. The first was the most economical, while the most convenient. The second, as far as one could tell, is adapted to illuminating smaller areas, such as for domestic purposes. He also the candle power developed by the voltaic arc was equal to 2,000 to 2,500 per horse power, while the figure by the incandescent mode is placed at about 170 candles.

Journal of Gas Lighting
THE GAS APPLIANCES AT THE MANCHESTER INDUSTRIAL EXHIBITION.

(FROM OUR OWN CORRESPONDENT.) Oct 18 1880

The Judges awards in the section of the Manchester Industrial Exhibition, three months after its opening, were announced on Friday, and the prizes given consist of twelve silver and nineteen bronze medals, eight of the former and eleven of the latter being awarded to exhibits in connection with the Manchester Corporation Gas Works. Some of the most valuable additions to the apparatus, so far as novelty is concerned, have already been noticed, but there are other additions of considerable interest that these are now briefly dealt with in a short sketch of some of the prize-winners.

Gas-cooking stoves, as I have already said, have been the chief features in the section. The exhibits have included all the best known as well as the most recent inventions in cooking by gas, and the list of silver medals have been awarded to this particular class of apparatus, the bronze medals being also given to stoves. The Corporation exhibit, which gas is now, amongst manifold other uses, better applied to the purposes of cooking.

Amongst the gas stoves, we have already alluded to Messrs. Greene and Son's exhibit, to which has been awarded a Corporation silver medal, and Messrs. Stark and Co.'s bronze medal for gas-cooking stoves, to which has been awarded a Corporation bronze medal. Messrs. Greene and Son have a large and varied collection of cooking stoves, and the introduction of instantaneous water heaters, which is a very important feature in supplying hot water to baths, kitchens, or for general use. The apparatus is very simple in its construction, and consists of a small upright boiler, which requires no fixing, containing inside a coil of copper piping, which in operation is brought in contact with a number of small gas-burners, and the water passing direct from the supply-pipe through the copper coil becomes instantaneously heated, and passes off at the other end. The heaters have the appearance of a cross as now exhibited. A third silver medal has been awarded to Messrs. Greene and Son for a collection of Holtzapffel's patent brewers' and distillers' apparatus, which is very complete in its arrangements for supplying hot water to tubs, blockers

Communicated Article.

IS A HIGH YIELD OF GAS PER TON OF COAL CARBONIZED AN INFALLIBLE TEST OF GOOD MANAGEMENT?

By Mr. George Livesey,
Secretary and Engineer of the South Metropolitan Gas Company.

The interesting articles by Mr. H. Leicester Greville, on the amount of light naphtha in coal tar and its illuminative value, which were recently published in the JOURNAL, invite attention to a question of some importance to gas managers and to gas companies and corporations owning gas-works. It seems to be assumed that a high make of gas per ton of coal is indisputable evidence of good working, reflecting credit on the manager, and bringing profit to the undertaking. It is, therefore, one of the usual things for the chairman at a meeting of shareholders to make a great flourish of trumpets over a make of, say, 10,000 feet of gas per ton of Newcastle coal carbonized; but he never tells his audience the cost at which this result has been attained—probably supposing, and certainly leading his hearers to suppose, that the increased yield has been obtained without any increase of cost whatever.

If the increased yield is brought about by the prevention of leakage from the retorts, or the removal of the dip, or the prevention of oscillation and the working with a steady level gauge, or by improvements in charging, or more regular heats, while all other conditions remain unchanged, the additional make per ton—provided the illuminating power be not reduced—is a clear gain. Supposing, however, that the additional make is the result of harder firing—which is usually the main element in producing an enlarged make of gas—there is not a clear gain by any means.

It is well known that when the economical maximum is attained, the cost of going beyond that point increases in a very rapid ratio until the gain, however great, is more than counterbalanced by the cost of obtaining it. This is strikingly illustrated in the speed of steamships, and the same principle must apply to gas making.

If an extra 500 feet of gas per ton of coal carbonized is obtained by higher heats, experience shows that the quantity is increased at the expense of the quality. It appears from Mr. Greville's investigations that the quantity of light naphtha found in the tar is very nearly sufficient, if entirely absorbed by the gas—to add one candle to the illuminating power, or to prevent the reduction to that extent. As this, however, does not appear to be the case, it is probable that high heats have but little effect in transferring the light naphthas from the tar to the gas. If they were transferred, a valuable consideration would be taken from the tar, thus reducing its value, and causing a loss on the tar approaching, if not quite equal to the gain on the gas. "You cannot eat your cake and have it."

Seeing that an extra 500 feet per ton is an item that stands out clearly, whilst the items on the other side are to a great extent wrapt in obscurity, and of unknown value, it is not surprising that the one should have been brought prominently forward and the others overlooked or forgotten.

It is very desirable that some attempt should be made to ascertain the economical maximum make of gas per ton, and to this end the following *pros* and *cons* ought to be suggestive, and lead to the necessary experiments that should be undertaken to clear up the doubtful points. It is quite open to any one to set his value on the various items in the annexed statement:—

Statement based on the Comparison of 9800 *Feet of* 15½-*Candle Gas against* 10,300 *Feet per Ton of Newcastle Coal in London.*

Estimated reduction of illuminating power at least half a candle, requiring 3½ per cent. of cannel, producing 30-candle gas, to make up the deficiency of light, the extra cost of the cannel and the diminished value of its coke will add from 10d. to 1s. per ton to the cost of coal, say		
Extra fuel estimated at least 10 per cent.	0s. 10d.	
Less tar produced, estimated 1 gallon	0 2	
Increased wear and tear of retorts and trouble with stopped pipes, say	0 1	
Deduct—	1s. 3d.	
An increase of 5 per cent. in the make per ton is equivalent to a saving of 5 per cent. of carbonizing labour, which, according to Mr. Field, is rather less than	2d.	
5 per cent. less of retort-houses and retorts for the same amount of work effects a saving of plant, which at 10 per cent. interest amounts to	1d.	
	0s. 3d.	
Difference	1s. 0d.	

If this is correct, it appears that the net cost of producing an extra 500 feet of crude gas is 1s., the said gas being not worth more than 6d. in the retort-house.

Can this be even approximately correct? If so, three vaunted high makes per ton, where cannel has to be used to keep up the quality, are a great mistake, and even where the reduction of quality is of no consequence, and cannel is not required, the 6d. worth of gas is not by any means obtained for nothing.

The object of the writer for many years has been to produce, with the smallest amount of cannel, gas of the required quality of 16 candles, being content with a make of 9800 feet per ton. Experiments are about to be made for the purpose of ascertaining the point at which it ceases to be economical to increase the make per ton; and it may be found better to produce only 9000 feet or so without cannel, than any larger quantity with the addition of that expensive article. The result of those experiments shall be placed at your service, and if others will give to your readers the benefit of their experience on this important question, even if it goes to prove that the writer is altogether mistaken, no one will be more pleased than he to see a satisfactory conclusion take the place of the present uncertainty.

London Oct-29-80

I.R.O.N.

GAS-METER RENTS.

A very useful discussion on the subject of gas-meter rents took place at the meeting of Midland gas engineers held last week at Birmingham. A paper was read in which the principle of charging such rents was supported, it being urged that without a charge of the kind the supply of gas would be attended with loss in the case of small consumers, considering the outlay in putting in the service. The instance of Leeds, where 10 per cent. of the consumers pay under ten shillings per annum for their gas, was cited in support of retaining meter rents. In the discussion which followed, it was objected that the arguments used were in favour of a differential rate, but not of the retention of the rents. It was recommended that the charge should be abolished, and that meters should be looked upon simply part of the stock-in-trade of a gas company, just as services and mains and other appliances. Gas managers from various towns took part in the discussion, and the general opinion was strongly in favour of the abolition of meter rents.

Gas Light

Is a High Yield Economical?

We call especial attention to the following article from no distinguished a source as the pen of Mr. George Livesey. The point made is a very important one, as well as a very important one; and we would urge our gas makers to comply at once with Mr. Livesey's request to make an exhaustive set of experiments on this subject and to publish the same. We shall gladly give the largest amount of space to the result of such workings, and trust that the American gas makers may be able and willing to throw some light upon the subject.

[Communicated Article to the London *Journal of Gas Lighting.*]

IS A HIGH YIELD OF GAS PER TON OF COAL CARBONIZED AN INFALLIBLE TEST OF GOOD MANAGEMENT?

By Mr. George Livesey, Secretary and Engineer of the South Metropolitan Gas Company.

The interesting articles by Mr. H. Leicester Greville, on the amount of light naphtha in coal tar and its illuminative value, which were recently published in the *Journal*, invite attention to a question of some importance to gas managers and to gas companies and corporations owning gas works. It seems to be assumed that a high make of gas per ton of coal is indisputably evidence of good working, reflecting credit on the manager, and bringing profit to the undertaking. It is, therefore, one of the usual things for the chairman at a meeting of the shareholders to make a great flourish of trumpets over a make of, say, 10,500 feet of gas per ton of Newcastle coal carbonized; but he never tells his audience the cost at which this result has been attained—probably supposing, and certainly leading his hearers to suppose, that the increased yield has been obtained without any increase of cost whatever.

If the increased yield is brought about by the prevention of leakage from the retorts, or the removal of the dip, or the prevention of oscillation and the working with a steady level gauge, or by improvements in charging, or more regular heats, while all other conditions remain unchanged, the additional make per ton—provided the illuminating power be not reduced—is a clear gain. Supposing, however, that the additional make is the result of harder firing—which is usually the main element in producing an enlarged make of gas—there is not a clear gain by any means.

It is well known that when the economical maximum is attained, the cost of going beyond that point increases in a very rapid ratio until the gain, however great, is more than counterbalanced by the cost of obtaining it. This is strikingly illustrated in the speed of steamships, and the same principle must apply to gas making.

If an extra 500 feet of gas per ton of coal carbonized is obtained by higher heats, experience shows that the quantity is increased at the expense of the quality. It appears from Mr. Greville's investigations that the quantity of light naphtha found in the tar is very nearly sufficient—if entirely absorbed by the gas—to add one candle to the illuminating power, or to prevent the reduction to that extent. As this, however, does not appear to be the case, it is probable that high heats have but little effect in transferring the light naphthas from the tar to the gas. If they were transferred, a valuable consideration would be taken from the tar, thus reducing its value, and causing a loss on the tar approaching, if not quite equal to the gain on the gas. "You cannot eat your cake and have it."

Seeing that an extra 500 feet per ton is an item that stands out clearly, whilst the items on the other side are to a great extent wrapt in obscurity, and of unknown value, it is not surprising that the one should have been brought prominently forward and the others overlooked or forgotten.

It is very desirable that some attempt should be made to ascertain the economical maximum make of gas per ton, and to this end the following *pros* and *cons* ought to be suggestive, and lead to the necessary experiments that should be undertaken to clear up the doubtful points. It is quite open to any one to set his value on the various items in the annexed statement:—

Statement based on the Comparison of 9800 *Feet of* 15½-*Candle Gas against* 10,300 *Feet per Ton of Newcastle Coal in London.*

Estimated reduction of illuminating power at least half a candle, requiring 3½ per cent. of cannel, producing 30-candle gas, to make up the deficiency of light, the extra cost of the cannel and the diminished value of its coke will add from 10d. to 1s. per ton to the cost of coal, say		
Extra fuel estimated at least 10 per cent.	0s. 10d.	
Less tar produced, estimated one gallon	0 2	
Increased wear and tear of retorts, and trouble with stopped pipes, say	0 1	
	1s. 3d.	
Deduct—		
An increase of 5 per cent. in the make per ton is equivalent to a saving of 5 per cent. of carbonizing labour, which, according to Mr. Field, is rather less than	2d.	
5 per cent. less of retort-houses and retorts for the same amount of work effects a saving of plant, which at 10 per cent. interest amounts to	1d.	
	0s. 3d.	
Difference	1s. 0d.	

If this is correct, it appears that the net cost of producing an extra 500 feet of crude gas is 1s., the said gas being not worth more than 6d. in the retort-house.

Can this be even approximately correct? If so, three vaunted high makes per ton, where cannel has to be used to keep up the quality, are a great mistake, and even where the reduction of quality is of no consequence, and cannel is not required, the 6d. worth of gas is not by any means obtained for nothing.

The object of the writer for many years has been to produce, with the smallest amount of cannel, gas of the required quality of 16 candles, being content with a make of 9800 feet per ton. Experiments are about to be made for the purpose of ascertaining the point at which it ceases to be economical to increase the make per ton; and it may be found better to produce only 9000 feet or so without cannel, than any larger quantity with the addition of that expensive article. The result of those experiments shall be placed at your service, and if others will give to your readers the benefit of their experience on this important question, even if it goes to prove that the writer is altogether mistaken, no one will be more pleased than he to see a satisfactory conclusion take the place of the present uncertainty.

Nov. 2, 1880. American Gas Light Journal

[Official Report.]

Eighth Annual Meeting of the American Gas Light Association.

Held at Chicago, Ill., October 13, 14, and 15, 1880.

Morning Session—Oct. 13.

The meeting was called to order at 11 A.M., the President, Mr. W. H. Price, in the Chair.

THE ROLL.

During the meeting the following members were present:

Honorary Member.

G. Warren Dresser, C.E., New York City.

Active Members.

Allen, A. L., Poughkeepsie, N. Y.
Allyn, H. A., Cambridge, Mass.

Death of Samuel P. Parham.—Samuel P. Parham, late Chief Engineer of the Mutual gas company, and formerly Engineer of the Metropolitan gas company, died suddenly of paralysis at his residence in Philadelphia, on Nov. 20th, in the fifty-sixth year of his age.

THE MAXIM ELECTRIC LAMP.

During the past month the attention of the public, and more particularly of inventors, has been called to the Maxim Light, as exhibited by the United States Electric Light Company in the Hale Dayrolk Vaults under the Equitable Building. The good taste and good sense displayed in this exhibition are worthy of commendation. The rooms are elegant in all their appointments, being evidently arranged under the highest advantages of the decorative scenic, being evidently arranged under the highest advantages of the decorative scenic, being evidently arranged under the highest advantages of the decorative scenic

WATER-GAS AS A SUBSTITUTE FOR GAS-COAL GAS.*

Translated for the Engineering and Mining Journal by Dr. Henry Wurts, from the Journal fur Gas-Beleuchtung.

Herr von Quaglio, of Wiesbaden, made a communication, as follows, upon Water-Gas as a Substitute for Gas-Coal Gas:

GENTLEMEN: I feel specially honored that it has fallen to my lot to present to so distinguished a body this exposition of a subject which now occupies the attention of all technologists.

How high a value attaches in America to the verdict of German experts, I may render by quoting the following passage from a letter of one of the most prominent technical chemists of the new world, Dr. Gideon E. Moore, written on hearing that Mr. Dwight and myself had the intention of clearing a path for the restoration of water-gas, even in Germany, by the introduction of the Strong and Pierce processes.

"Nowhere else in the world can you hope to obtain a fairer or more enlightened judgement as to their intrinsic merits, and when submitted to the test of impartial scientific investigation, there can be no diversity of opinion as to result. I consider, as I have said before, that the water-gas manufacture is the most important new thing that has been in the motive of [illegible] for [illegible] and I feel both in respect to engineering and mechanical detail and chemical ethos, your processes will especially the Strong process will unitedly in advance of any that have been subjects tried or suggested."

Since, so to close [illegible] last century, I consider, as a result of his investigations by the combustion of water, obtained the foundation of modern [illegible] as a [illegible] of water and leads to its chemical accomplishment, and [illegible] technically useful, both the constituents of water and leads to its chemical technically useful, both the constituents hydrogen, and the sole supporter of combustion, oxygen. For the sake of brevity, I may be allowed to assume, in accordance with the results up of experts, that all the modern investigations and discoveries up to this time are familiar to you, especially those relating to directly utilized journal presents comprehensive digests thereof, and to anxious few find up to the progress of the age.

Thus I can immediately pass on to my subject. One definition of what is up to day I mean the best process known for the decomposition of water, the "Strong process." This process like nearly all related processes, rests also on the reciprocal decomposition of steam and coal, and the products are the same [illegible] a mixture of hydrogen, carbonic acid, and carbureted hydrogen gases, with carbonic acid, nitrogen, oxygen, with accidental sulphur-compounds, ammonia, and tar-vapor as impurities; such residual being now called by technologists generally "wassergas" (in England and America "water-gas"), a designation which is now adopted by Von Karsmann, Bischoff von Wagner, Hoffman, and others.

But before I enter especially upon a description of the Strong apparatus and its regulations, I must, for clearness, premise with some purely theoretical considerations.

Against the different statements of the results of Strong's process has been brought the objection, especially on the part of pure theorists, that we claim to have obtained from the coal, after its transformation, in a gas, more calories (heat-units) than the coal consumed contains altogether, and that this is a matter of impossibility.

From no substance, however transformed, can we evolve more power (energy) than resides in it, and moreover, we must bring into the account the unavoidable losses during such transformation.

THE PHARE GAS-BURNER.

THE visitor in Paris, standing with his back to the New Opera, has an opportunity of comparing the different systems of lighting three converging streets. In front is the Avenue de l'Opéra, illuminated by the electric light on the Jablochkoff system. To the right, the Rue de la Paix may be taken as the representative of ordinary gas-lighting; but the standards are placed nearer together than in London, and have each three lanterns. To the left is the Rue du Quatre Septembre, illuminated by the Compagnie Parisienne du Gaz, on the Phare system, a new method, intended to demonstrate the power of gas to hold its own against the electric light, and which was briefly noticed in the March last. The Paris municipal authorities determined the cost of lighting a square metre of pavement by the Jablochkoff system, and invited the Compagnie Parisienne—who have the monopoly of supplying gas to the French metropolis—to produce the same effect at the same cost. The Company, accordingly, placed ordinary lamp standards, raised 24 feet on cast-iron bases, about 40 feet apart, and supplied them with their new combination of six burners, consuming together 1400 litres (49·5 cubic feet) per hour, and giving an illuminating power of 140 standard candles. The six burners separately, consuming the same quantity of gas, would only give an illuminating power of 66 candles; and the difference is due to the increased temperature and the superior combustion, caused by the flames impinging on one another and by the currents of air directed by the glasses of the new lamp.

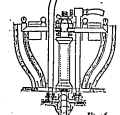

Fig. 1.

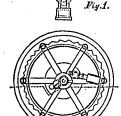

Fig. 2.

In the annexed engravings, fig. 1 shows a vertical section, and fig. 2 a plan of the Phare Gas-Burner. Six burners are arranged equidistantly in a circle of about 6 inches diameter, so that the impingement upon one another of the flames causes additional and perpendicular flames between each, the whole forming a perfect and very steady *corona* of light. Annular currents of air are directed, one inside and the other outside the flame, by the two glasses, the lower one corrugated as shown. Other currents of air, passing both inside and outside the two glasses, serve to reduce the temperature, and prevent the glasses from breaking. Altogether, it is calculated that between one and one cubic feet of air pass through the lamp in an hour. The small horizontal burner, protected by a shield, shows to the right in the engraving, is the *veilleuse*, which always remains lighted, for igniting the jets from the other burners when the gas is turned on to them, so that there is no necessity for opening the lanters. The burner on the left, rising above the others, is for use alone after midnight, when less light is required. The cock is so arranged that, on its being turned in one direction, the gas passes into the single burner, and not into the others, and on its being turned in the other direction, the gas passes into the six other burners, and not into the single one, whilst in the middle position gas only passes to the *veilleuse*. A chronometer is supplied below the cock for equalising the flow of gas.

The lamps, each giving a light of 140 standard candles, are claimed to be superior in illuminating power to the Jablochkoff standards in the Avenue de l'Opéra, which are estimated as equal to only 121 candles each; but a fairer comparison is by area of surface illuminated. The engineers of the gas company put the cost of lighting each square metre of the Rue du Quatre Septembre for six hours at 1·8 centime, while the electric light for the same time and area costs 3 centimes. It is but fair to add that gas is charged to the municipality for public illumination at only 15 c. per cubic metre (35 cubic feet), whereas private consumers pay 30 centimes. This burner has also been adopted by the Brussels Municipality in the Place Royale and outside the Colonies St. Hubert.

THE "ALEXANDRA" MULTITUBULAR GAS BOILER.

The lamps, each giving a light of 140 standard candles, are claimed to be superior in illuminating power to the Jablochkoff standards in the Avenue de l'Opéra, which are estimated as equal to only 121 candles each; but a fairer comparison is by area of surface illuminated. The engineers of the gas company put the cost of lighting each square metre of the Rue du Quatre Septembre for six hours at 1·8 centime, while the electric light for the same time and area costs 3 centimes. It is but fair to add that gas is charged to the municipality for public illumination at only 15 c. per cubic metre (35 cubic feet), whereas private consumers pay 30 centimes. This burner has also been adopted by the Brussels Municipality in the Place Royale and outside the Colonies St. Hubert.

Death from Gas.

The Board of Coroners was yesterday notified that Sofia Ingenito, twenty-one years old, had been suffocated by inhaling gas, which had escaped from an open burner in her room at the Annex House, No. 76 Spring street.—*N. Y. Herald*, Nov. 1st.

Another case of suffocation from gas has come to light, the victim being a young man named Thomas Jackson, son of a farmer of that name residing on the Dundas road. He came to Toronto quite recently, and engaged with Mr. Wm. Boyd, carriage agent, corner of Mill and Cherry streets. On Monday night he retired to bed in the best of health, and yesterday morning he was found dead by Mr. Boyd who went to call him. He had turned on the gas light, but had not turned off the gas properly, and when his room door was opened the place was full of it. Dr. Riddell was notified of the occurrence, but he saw no occasion for holding an inquest. It appears that Mrs. Boyd spoke to young Jackson previous to his retiring about the way in which he should turn off the gas.—Toronto *Globe*, Nov. 3d.

Bertha Weiss, a servant in the employ of Mr. Isaac Deutsch, at No. 223 Henry street, was suffocated yesterday by inhaling gas from a burner in her bedroom. The girl arrived in this city a few days ago on the steamer Wieland from Germany. She was taught by her mistress how to turn off the gas, but it is supposed that she made a mistake.—*N. Y. Herald*, Nov. 6th.

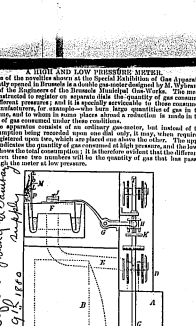
Scranton, Pa., November 6th.—At an early hour this morning Charles Mulrooney, aged twenty-four, residing in Hyde Park, was found in an unconscious condition in a room at the Scranton House, on Lackawanna avenue, instead of turning it off.—*Evening Telegram*, Nov. 8th.

In the broad silk department of W. H. Cogeett & Co.'s silk factory, Nepperhan avenue, Yonkers, on Friday morning, by the escaping gas, about 15 of the employees of that room were prostrated.—Yonkers *Gazette*, Oct. 10.

A HIGH AND LOW PRESSURE METER.

One of the novelties shown at the Special Exhibition of Gas Apparatus recently opened in Brussels is a double gas-meter designed by M. Wybrouw, one of the Engineers of the Brussels Municipal Gas-Works. This meter is constructed to register on separate dials the quantity of gas consumed at different pressures; and it is specially serviceable to those consumers —manufacturers, for example—who have large quantities of gas in the course of their operations, and to whom even a reduction is made in the price of gas consumed under these conditions.

The apparatus consists of an ordinary gas-meter, but instead of the consumption being recorded upon one dial only, it may, when required, be registered upon two, which are placed one above the other. The upper dial indicates the quantity of gas consumed at high pressure, and the lower one shows the total consumption; it is therefore evident that the difference between the two readings represents what will be the quantity of gas that has passed through the meter at low pressure.



The working parts of the apparatus are arranged in a very simple way, as shown by the above diagram. The valve-box, A, is of the ordinary kind. The drum, B, is revolving, communicates a rotatory motion to a vertical shaft, C, which, by means of ordinary meter, sets in motion the hands of the lower dial, D—that indicating the total consumption. A small pipe, E, passes from the upper part of the meter to the regulator, which consists of F, placed at the back part of the meter, and upon the interior of which is suspended the drum. This reservoir is sealed by the vessel which dips into it, and is covered with a leather or India-rubber lid, that falls or rises according as the pressure of the gas is low or high. This lid is attached to a lever, G, which, by the movement of which, it is fixed alone to the centre of the dial box. The extremity of the lever on the other side of the fulcrum ends in a fork, that rests upon the valve-rod, H, which governs the supply of gas at high pressure. The upper vertical rod, I, which constantly corresponds with the lower one, and actuates the dial indicating the consumption of gas at high pressure.

Supposing the gas to be at the usual day pressure, some small weights, J, placed upon the regulator-lid, will cause it to descend a very few inches; consequently, the fork-extremity of the lever being raised, the connection between the two rods is broken, and the valve closed by the action. When the night pressure is passed, and the low pressure of the compensating piece, H, descends, and a small horizontal rod, K, fixed upon the lower vertical rod, is checked by the tooth of the revolving piece, and the two pieces both dials are brought into action.

The apparatus is very ingenious, but has been assumed that the pressure of the gas is high during the evening and low in the daytime; whereas the reverse is sometimes the case. It would be necessary to modify that given in the daytime. The compling arrangement works uninterruptedly, whether on evening or morning, whatever may be the variations in the pressure. The apparatus is constructed to act with a certain fixed day upon it a small weight, L, suppose the rectangular vessel carries water, it does not rest in the notch, M, from the night pressure is on, the lid, N, is pressure down, the notch, M, rises the small weight, L, and the water flows into the vessel, and the lever descends, a second notch, P, which is smaller than the other, causes the panel to fall again into its former position.

The Recent Gas Explosion

On my return after the vacation the experiments on the explosion of gases in tubes were continued.

A tube was constructed by winding narrow strips of paper helically round a glass tube about 8 mm. in diameter; two inches of the width of the paper being glued, it was so wound as to make a tube of about three-quarters of an inch bore. The tube was 1,500 mm. long, and contained 208 joints. At the end—that nearest the gas—a cork stopper, 2 mm. in diameter were fixed, one being perforated to allow the wires in order to indicate the velocity of the flame at the two ends of the tube was 1,260 mm.

The tube was filled with a mixture of 2 volumes of oxygen, to the end of the glass tube—the fine wires also plugged with wet cotton wool, the other tube being closed with an India rubber cap; a spark was then passed. At a distance of 630 mm. from the open end, at which the ignition took place, the outer covering of the tube was split; at a distance of 1,000 mm. from the same point was a hole, at 30-30-300 another split, and at 1365-1100 a third hole. The explosion in each case was blown off the end of the tube. At the split holes the interior coating of the tube was torn and pushed outwards towards the opening, showing that the reflected wave allowed the escape of gas from both directions. Measuring the distances between the holes and the ends of the tube, we have the following numbers:—From end to first split, 630 mm.; from split to first hole, 1250; from first hole to mean of second and third, 1200; from this point to end of tube, 1260.

There seemed to be some doubt as to the uniformity of this tube, so another was made by rolling a strip of paper helically along a glass tube in such a manner that the edges did not overlap. A glued strip was wound over this so as to cover the joint; and a third to cover the joint of the second, the edges not overlapping and yet touching one another throughout. The process was very tedious, and the result showed, not successful. This tube was 975 mm. in diameter, and the glass only 4 %, the total length being 8390 mm. The end of the tube farthest from the wires was firmly closed, after introducing the explosive mixture. When the gas was exploded in the tube 9 holes were made, in some places the tube giving way at joints, but without any great tear of the paper. Starting from the end of the tube the first hole was at 620 mm., the other holes being distant from one another 630, 630, 600, 475, 375, 320, 280, 255, 220, 265, 2115, 365, 85, and the other end 265 from the last hole.

A third tube was next constructed, but on a different principle. A sheet of glazed paper was wound round a brass tube and all once removed; in this way a tube about 275 mm. long and 13 wide, and consisting of about 3 layers of paper was obtained. Thirty-two of these were made, and so as to by gluing narrow strips of paper round the joints. The tube was wound with double strips of paper instead of single, and was 9000 mm. long. The experiment was made in other ways, and it was not found that any additional quantity of water had entered the tube from the gas-holder while introducing the gas. In this case the explosion made no holes, but the joints obviously considerably strengthened the tube in their neighborhood. The distances between the holes were not more regular than in the previous case. From the end to first hole 772 mm.; the other holes being distant 660, 1295, 146, 484, 230, 295, 308, 1325, 585, to end 2615. The end was not spared by the explosion.

Although these experiments have not exhibited the regularity I anticipated, they show that a tube burst by an explosive mixture need not be expected to span along its whole length.

Cooper's Hill, October 25. HERBERT McLEOD

THE USE OF OZONE OR IRON IN GAS PURIFICATION.—Mr. J. Hall, of St. Andrews, N.B., sends us some interesting figures—which have been forwarded to him by Mr. Thomas Hyde, Engineer to the Metropolitan Works of the South Australian Gas Company—showing the advantage gained by using oxide of iron in conjunction with lime for gas purification, in preference to the latter only. These show the following results:—

Lime used from May 1, 1877, to Aug. 31, 1878		1,056,000 bushels.
Do. May 1, 1878, to Aug. 31, 1880		1,056 "
Saving effected		77,000 bushels.
Number of purifiers charged during the year 1877-78		1,104
Do. do. do. 1878-79		1,104
Saving effected		Nil
Gas made during the year 1877-78		193,600,000 cubic feet.
Do. second period 1878-79		172,925,000 "
Increase in second period		17,675,000 cubic feet.
Gas purified per bushel of lime during first period, with-out oxide		1,452 cubic feet.
Do. during second period, with oxide of iron		1,452 "
Less gas purified in second period, with oxide of iron		Nil.
Lime per bushel required to purify gas made during first period		0·726 bushels.
Do. do. second period		0·726 "
Actual quantity used		19,231 bushels.
Do. do. do.		4,230 "
Total lime saved		14,831 bushels.
14,831 bushels of lime, at 1Sl.		£311 7 6

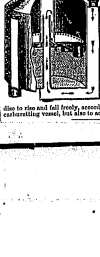
Note.—The oxide had been in use for 18 months up to Aug. 31, 1880, and had purified 1,163,300,000 cubic feet of gas.		

At Elstree a committee of three of the Board of Supervisors has been appointed to examine into the merits of a "gas saving apparatus" exhibited to the Board. 'There is one way to save gas, and that is not to burn it.' Gas is a luxury—clean, bright, pleasant. Kerosene is cheap, but it explodes, it is troublesome and it smells. Those who use gas, and use it lavishly, must expect to pay for it. No saving apparatus can save, where you want bright light and plenty of it.

THE "IHILIOD" CARBURETTING APPARATUS.

The Universal Carburetting Company, of No. 31, Threadneil Road, E., have introduced a new apparatus for carburetting coal gas, which they style the "Ihiliod"—the invention of Mr. Reuben Trotman, of Yeovil. The patent for the apparatus (No. 3211 of the present year) was taken out on the 18th of July, and the specification states that the invention is for "improvements in Apparatus for Saturating Atmospheric Air or Gases used for Heating or Illuminating Purposes with Liquid Hydrocarbon."

The apparatus—which, by preference, is circular in shape—consists of an



outer and inner chamber, the latter being so constructed as to intercept the gas from the meter or other source of supply. As shown, the gas enters by a pipe, at the bottom, and passes through a perforated diaphragm, which causes it to be thoroughly mixed with the saturating vapour before actually reaching the bottom of the inner chamber. Attached to the bottom of this inner chamber is a cup which the gas enters before it rises to the top; and therefore passes out at the side. This discharge is supported by a float, which rises and falls with the surface of the liquid hydrocarbon in the outer chamber, and which, by means of a valve, regulates the flow of gas from the inverted chamber. The gas, although thoroughly saturated with the vapour of the oil, is not under pressure, and therefore passes out at the top of the apparatus without the aid of any mechanical contrivance. The oil, by the evaporation of the gas, is reduced in volume, and after performing the saturation. At the commencement of the day the inner chamber is reduced a gauge of suitable depth, to prevent the passage of the gas altogether, but as the oil is consumed it gradually rises to the level of the lipsbecause in the outer chamber, and when this is reached the gas passes out freely, according

15 — E. G. LOVE, Ph.D., *Gas Examiner.*

GAS PURIFICATION IN NEW YORK CITY.

The matter of purification is one of general interest to all gas men, and the question often arises how can it be accomplished most effectually and economically. The effectual purification should always be first considered; but in judging from results many give the economical part of the operation more prominence. In many cases, however, a poor gas purification is due more to ignorance as to setting at requirements, value of material, etc., than to any intentional slighting of this part of the manufacture. In this country the thoroughness of purification is left, in the majority of cases, to the engineer of the works, with little or no interference on the part of an official inspector. In England, however, the engineer is fully aware that the gas he sends out will be examined by those appointed in the interests of the public and hence there is added to this check to any carelessness on his part. Gas, like every other article of manufacture should be made to suit the circumstances will permit. Carbonic acid and sulphuretted hydrogen should never be allowed to exist in the gas, if it is possible to remove them. The former injures both manufacturer and consumer, and the second the consumer more than the manufacturer. And this matter has a financial bearing in view of the more extended application of electricity as an illuminating agent.

In England the use of oxide of iron in purification has become very extensive, especially in thickly populated districts, on account of the offensive odors arising from the lime. The lime that is used is for the removal of the carbonic acid, the resulting carbonate being quite inoffensive, while the oxide of iron is depended upon to remove the sulphuretted hydrogen and part of the other sulphur compounds. The spent oxide is often sold at a price sufficient to cover the cost of new oxide. In this country lime is used to a greater extent than the oxide and it must be said that in many cases which have come under our notice where oxide was used the results were far from satisfactory. Practically, the oxide of iron when properly used will remove all the sulphuretted hydrogen, but it has little or no action on the bisulphide of carbon and carbonic acid. Not all oxides of iron are effectual in purification, nor is it possible to say just which oxides will accomplish the purpose, and which will not. It is generally the hydrated sesquioxide which is employed, but sometimes anhydrous oxides will do the work where the hydrated oxides have failed, and none can be relied upon without some practical trial to determine their efficiency. Natural oxides are principally used in England, and of these the Irish oxide seems to furnish the best results. In this country it is more generally the custom to prepare a mixture of a natural oxide with sawdust and some porous material as charcoal or sawdust. Of the New York companies the only one using oxide exclusively is the Harlem. "They employ some such mixture as that already mentioned, and it must be said the results are not entirely satisfactory." The gas frequently shows the presence of sulphuretted hydrogen and carbonic acid. There is no reason why the former should not always be taken out if the oxide employed is suited to the purpose and is made to do its full duty. Sometimes the gas will give an immediate indication of sulphuretted hydrogen, while at other times it shows itself but slightly after a long exposure of the test paper. As to the total sulphur in the gas of this company, it has reached as a maximum 58.57 grains in 100 cubic feet, and 40.24 grains as a minimum, the average for the past three years being 48.10 grains.

We naturally look for more sulphur in the oxide purification on account of the non-removal of the bisulphide of carbon, and doubtless the sulphur in the present case is largely due to this cause. Nor is it surprising that some carbonic acid exists in the gas, if, as we understand, no lime is used to remove it. One per cent. of carbonic acid will diminish the illuminating power 10 cent. seven per cent, and it is a poor policy to add enrichers to counteract the effect of this impurity.

The Manhattan Co. use lime entirely, and the gas is free from sulphuretted hydrogen and carbonic acid. The bisulphide of carbon which forms the larger part of the sulphur compounds present, is best removed by the sulphide of calcium, but it is a matter of some difficulty to maintain the conditions calculated to effect this. The largest amount of total sulphur obtained within the last three years was 72.72 grains per cubic feet, and the lowest 12.8 grains, the average being 20.66 grains.

Ammonia is present in greater or less quantities, the highest being 8.68 grains, and the lowest 2.42 grains, the average, 5.23. The scrubbers remove all the free ammonia, but are not equally effective with the ammonia compounds, which coming in contact with the lime of the purifiers are broken up, the free ammonia passing into the commercial gas.

The water gas as manufactured by the New York and Municipal companies, is free from ammonia and sulphuretted hydrogen, and the nature of the process will insure a tolerable freedom from sulphur compounds. The Municipal company use lime for purifying, and the gas is free from carbonic acid. The New York Company have not adequate purifying capacity, and at present the gas contains carbonic acid. The effect of this may often be roughly traced from day to day, in the varying illuminating power and gravity of the gas. It is no unusual thing for the specific gravity to increase and the illuminating power to decrease at the same time, a condition which can readily be explained on this ground if on no other.

The average total sulphur in the Municipal gas is 3.65 grains per 100 cubic feet, while in the New York gas it is 7.09 grains. When the New York Company was making gas from coal and purifying by oxide of iron the average total sulphur was 27.09 grains.

The Metropolitan Company purify by lime and the gas is free from carbonic acid and sulphuretted hydrogen, but sulphur compounds, other than sulphuretted hydrogen, are present, the average for the past three years being 19.31 grains per one cubic foot of gas. The largest quantity found was 23.89 grains, and the smallest 11.72 grains. The purification of the bisulphide of carbon is an interesting, inasmuch as both lime and oxide of iron are employed and the gas contains both sulphuretted hydrogen and carbonic acid. To understand the case it is necessary to say that the mixture of the coal and wood gas which forms the body of the commercial gas is purified before carbonating, and not afterwards, as with the water gas. With regard to the carbonic acid it is either not entirely removed in the "fixing" of the naphtha vapor in the hot retorts, from some slight admixture of air. In such a case, however, we should not usually expect the lower oxide of carbon, and on the whole it seems probable that the carbonic acid produced in the manufacture of wood gas is not entirely removed.

The sulphuretted hydrogen is found in considerable quantity, at times sufficient to blacken a paper test of moderate exposure. The presence of this impurity may be due not to imperfect purification, but to its subsequent formation by the decomposition of bisulphide of carbon. It is well known that if a mixture of hydrogen and vapor of bisulphide of carbon be passed through hot lime the latter is broken up, the carbon being deposited, and part or all of the sulphur combining with the hydrogen to form sulphuretted hydrogen. This same result is effected by passing the gaseous mixture through a hot retort, as in the process of "fixing" the naphtha vapor, so that in the present case if some bisulphide of carbon still exists in the commercial gas, sulphuretted hydrogen could appear in the commercial gas. It is obvious, that by purifying the gas with oxide of iron only could be avoided, and it may be expected that this impurity will disappear when the improvements of the company make the gas entirely from wood, is carried out. The use of wood in part in the manufacture of the gas has reduced the average total sulphur from 9.15 grains to 5.18 grains per one cubic feet.

"The gas stoves at the stations of the Sixth avenue Elevated Railroad, have been replaced by coal stoves, and in the words of the *Herald*, like faith: evidence of things hoped for and the substance of best not fait."

THE SANITARY ENGINEER.

paratus was placed therein, and since that time has maintained a sufficient moisture, and a temperature of 140°, without a variation of over 2 to 3 degrees. The air is conducted to the burners in the heaters by a flue from the outside, the products of combustion being carried out of the room. A large evaporating pan is placed over the heater, and directions maintained by a considerable quantity of pipe brought into contact with the products of combustion. This water is maintained at a uniform level from the outside by a suitable arrangement designed for the purpose.

Tobacco men tell me that heretofore they have had considerable trouble in maintaining the temperature to within 20 to 30 degrees of what they desired. The object is to color the leaf. Before being placed in the sweating room it is quite light and yellow; after submitting the leaf to this process it comes out a rich brown color, and looks equal to the best Havana leaf. By this means Connecticut and Pennsylvania tobacco is made to rival Havana in appearance. Gas has been called to the aid of the tobacco men, and it has proved a success.

Mr. Littlehales—Have you any idea of the relative cost as compared with the cost of coal that would have been necessary to have accomplished the same result?

Mr. Goodwin—The amount of gas used by the first parties was about 15 feet per hour, until the temperature desired was reached, after which the gas was lowered to probably 8 or 10 feet per hour. In the large room, two burners, of 15 feet each, were placed in the heater, making a total of 30 feet per hour. After the desired temperature was reached, one of the burners was dispensed with, the other being sufficient when lowered to from 10 to 12 feet per hour.

Mr. Littlehales—Was the room specially constructed for the purpose of heating by gas?

Mr. Goodwin—Yes, sir; I told the parties that if they would construct the room in the way I suggested I would undertake the job. I have had the least difficulty in getting the heat up to 150°, which is all they require, and maintaining it at that point constantly.

Mr. Littlehales—I move that a vote of thanks be tendered Mr. Goodwin for the valuable information he has given us. (Carried.)

The President—Our papers have all been read and discussed, and we are about through with our business, with the exception of Mr. Page's address this evening upon the subject of coal tar and its products. But before he begins his address, I believe we have an hour to remain in session for members who died last year. Many of those men were distinguished in their profession, and I suppose some of the members present will desire to say something in reference to them.

Mr. Wood—It has occurred to me that it would be more satisfactory to appoint a suitable committee for the purpose of preparing, on behalf of the Association, a proper expression of our respect for the memories of these deceased members. The report of the committee can be published in our regular proceedings.

Gen. Hickenlooper—In the case of similar proceedings in a society with which I am connected, it has been the custom for a member of years for the president and secretary to constitute a committee to take the course suggested by Mr. Wood. They compile a biographical sketch of the lives of the deceased members, their character and services, and present it at the next meeting.

The Secretary—The very object I had in view in proposing that remarks be made by the members was to avoid the stereotyped, bald and unfeeling business of resolutions. A committee is appointed, and resolutions are prepared which are the merest platitudes. I think we ought to spread upon the record, and transmit to the families of the deceased members, a spontaneous and heartfelt expression of our respect for their memories and regret at their loss. For my own part I would rather have one such tribute paid to my memory from one who knew and loved me than volumes of resolutions. There is another view of the matter that I should like to have passed upon, and that is that when notice of the death of a member reaches the Secretary, he should be empowered to send a brief circular to each member of the Association stating the fact that such a member has departed this life. As it is now, twelve months must elapse before, as an Association, we know that a member has passed away.

Gen. Hickenlooper—The object suggested by the Secretary is accomplished by the course I have suggested. In that way we avoid all this wholesale flattery, and simply make a short biographical statement of the character and services of the deceased members, expressing, at the same time, in fitting language, our appreciation of their character and services. This is preserved in an imperishable form, and can be transmitted to the family and friends of the deceased.

The President—Do you make that motion?

Mr. Wood—I accept the suggestion of General Hickenlooper that a committee, consisting of the President and Secretary, be requested to prepare brief biographies of those deceased members, and agree them to be published in the forthcoming volume, and also that the Secretary notify the Association of the death of members when they occur. (Carried.)

On motion, the Association then adjourned until eight p.m.

EVENING SESSION—OCTOBER 14TH.

The Association met at eight p.m., pursuant to adjournment.

The President introduced Mr. Geo. Shepard Page, of New York, who delivered the following address upon

SECOND PRODUCTS.

Mr. President, Ladies and Gentlemen:

It is needless for me to premise what I have to say by assuring you that I appreciate the honor of standing before you on this occasion. The engineer of the Marquette Gas Light Company sent a small specimen of a substance he had extracted from coal tar, supposing it to be anilline oil. The Association referred it to me to determine what it was. I think he has been, in a small way, distilling his coal tar in order to obtain the light products, and the oil to use again in enriching his gas; (Laughter.) It is evidently the light oil of the coal tar, containing, perhaps, some ammoniacal liquor. Anilline oil is a very different substance. This would be worth, perhaps, ten cents per gallon; but anilline oil, used in making the best aniline dyes, such, for example, as are used in those beautiful fabrics before you, is worth about five dollars per gallon. I think, however, that this engineer located in the wilderness, as we may say, deserves great credit for investigating one of his residual products. I am sure that one beginning thus will steadily advance in the acquisition of knowledge concerning his coal tar products.

I understand, in the announcement was made this afternoon that I would talk to you this evening simply upon the subject of coal tar, its products and their uses. But in the invitation extended to me I was also requested to explain the value of that other residual product—ammoniacal liquor. In this connection, permit me to exhibit to you on the blackboard a drawing of the most complete apparatus for the manufacture of sulphate of ammonia. After you have examined this drawing, I will show you some of the results of this process, and will exhibit to you various ammoniacal products that are found in the market. Most of these products you have seen; I presume most gas engineers have seen ammoniacal liquor. (Laughter). Here is a specimen. Perhaps the ladies would like to test the odor. (Laughter). This was taken from the last gas house we visited yesterday. I have not tested it; but I should judge it to be what is termed "three ounce liquor." It is not beneficial to the manufacturer of sulphate of ammonia to use ammoniacal liquor of much less than eight or ten ounce strength, which is being obtained in some of our large cities by what is termed the "Mann system," or the "Tower scrubber." I presume most of you have seen it; and it is, therefore, needless for me to describe it in detail. The tower is usually filled with coke, boards or lath, scrap tin, various appliances being used to divide the current of gas passing from the lower section to the water passing down. The objection all undoubtedly find to that system is that a portion of the gas passes up the channels generally constructed without coming in contact with the water, so that the ammonia is not all taken from the gas. I presume you will all agree with me that it should be all taken out in order to get the highest illuminating power. The scrubber that is now extensively used in Europe, introduced about three years ago, is what is termed the "standard scrubber." It is a horizontal apparatus of iron, from six to nine feet in height, and four or five to six feet in diameter. A shaft runs through the centre dividing it into sections of from five to ten or eleven each. On the shaft are arms carrying discs of sheet iron—forty of these on each one. Discs are bolted on all over these discs. This shaft revolves four or five times per minute. The gas passes in one way and the water passes in at the opposite end. The water is drawn off at the other end, and the result is unmanufactured liquor of from ten to thirteen ounces. All the free ammonia is taken from the gas, and a large percentage of sulphuretted hydrogen and carbonic acid. Its cost is much less than the tower scrubber. Small works can introduce this one to advantage. I think the question of producing as much ammoniacal liquor as possible will speedily become an important one as companies so that of receipts for coal tar; and my object in bringing this apparatus to your attention is to do what I can in hastening the time when the largest amount of profit is derived from the sale of ammoniacal liquor.

Let me tell you what is done on the other side. About ten years ago I visited Dublin, and I found all the ammoniacal liquor utilized and converted into sulphate of ammonia; and, upon further investigation, I discovered that there was not a single gas company but what utilized that product in one way or another.

The process of manufacturing sulphate of ammonia, which is the chief method of utilizing the ammoniacal liquor, you will see represented on the blackboard, and I can refer readily and more intelligently to it by reading a description of the drawing.

Referring to pipes for securing salty matters, etc., placed in a suitable position above the level of the condenser. B, closed tank containing condensing

Miscellaneous News.

A REVIEW OF THE MANUFACTURING OPERATIONS OF THE PARIS GAS COMPANY IN 1879 AND 1880.

The following is the report of the Commission nominated by the French Minister of the Interior, early in the present year, on "The Gas Supply of Paris," which appeared in the last number of the JOURNAL:—

In the present report the Commission proposes following, step by step, the processes employed by the Paris Gas Company, from the reception into the Company's illuminating gas from the delivery of the manufactured gas through the distributing pipes, down to the consumption of the gas delivered gas through the distributing mains, down to the consumption of the gas delivered. In doing so, it will be convenient to divide the subject into three stages, viz.: (1) the distillation of the coal; (2) the purification of the raw products; (3) the chemical purification and the gasometers of the tar-producers; (3) the chemical purification of the gas; (4) its storage; and (5) the treatment of the residual products—coke, tar, and ammoniacal liquor.

I. *Distillation of the Coal.*

Of the several operations comprised in the manufacture of gas, the distillation of the coal is assuredly the most important, as it is upon the quantity obtained by distillation that the principal return depends. This work the Paris Gas Company have succeeded in making more profitable than it formerly was, and the improvements they have effected from time to time have had an important influence on the quantity of gas obtained from the coal put into the retorts. In order to appreciate correctly the extent of this influence, the Commission applied to the Managing Director of the Company for information from the official returns showing the quantity of gas produced during the last 21 years from each hundredweight of coal carbonized, and the following figures were supplied:—

Year.	Gas Made. Per 100 kilos. Cub. Metres.	Per Ton of Coal. Cub. Feet.
1863	29·05 = 10,088	
1864	29·31 = 10,178	
1865	29·34 = 10,187	
1866	29·53 = 10,421	
1867	29·67 = 10,195	
1868	29·83 = 10,177	
1869	29·77 = 10,546	
1870	29·10 = 9,233	
1871	29·03 = 10,253	
1872	29·13 = 10,293	
1873	29·23 = 10,331	
1874	29·20 = 10,556	

These figures show that the yield of gas, which before the year 1863 rarely exceeded 27 or 28 cubic mètres per 100 kilos. of coal (about 9,500 to 9,900 cubic feet per ton) has gradually increased to 29·20 cubic mètres (about 10,300 cubic feet per ton). This shows an increased yield of very nearly 2 cubic mètres, or about 7 per cent., per 100 kilos. of coal carbonized. This result is one of important fact; but it should be remarked, on the one hand, that it was not obtained all at once, but by successive stages (see table below); on the other hand, that it is simply a maximum result, and not to the introduction of any processes foreign to the system of manufacture employed in 1863, that this increased yield of gas is to be attributed. In fact, several causes have combined to bring about this result. The retorts have been manufactured with greater care; their form and dimensions, combined chimneys, working regularly and at trifling expense, have been studied with more attention; the quality of the coal employed has been carefully selected; more especially soft coal, obtained from Belgium, the north of France, and elsewhere, have been used together, and from this admixture of new material has resulted a more regular and more abundant production of gas than that hitherto yielded by single varieties of coal, or even by mixtures formed less carefully made. However, the influence of these causes has really been only a secondary one; it is in the distillation itself that the chief improvements have been effected. On the one hand, the retorts have been charged with more coal than formerly, and on the other hand, the working has been brought up to this temperature, that must be sought after and attained—the increased yield of gas is which allusion has just been made.

When, some 15 or 18 years ago, gas makers began to substitute, for the comparatively low temperatures previously employed in distillation, the high temperatures at present in use, they found that the quantity of gas obtained from a given weight of coal had to be increased to draw off as quickly as possible the gas produced at this high temperature, and in order to do so the method adopted was to charge the retorts, only two-thirds actually required for the expansion of the coke. It was thus that the Company were gradually led to increase the charges of each retort, which formerly rarely exceeded 60 kilos. (132 lbs.), to 70 kilos. (172 lbs.) in 1863, 80 kilos. (176 lbs.) in 1865, 90 kilos. (198 lbs.) in 1867, 100 kilos. (220 lbs.) in 1868, 120 kilos. (264 lbs.) in 1869, and to the present statement figures at which it now stands—viz., 130 kilos., 286 lbs. It is in this way that the Company have succeeded in obtaining their high yield of gas, which since 1870 have risen to 29·23 cubic mètres per 100 kilos. of coal carbonized (about 10,425 cubic feet per ton), and have only fluctuated to a very slight degree above or below this figure, such fluctuations being in all cases attributable to the quality of the coal employed in the retorts.

In some of the foregoing statements it is possible to recognize processes foreign to the system of manufacture previously employed by the Company. It is simply to some skilful manipulation, and not to the employment of any arrangements answering to the definition of new processes, that is to be attributed the increased yield of gas which the Commission found had been obtained. But even if this were otherwise, the Commission, in the interests of economy, would not recommend the adoption of the Company's concession has been understood to entitle her. But, on the one hand, the economy of combustible which the use of the Siemens furnaces in glass-making, metallurgy, and similar operations, makes possible of realization, is very considerably reduced in the face of the lower temperature suitable for the manufacture of gas, and is moreover largely counterbalanced by the increased expense of first establishment necessitated by their employment; on the other hand, it was at a period considerably anterior to 1855—namely, in 1850—that furnaces constructed at their Vaugirard station, the first four Siemens furnaces set up in France were put in operation. In fact, the results are clearly established in a report presented to the Council of Hygiene of Paris on the 20th of January, 1857, by the present Managing Director, M. Graviss. As another copy of this report has been submitted to the Commission, and it shows that the economy in fuel realized by the employment of these furnaces amounted to 30 per cent., as compared with the distillation of gas in fire-clay retorts, which for all other details of the manufacture were identical with the Siemens furnaces. The saving thus effected was the equivalent to 1,950 fr. (£78) per furnace per annum, while the cost of setting, which for all other settings blows with the Siemens furnaces is increased by 1,950 fr. (£78)

...of Mexico expressing a doubt of it, nor have ...heard any doubt expressed by any one in the country. The people seem to accept the survey which has extended the engineering works of Captain Eads as an ample guarantee of his ability to carry out what he proposes, and, while his recognition has been devoid of any theatrical display, the manner in which he has been received and treated by the Mexican government and people has been a source of the liveliest gratification to American residents in Mexico. At his request a costly expedition, comprising about fifty individuals—engineers, assistants, laborers and soldiers—was sent him in making a survey of the isthmus to determine the most practical route for the ship-railway. He has been prepared by the Mexican government and has started for the scene. This commission is under the direction of the eminent civil engineer, Francisco De Garay, who is in charge of the drainage of the Valley of Mexico, and who was commissioned to represent the Mexican government at the Paris Canal Convention. He is directed by the government to assist the engineers of Captain Eads in the instrumental survey of such routes as he may designate. Messrs. Williams and Corthell will direct the survey starting the absence of Captain Eads, who has started with the expedition to the Isthmus to inspect the rivers and harbors, and give the party such instructions regarding the work as he may deem necessary. As an additional evidence of the respect of the government for Captain Eads, he has ordered one of its war vessels, the Independencia, to take him from the Isthmus to the port of New Orleans on his way to Washington.

THE PANAMA CANAL.

(Boston Advertiser (Rep.), Jan. 7.)

There can be no doubt that the financial owners of the Panama Canal, so far as known, are no longer satisfactory than the political elements in which they belong to it. M. de Lesseps has spent all the money he could put into $80,000,000. For this he will undertake to say that a canal is completed the shares holders will get 1 per cent. in annual interest. Some such arrangement is possible at first, but where the unhappy Khedive furnished more laborers and more cash than accessible accounts report. It was possible with the Pacific Railroad which was largely guaranteed by the credit of the United States, and still owns a whole kingdom of fertile lands. The men who bought the shares and bonds of the road received an equivalent, very much as a man who takes a national bank bill receives substantial value. The owners of Panama stock, so far as human eyes can see, receive only the promise of value or possible value—prospective value. There is neither Egypt nor America to fall back on in case of a deficiency. Where, then, is the interest to come from until the canal will be earning money? If it be supposed that the canal is complete in ten years and the $80,000,000 will build it, is it not evident that $30,000,000 have to be paid out in interest alone before the canal will earn anything? Even if the $80,000,000 were signed and paid in, what would be left for building purposes after the annual interest on the shares, and the incidental expenses have been paid? M. de Lesseps surely owes the world some explanation of this remarkable financiering.

...the Gas Trust, paying them $125,000 of six per ...cent. bonds, and $48,000 of five per cent. bonds, ...the stockholders also having the net profits from ...the gas works to that time. The management of ...the works was continued the same as before, however, to protect the bonds thus outstanding. How profitable the manufacture of gas has since proved is shown by the fact that down to Jan. 1, 1879, the sums created for the purpose of developing the gas works have amounted to $6,120,740. Of this amount there was outstanding:

Jan. 1, 1879	$6,300,740.00
Sinking funds	1,555,908.72
Leaving the net outstanding loans Jan. 1, 1879,	$4,744,831.28
for which the city owns bills, at	

...he Trustees, Jan. 1, 1879, estimated the value ...of the works, gross mains, services, meters, ...etc., at cost, at $11,172,380.58
...There has been realized on account as a sinking ...fund for the redemption of loans: 3,256,740.55
...$10,561,139.11
...Sum which deducts the total amount of loans ...and stocks 8,120,740.00
...Leaving the amount paid out of the profits $8,440,300.11
...and interest upon investments 3,120,740.00
...Showing the net value of the works to the city.

With this showing, it is not to be wondered at that the citizens of Philadelphia are clamoring for cheaper gas, and claiming that the exorbitant prices of the past have enabled the Trustees to not only pay the interest upon the capital engaged in manufacturing gas, but to create that capital itself.

The citizens are now agitating the question of taking the workcast of the hands of the present Trustees, but are met by the claims upon the part of the Trustees that no change can be made until the last of their loans expire, which is in 1885, although at the present time there is in hands of the Trust more than double the amount of the loans of 1885.

IMPROVED GAS BURNER.

The accompanying engraving represents a new form of gas burner invented by Dr. Steinberger. It is claimed that it is very economical in burning coal gas, giving a brilliant illuminating power, and is especially adapted to secure perfect combustion, thereby preventing the deposition of lampblack and carbonic acid gas, which vitiates the atmosphere very rapidly. The burner shown in the engraving is so arranged as to increase the formation of poisonous gases, and thus, in time, poisons by smoke and gas, the atmosphere of the room. *Scientific American*, of 50 per cent. according to the second by an increase of illuminating power, and a decrease of consuming the same.

In this burner, which has been named the "force gas burner," the gas, side jets are directed to a point at the center of the flame, thereby throwing heated gas upon the flame. By this means the gas is greatly increased in volume and expanded, and an additional supply of oxygen is conveyed to the flame. The formation of carbonic acid is thus prevented, and the gas being superheated—are reduced to a state to give out the greatest amount of light. This more perfect combustion also checks the production of carbonic acids.

Gas, like steam, admits of expansion by heat to almost any limit. The more the particles are heated and separated, the more perfect combustion is secured, and a larger proportion of light is produced. In the burner in use, a sufficient expansion is given through it to carry the burner to within about two inches of the flame. This is the "force burner" by a novel check, which is very simple and effective. No complicated valves or any kind of apparatus, which are liable to become smutty and fill up, are used.

The inventor gives the following photometric test, made in May last, at Ills. pressure:—A common burner, placed upon the table, gave an average of 22 candles light, light emitted equal to six star candles. The "force burner," with the same amount of gas, light emitted equal to 112 candles. The burners are made by Mr. J. C. G. Pellington, 27, Park-place, New York.

A "NEW GAS" BURNER.

A "new gas" has been introduced for lighting the large engineering and boiler-making works of Messrs. Dunoon, Hawsley, and Co., Glasgow. Col. A. P. Chamberlain, who invented, and the Company manufacture, the thus named gas. In this, Perm's formula, about 95 grains and 5 grains of benzoline are mixed with a small admixture of alcohol. The alcohol is a gaseous nature, about 70 cubic feet of which are required to take three weeks, and through which air is passed, a combination of mineral oil, water, and air, which enter through a small pipe, carried down to the tank to the front of the burner, and the gas finds an exit through a fine slit at the back of the retort. The vapour is carried to the premises, where Messrs. Dunoon, Hawsley, and Co. are on the roof behind the funnel. There it is carried into the gas-holder, and thence through the old pipes in the works to the various machines and benches in the shop, supplying about 1,000 burners. The gas gives a whiter and purer light than that of coal-gas, or something between that of coal-gas and the electric light.

That investors in gas-shares are not alarmed by the progress of the electric light was shown last week, when some additional stock of the South Metropolitan Gas Company was put up and "bids" of wood, cut straight, lapped and ...ed together in the strongest manner, ...ollect very little dirt, are cross-cutted to ...the better with saws, thus forming a ...durable vehicle which may be left out in the ...weather with little harm. Experience and all ...of the gases, dogs, and coal-drivers of the ...roads are readily cleansed by any one of these ...three pails of water I have in use. ...Here is economy of time and trouble in the ...struction of a vehicle made specially for its ...filling purpose in use as long as it lasts, which ...should be longer than the average of light carts, ...even though used for station, market, and trade ...purposes; for the simple reason that decay, the ...prime cause of wear and freshness, is not con... ...cerned between wheels and the ...ground, and the soundness and ...through the centre of the ...ed wheels, which ...being "washed-out," ...heavy "split-cushioned" ...

MR. C. F. Ansell, an Englishman, the inventor of the Breadalbane indicator, has recently applied the principle of that apparatus to the production of a handy little instrument for the detection of gas leaks. The action of Mr. Ansell's breadamp indicator is founded on the fact that different gases have different rates of diffusion through a porous body, the velocities of diffusion being inversely as the square roots of the respective densities of the gases. In the gas leak indicator in question, a small quantity of ...s follows:—A small chamber is provided, having its back formed by a disk of terra cotta, this chamber being described with a small stop-cock, by which communication is established in communication with the outer air. Ill, when this stop-cock inclosed, an indicator be taken into a room where a gas-leakage exists, the gas, in virtue of the above-named law of diffusion, enters the chamber through the terra cotta disk more rapidly than the inclosed air escapes, and the pressure in the chamber is consequently raised. This increase of pressure is indicated to move a fluid in a dial at the front of the instrument, such pressure corresponding to a certain percentage of gas in the atmosphere in which the instrument is set. The dial is graduated, which is done by placing the instrument over, supplied to show what percentage of gas is not explosive. The instrument is extremely sensitive and prompt in its action, and has developed itself as a very useful purpose. The instrument is being introduced by Messrs. J. Macpherson & Co., of the Coal Exchange, London, Eng.

portion of final charges that each thousand feet has to bear; and there is no question but that a lower price, judiciously established, will increase the amount of business, and, consequently, the amount of profits.

That good sixteen candle gas is the best and most economical for both the maker and the consumer cannot be doubted. It can be more perfectly consumed, with less trouble, and more light and better diffusive power can be obtained from it, in proportion to the quantity used, than from a 22 candle gas, simply from the fact that larger flames can be secured without smoking.

The true policy would be to sell the gas as low as possible, and pay ten per cent. on a reasonable capital, and be sure that the gas was uniformly a good, honest sixteen candle gas.

RESIDUAL PRODUCTS.

In our last issue we gave in full the lecture of Mr. Geo. Shepard Page, before the American Gas Light Association at Chicago, upon the subject of the value of residuals. The facts there stated certainly ought to be enough to arouse the managers of works to the importance of looking into this matter in a most thorough and practical manner.

We are aware that aggregates of small amounts sometimes show very largely, and that much labor, expense, and some disappointing experiments have to be endured before the totals given by Mr. Page could be realized in this country; but as long as the possibility exists efforts should not be spared to discover a practical way of obtaining at least a large portion of the benefits that may be derived from the working up more perfectly the by-products of the gas industry.

As in this issue we give two papers read before societies in England and Scotland upon this same subject, with the discussions thereon, which contain many valuable statements as to results actually obtained by numbers of smaller works, as well as an account of the different processes used, those facts are valuable contributions to the literature of the subject, and show, in every case, a clear profit to the Companies. As the price of gas is constantly expected to decline, the reduction in receipts for gas must be made up by increased revenue from residual products.

Paw Paw's Legend

And Paw-kon-wis told them stories—
Stories that were not all fiction;
Told them of his own half-brother,
Gas O Meter*—the great liar,
He whose name would scare the boldest,
He who reads the strong men humble:
He who could deceive the wisest,
He whom ways were past all knowledge
He the most consummate villain,
He the everlasting lyre;
For he sang in every wigwam,
And his voice was low and soothing,
And he lulled all their suspicions—
Then he came down like a wind storm,
Changing them unheard of prices—
Prices that were simply monsous,
Charged them ten times what he should have—
Charged for time he had been singing;
Till at last they had him muzzled—
Brazished with his tongues of fire
To the land of Hocus-Pocus,
"To the land of the Hereafter."

IRA JOYCE.

* The irregularity of the verse is caused by introducing gas into the meter.—*Norristown Herald.*

Lights and Lighting.

The importance of good light, to enable work to be done after dark, is very great, and during the long evenings and when the hours of night encroach upon those of the working day, shops where orders are pressing feel the importances of some method of practical illumination. The first result of poor light is that the work is imperfectly done. The workman is not able to judge of the quality of what he is doing, and so the character of the product falls off, even though he may do his best. The quantity of work produced is also diminished, owing in part to the difficulty of seeing, and in part to the discomforts which are always entailed by an attempt to do anything by an imperfect light. There is always a wear of eyesight, too, which, though it may not be noticed at the moment, contributes to the exertions of the labor. A good light is a necessity in almost every manufacturing operation that can be carried on upon a large or small scale. In many lines indeed, as important is this that the length of the working day in winter is always determined by the hours of daylight, and always ends before artificial light is needed.

In the great cities and most of our manufacturing towns there are at least three methods of artificial illumination which are available for work on a large scale. First in order of intensity is the electric light; second, gas; and last, oil, the latter, with the burners now available, having least power. The electric light, when it can be employed even under ordinary conditions, is very cheap, its cost being practically nominal. When an establishment has power available at night, the amount needed to drive the electric machine is so small that no ordinary establishment would ever miss the quantity needed for the largest light. With the present price for coal, a horse power can hardly be estimated to cost in a large engine more than a cent per hour, and all the other expenses will not more than double that figure. The consumption of carbons is not large, and with an outside estimate for power the total cost of a light of 1000 candle power for six hours would not be more than 40 to 50 cents. To this, if we calculate interest on the plant, we should perhaps add 15 or 16 cents, making a total of about 65 cents for six hours.

The electric light appears to be applicable in all places where power is used and where an abundant and intense light is needed. There are drawbacks, however, to its use, and these are somewhat serious. The light given is not a pure white; it has a strong tinge of red and blue, and is notably wanting in the yellow. This makes the blues and reds, as well as all shades of green, unnaturally brilliant, while the yellows are exceedingly dull. This causes the peculiarly ghastly appearance which is so characteristic of the electric light. Another fault is that the source of light is practically a single point; hence the shadows are as sharp as though the boundaries were marked with a knife. This prevents the possibility of soft shades, and makes every shadow of the deepest black. The tendency of this is to cause all objects to appear flat, even when they are round. Until these objections are removed the utility of the electric light will have well-defined limitations.

Wherever there are gas works an illumination, in some respects greater than that possible from the electric light, may be obtained by the use of large burners, and at a much less cost than is usually deemed possible. Professor Hasy, of London, 700 candle power can be obtained at a cost of about 25 cents per hour, or $1.50 for the six hours. This, it is true, is somewhat greater than that of the electric light, but no power is needed and no supervision required. At the office of the American agents of these burners we have seen much better results than these, but we have taken figures which are entirely within the results obtainable in practice. Gas has the advantage of throwing a diffused light, which is very valuable. The light, although not as white as that produced by the electric lamp, inclines to the yellow instead of toward the blue, and hence is not only more agreeable to the eye, but of more value to the workman.

In many of our country towns the only means for lighting is oil. Unfortunately, no large burners are in the market which are applicable to ordinary 48 candle power. The cost of running these burners for, say, six hours would amount to the expenditure of perhaps a pint of oil. These are much better than a number of small burners consuming the same quantity, and, so far as we know, are the best that can be had in the country. By them my shop may be well lighted, and work carried on with almost the same ease as with gas. The main object is to get light enough.

In all cases a concentration of the sources of light, rather than a dispersion of them, is needed, except in the case of the electric light, when, for the sake of dispersing the dark shadows, it is sometimes necessary to divide the light and use two instead of one. A great loss of light, however, takes place when this is done, either with the electric, gas or oil lights. With oil and gas the burners should be kept as few in number and as close together as possible. One large burner is always better than two small ones, both on account of getting more from the same amount of oil or gas, and because one flame of double power or two flames close together are more effective than two similar flames separated by a considerable distance. The reason for this we cannot here discuss, but it is easily demonstrated.

Whatever light is used, let it be remembered that an abundance pays, not only in the amount of work and its quality, but in a thousand other ways. In the large cities, for example, an abundant light is made to pay for itself in enlarged sales, simply as an advertisement, and for this purpose alone it is also quite valuable in the country.

How much more attractive is the store or shop that is well lighted than the one that is dark and dingy. The subject is well worth the careful attention of our readers from a business point of view alone, independent of the care of the eyesight.

Oils are everywhere so cheap at the present time, and gas, in most places, is so reasonable in cost, that liberality in the matter of lighting cannot be regarded as extravagance by any one. On the contrary, it is true economy.—*Iron Age*, Dec. 30, 1880.

[From the London "Journal of Gas Lighting."]

Southern District Association of Gas Engineers and Managers.

The Quarterly Meeting of this Association was held, at the usual time, at the Guildhall Tavern, London—Mr. James Hunter, the President in the chair.

Mr. D. F. Goddard (Ipswich) read the following paper—

MANUFACTURE OF SULPHATE OF AMMONIA.

In bringing this subject under your notice, I feel I owe you some apology for dealing with matters on which so much has already been written; but it appears to me that there are comparatively few gas managers who, as yet, are working up their ammoniacal liquor, while so many might do so with great advantage. I do not propose to take up your time by going into the question of washing or scrubbing gas, nor to enter upon a minute description of the apparatus used in manufacture—this having been so efficiently done by the late Mr. Esson, of Cheltenham, and Mr. Eldridge, before the British Association of Gas Managers, as also in the article in "King's Treatise on Coal Gas"—but briefly to compare the different methods in use with a view to ascertain the most effective as well as the most economical means of making sulphate of ammonia.

The systems adopted for this purpose are many and varied, but the principles on which these systems work are few and simple. Omitting the most primitive method—namely, that of mixing the acid and the liquor in a lead vessel and evaporating down the resultant liquid to crystallization—as obsolete, on account of its nuisance, danger, and expense, I find there are mainly two, and very often three, operations in every system, viz.:—

1. A means of obtaining the ammonia from the liquor in a gaseous form.
2. An apparatus for fixing the ammonia vapor with sulphuric acid.
3. An evaporating pan to reduce the liquid sulphate of ammonia to the crystallizing point, and sometimes a means of breaking up the fixed salts of ammonia—the spumaline and sulphomyeline—which will not be given off by the simple application of heat.

I think it will simplify the discussion to follow, if I consider each operation *per se*, rather than deal with complete processes.

First, then, the means of obtaining the ammonia in a gaseous form. For this purpose some use an ordinary egg-shaped boiler, or, at all events, a boiler without internal fines, into which the liquor from the works is placed. It is heated either by the direct action of a fire over which it is set, or by the introduction of steam into the liquor; the latter way being decidedly preferable, except on works too small to have a steam boiler. The heat must be applied slowly at first, until the carbonic acid and other noxious vapors are all driven off; the ammonia vapor, as formed, then passes from the boiler through a pipe to the sulphuric acid vessel. When the ammonia is all driven off, some lime is introduced into the boiler to break up any fixed salts of ammonia which may remain in solution.

Others use a column, after the design known as a Coffey still, containing many shelves, over which the liquor, entering at the top, passes, traversing each shelf in succession until it reaches the bottom, where it finds an outlet. The steam enters near the bottom, and passes also over the trays, but in an inverse direction, leaving the liquor, and causing it to give up its volatile ammoniacal vapors, which, with the steam, pass out at the top of the still to the acid chamber. To obtain the best results, the liquor from the still should be passed into another vessel, and heated or stirred up with lime, to ensure no ammonia being lost as fixed salt.

In connecting these two systems, it seems that the former has the one advantage of dealing with the fixed salts of ammonia in the same operation as the volatile salts; while the latter requires another operation for this purpose; but, in my opinion, this does not compensate for the other advantages gained by using the Coffey still—namely, a saving of fuel by not having to heat so large a volume of liquid; less danger of nuisance from the foul gases (these, being given off more regularly and in smaller quantities, may be effectually burned in the boiler furnaces); and from its being almost a continuous process—there being no boiler to empty and refill—more work in a given time.

Secondly, the apparatus for fixing the ammonia vapor with sulphuric acid. This, commonly called the saturator or chamber, is also of two forms, which may be designated the open or crystallizing saturator and the closed saturator. The former is usually of a rectangular form, made of stone timbers lined with 14 lb. lead. Half the top is covered over and divided from the other part by a lead partition, which descends nearly to the bottom. Into the covered portion the pipe from the still enters, and lies along the bottom being perforated with holes for the emission of the ammonia into the acid, while from the cover there rises a pipe to carry off the carbonic acid and sulphuretted hydrogen evolved. Some mother liquor and acid are put into the saturator, sufficient to seal off the covered portion, and the still is started; acid being added constantly as needed, and of such a strength as to produce crystals which are raked out and placed on a drainer. With the boiler arrangement of still this goes on until all the ammonia is driven off; with the Coffey still it may be continued as long as desired.

The closed saturator may be of similar construction, with the simple difference that the top is all covered in and quite tight. A charge of sulphuric acid is put into it, care being taken that the acid is not too strong, or crystals will be formed in the saturator—a result to be particularly avoided. I find acid of from 40° to 50° Twaddel the best strength. When the charge has been neutralized, as is ascertained by testing, it is run off through a regulus cock or lead plug into an open vessel, where any foreign matter or dirt may settle. Thence it is passed on to the evaporating pan, where, by means of steam pipes, it is reduced to its crystallizing point, and the anilinate taken out as formed, and placed on a drainer.

The treatment of the carbonic acid and sulphuretted hydrogen is similar in both forms of saturators. The pipes conveying them may I believe, be advantageously intercepted with another box containing sulphuric acid, to arrest any ammonia that might be taken up with the foul gases; but I cannot speak from experience on this matter. It must then pass through some form of condenser, and the uncondensable gases are carried into the boiler furnace or into the fire of the retort stack.

In comparing these two methods of fixing the ammonia, it would appear that what is done in the open saturator in one vessel requires three vessels when using the closed saturator. The former is therefore undoubtedly the cheaper to erect, and probably the more suitable for small works. Where it is desirable to make white salts, the results are more likely to be satisfactory by using the weak acid saturator and evaporating pan rather than that in which strong acid is used, as this tends to clear and blacken any organic matter that may be present. It will also be more difficult to maintain the highest percentage of ammonia in the salts when these are taken from a strong acid solution, as the salt which hangs to the crystals would increase the weight, besides rendering the sulphate more liable to deliquesce. I may say, however, that I have seen some very excellent white sulphate produced by Mr. Browning, of Colchester, with the open saturator.

To come to the points of most importance to gas managers. Is it better to sell the ammoniacal liquor than to erect plant and manufacture sulphate? I think, with few exceptions, certainly the latter. Where works are so situate as, by water carriage and proximity of manufactures, to command such a price as 1*s.* per ounce per hour, or say 20*s.* per ton of liquid, I should think to wisest to let well alone; but then how few have such offers. The usual price with us is about half the sum I have named, and in all such cases it will be found highly advantageous to manufacture and sell the produce, as the following figures will show; they are based on a fair week's work, although the quantity produced could be increased by working for a greater number of hours—

Three tons of sulphate, at £18 5*s.* per ton.....	£54 15 0
Labor (one man), at 30*s.* per cwt.....	£2 10 0
Fuel (rough breeze) 22 cwt., at 9*s.* per ton.	1 3 5
Acid, 3 tons, at 70*s.* per ton.....	10 10 0 ·
Repairs, etc., 15 per cent. on £500.....	1 8 9
	£15 12 2
Balance of profit.....	£39 3 10

I estimate that it would require 8640 gallons of 10 oz. liquor to produce 3 tons of sulphate—that is 80 butts, at 1*s.* per ounce per butt, £40, showing at that price a slight advantage in favor of selling the liquor.

As to the question of the best apparatus to use, In small works a boiler set over a furnace, with the crystallizing form of saturator, would, no doubt, be cheapest and best; but in works where there is sufficient liquor to keep the apparatus generally in operation, I should recommend the Coffey still and closed saturator, as being most economical, most continuous, and requiring least attention.

I may say, in conclusion, that had I know, when the committee asked me to read a paper on this subject, that Mr. G. E. Stevenson would deal with the same topic before the Midland Association, and that we should have the pleasure of reading the description of his apparatus in the *Journal of Gas Lighting*, I, who was an almost identical form of plant, would have chosen another subject for consideration this afternoon.

Discussion.

The President said he was not a sulphate manufacturer himself, as he was able to get rid of his liquor at something like the price which had been named in the paper, and he was not, therefore, in a position to give a practical opinion on the matter, but no doubt many others present could do so. Mr. Bromley asked Mr. Goddard how he dealt with sulphuretted hydrogen in his apparatus. That point had not come out so fully in the paper as his (Mr. Bromley's) should have liked, for sulphuretted hydrogen was the principal difficulty, especially in small works.

Mr. Goddard said that at one time, after condensing the sulphuretted hydrogen gas as far possible, he passed it into the furnace under the boiler, though he found that it spoiled the boiler. After repairing the boiler they

it only produced 14 oz. of sulphate of ammonia per gallon, it would represent 21 lbs. of sulphate per ton of coal carbonized, without at all reckoning the liquor which was formed in some hydraulic mains or through the condenser. He, therefore, could see no difficulty whatever in the figures running up to 21 or 25 lbs. per ton of coal. Where some Yorkshire coal was used the figures that were quoted by the late Mr. Esson, of 21 lbs. per ton, might be correct. As to the question whether lime was sufficient to get all the fixed salts from the liquor resulting from the still, he did not think it was, for a moment, but that was easily tested. He had tested it, and found some sulpho-cyanide of ammonium left. Simply by applying a runnell of lime to the liquor, the presence of sulpho-cyanide of ammonium was detected by the deep red precipitate; and he found that really all the sulpho-cyanide of ammonium could not be got rid of. However, a great deal of it could be got rid of—quite enough to make it worth while. As to the waste of steam, which Mr. Condon complained of in using the Coffey still, he (Mr. Goddard) could not say that he found the difficulty he spoke of, of the steam coming out from the bottom of the still. Probably he did not work in exactly the same way. At Ipswich he did not get the liquid running from the still, but there was a space at the bottom of the still below the steives, and the liquor accumulated there to perhaps 12 or 18 inches. It was tested from time to time to see that the free ammonia was all extracted from it, and when this was found to be the case it was allowed to be run off, and the cock of the apparatus was shut again. By this means there was no material waste of steam. He need not enter into the question of labor, but his labor was a fixed sum. He paid his one man for the sulphate 10d. per cwt. according to the amount sold. In reply to Mr. Bailey, he might say that up to the present time he had not been in the habit of using the lime process at all, but he must first firmly believe it was worth while to do so, and was now erecting plant for the purpose of using it. As to putting a large quantity of water into the saturator, as recommended by Mr. Eldridge, he would remind them that the more water they had in the saturator, the more fuel would be required to evaporate it down to the crystallizing point, and that they had not the spent liquor, or fixed salt liquor, as he called it, in the washers, and that was certainly a way of getting rid of the liquor for a time, but he could not see that it did any permanent good to the gas. The fixed salt liquor had almost the same sulphide of ammonium and same sulpho-cyanide of ammonium in it, and in course of time its fixed salt in the liquor were removed. He, therefore, thought that the better plan was to remove it at once by means of the lime process, rather than use it in the washers. As to Mr. Marshall's question, whether the whole of the ammonia was extracted by steam, he did not think any sulphide of ammonium was extracted by steam, but simply carbonate and sulphate.

Mr. Marshall said the point was whether they were thoroughly extracted by steam.

Mr. Goddard thought that if the sulphide and carbonate of ammonia were not driven off by steam, they would be detected in the liquor by means of a test-paper. He thought, therefore, that these salts of ammonia, which should perhaps be termed the volatile salts, were all driven off, but that the sulphate and sulpho-cyanides were not touched at all. The question that [illegible] 30 bulbs of 8-oz. liquor would produce a ton of sulphate, was as near as possible, the same as the figures he had given—30 bulbs of 10-oz. liquor to produce 3 tons.

Mr. Marshall said this was the amount the London manufacturers were now reckoning upon, as that Mr. Goddard's amounts tallied very correctly with them.

[illegible] better quality than that now produced at some previous, and it is to be hoped at some future, time.

The Chairman moved that Mr. Pearson should be allowed to defend the company's case before a report was received for presentation to defend the Bill. Mr. Pearson seconded the proposition, which was agreed to.

Mr. Pearson replied that the company were willing to pay the costs of the opposition, which he had not the slightest doubt would be allowed to them by the Committee. He would, however, remind the meeting that the company had been put to a great deal of trouble and expense in connection with the Bill, and that the opposition had been entirely unnecessary, as they were willing to grant all that was required. He thought that the company had been treated in a most unfair manner by the Corporation, and that the opposition was entirely unnecessary. He would

METROPOLIS GAS SUPPLY.

The Chief Gas Examiner for the Metropolis (Dr. Williamson, F.R.S.) has just presented his report on the quality of the gas supplied by the Chartered, Equitable, Commercial, and South Metropolitan Gas Companies, during the quarter ending Dec. 31, 1880:—

I. With respect to *Illuminating Power*.—The averages for the quarter at each of the testing stations, in standard sperm candles, were as follows:—

The Gaslight and Coke Company—			
Beckton (common gas)		17·3	
Do. (Incandescent gas)		17·2	Station closed Oct. 8.
Piccadilly Place	"	17·6	" Nov. 5.
Jewry Street	"	17·6	" Nov. 5.
King Street	"	17·6	" Nov. 5.
Horseferry Road	"	17·6	Station opened Nov. 6.
Millbank Street (Carmel gas)	"	17·7	" "
Ladbroke Grove (common gas)	"	17·3	" "
Brook's Road	"	17·3	" "
Bow Common	"	17·6	Station closed for repairs Dec. 11.
Camden Street	"	17·6	" "
Graham Road	"	17·6	" "
Hackney Road	"	17·6	" "
Commercial Gas Company—			
Wellclose Square (common gas)		17·6	Station opened Oct. 23.
Parnell Road		17·3	" "
South Metropolitan Gas Company—			
Vauxhall (common gas)		17·3	" "

Notes.

Another Hot Air Gas-Lamp.

A novel form of gas-lamp has been invented by M. Clamond, of Paris, on the principle of supplying hot air to the flame, in combination with the principle of the lime light. The air necessary for supporting combustion is caused to pass downwards through a tube, which contains cylindrical pieces of refractory material as arranged as to break up the current of air, and cause it to strike repeatedly against the sides of the tube. This tube is in one arrangement heated, from without, by a number of horizontally directed gas-jets, issuing from several specially constructed burners that surround it. By this means the air is brought to a high temperature before it leaves the tube and mingles with the gas supplied to the burner. The flame is thus made intensely hot, and is then directed downwards upon a cylinder of lime or other suitable material, thereupon creating a brilliant white light from the incandescence of the material. Solid carbonaceous matter, such as powdered coal, coke, or charcoal, may also be used for heating the air and supplying gas. In this case the air tube is placed centrally within a funnel-shaped vessel containing the carbonaceous powder, and provided with air-inlet orifices for causing combustion of the powder. The carbonic acid gas produced by the combustion is caused to pass through the mass of intermittent powder, and thus becomes converted into carbonic oxide, which, in its turn, is burnt by the aid of the heated air, and its flame directed upon the lime cylinder, as before described. The inventor also claims an improvement in the formation of the refractory material which he uses in his lamps. Instead of the customary plain block of block of fire-clay, the whole, for convenience of carriage and safety of handling, being enclosed in a pasteboard "cartridge." When required for use this cartridge is placed beneath the flame, and the carriage is thereupon immediately burnt off, the rods being at once rendered incandescent.

Another Hot Air Gas-Lamp.

A novel form of gas-lamp has been invented by M. Clamond, of Paris, on the principle of supplying hot air to the flame, in combination with the principle of the lime light. The air necessary for supporting combustion is caused to pass downwards through a tube, which contains cylindrical pieces of refractory material as arranged as to break up the current of air, and cause it to strike repeatedly against the sides of the tube. This tube is in one arrangement heated, from without, by a number of horizontally directed gas-jets, issuing from several specially constructed burners that surround it. By this means the air is brought to a high temperature before it leaves the tube and mingles with the gas supplied to the burner. The flame is thus made intensely hot, and is then directed downwards upon a cylinder of lime or other suitable material, thereupon creating a brilliant white light from the incandescence of the material. Solid carbonaceous matter, such as powdered coal, coke, or charcoal, may also be used for heating the air and supplying gas. In this case the air tube is placed centrally within a funnel-shaped vessel containing the carbonaceous powder, and provided with air-inlet orifices for causing combustion of the powder. The carbonic acid gas produced by the combustion is caused to pass through the mass of intermittent powder, and thus becomes converted into carbonic oxide, which, in its turn, is burnt by the aid of the heated air, and its flame directed upon the lime cylinder, as before described. The inventor also claims an improvement in the formation of the refractory material which he uses in his lamps. Instead of the customary plain block of block of fire-clay, the whole, for convenience of carriage and safety of handling, being enclosed in a pasteboard "cartridge." When required for use this cartridge is placed beneath the flame, and the carriage is thereupon immediately burnt off, the rods being at once rendered incandescent.

Sale by Auction of Stock of the South Metropolitan Gas Company.

Tyler last, Mr. G. A. Williams offered for sale by auction, at the Mart, Tokenhouse Yard, E.C., £18,000, of ordinary 7l 2½ stock, and £12,000 of ordinary 5l stock of the above-named Company, being the first portion of additional capital authorized to be raised under the Company's Act of 1876 and the Amalgamation with the Phœnix Gas Company confirmed by Order in Council in March last year.

The Chairman (Mr. Alderman Wakley) stated that the Company had found it necessary from time to time to offer for sale what was then unappropriated South Metropolitan, Surrey Consumers, and Phœnix Gas Companies. The total capital of the Company, he said, amounted to £6,000,000, of which £850,000 was untaxed, and of this the £12,000 for which he was then asking was the last. He referred to the great diminution in the fact that the Company worked under the sliding scale, the operation of which was to reduce the price of gas as the dividend rose. With the Midland exception of less than 5½ per cent., which required by the present price of the gas supplied by the Company, would, for the half year ending June 30 next, be at that rate, and if not per cent. respectively.

The biddings were then taken, and the whole of the stock was disposed of at the following prices:—

The Gas Explosion in Glasgow.

There is very little to be added to what was reported in last week's Journal in connection with the disastrous gas explosion which occurred in Henderson Street, Glasgow, early on the morning of New Year's Day. All the victims, with one exception—that of Mary Cassidy, who has succumbed to her injuries—are progressing favourably, and it is to be hoped that they will soon be convalescent. Already the effects of the subscription which Provost Sandeman has been so active in getting up are manifesting themselves in what of the sufferers by the explosion, and contributions will be received either by Provost Sandeman, Mr. Alderman Dunlop, or Mr. Cassels, who are connected to act as Honorary Treasurer to the fund. A first list of donations will be found in our pages.

The inquiry into the cause of the disaster before the gas was cut off, it is stated that when the explosion took place a messenger was at once sent to the Gas Office in Dundas Street, and he informed himself on his return that of what had happened, and reported that a man should be sent at once to cut the pipe off. Mr. Alexander Wilson, the manager, was soon to be seen on the premises, assisted by a number of men out to attend to the gas, and by a man not yet in appearance at Henderson Street, a messenger was despatched to summon the attendance of the gas fitter. The officer could not get any gas to answer his knock, and on the latter arriving without the key, he and Mr. Alexander Wilson, the officer were about dispensing with the key, but failed. Then a fireman and a police constable were sent off with positive orders not to return without some one with the key to the gate; but after considerable delay—as it appears, unfortunately—they also failed to gain admittance to the gas premises, and had to return like the others. Then a messenger was despatched and had to return like the others. Then a messenger was despatched to Henderson Street, and the gas-fitter was found out, but not until some three hours had been lost, during which the firemen were comparatively helpless.

Sale by Auction of Stock in the South Metropolitan Gas Company.

On Friday last, Mr. G. A. Williams offered for sale by auction, at the Mart, Tokenhouse Yard, E.C., £18,000, of ordinary 7l 2½ stock, and £12,000 of ordinary 5l stock of the above-named Company, being the first portion of additional capital authorized to be raised under the Company's Act of 1876 and the Amalgamation with the Phœnix Gas Company confirmed by Order in Council in March last year.

The Chairman (Mr. Alderman Wakley) stated that the Company had found it necessary from time to time to offer for sale what was then unappropriated South Metropolitan, Surrey Consumers, and Phœnix Gas Companies. The total capital of the Company, he said, amounted to £6,000,000, of which £850,000 was untaxed, and of this the £12,000 for which he was then asking was the last. He referred to the great diminution in the fact that the Company worked under the sliding scale, the operation of which was to reduce the price of gas as the dividend rose. With the Midland exception of less than 5½ per cent., which required by the present price of the gas supplied by the Company, would, for the half year ending June 30 next, be at that rate, and if not per cent. respectively.

The biddings were then taken, and the whole of the stock was disposed of at the following prices:—

Journal Gas Lighting Jan 11 1881

Journal of Gas Lighting Jan 11 1881

The Gas Explosion in Glasgow.

There is very little to be added to what was reported in last week's Journal in connection with the disastrous gas explosion which occurred in Henderson Street, Glasgow, early on the morning of New Year's Day. All the victims, with one exception—that of Mary Cassidy, who has succumbed to her injuries—are progressing favourably, and it is to be hoped that they will soon be convalescent. Already the effects of the subscription which Provost Sandeman has been so active in getting up are manifesting themselves in what of the sufferers by the explosion, and contributions will be received either by Provost Sandeman, Mr. Alderman Dunlop, or Mr. Cassels, who are connected to act as Honorary Treasurer to the fund. A first list of donations will be found in our pages.

The inquiry into the cause of the disaster before the gas was cut off, it is stated that when the explosion took place a messenger was at once sent to the Gas Office in Dundas Street, and he informed himself on his return that of what had happened, and reported that a man should be sent at once to cut the pipe off. Mr. Alexander Wilson, the manager, was soon to be seen on the premises, assisted by a number of men out to attend to the gas, and by a man not yet in appearance at Henderson Street, a messenger was despatched to summon the attendance of the gas fitter. The officer could not get any gas to answer his knock, and on the latter arriving without the key, he and Mr. Alexander Wilson, the officer were about dispensing with the key, but failed. Then a fireman and a police constable were sent off with positive orders not to return without some one with the key to the gate; but after considerable delay—as it appears, unfortunately—they also failed to gain admittance to the gas premises, and had to return like the others. Then a messenger was despatched to Henderson Street, and the gas-fitter was found out, but not until some three hours had been lost, during which the firemen were comparatively helpless.

An Examination of the Wrecked Building

An examination of the wrecked building was made on Monday last week by skilled workmen, with the object of reporting on its suitability to the Dean of Guild Court; and afterwards the Lord Provost and the Dean of Guild, accompanied by Mr. White, Assistant Master of Works, made an official inspection. In the afternoon the pavement in front of the houses affected by the explosion was opened with a view to ascertain the condition of the main-pipe at the point where the fracture had occurred. It was found that the pipe was broken right across at that point, and that while the ends of the fracture were close on the top, the lower edges were about 4-inch apart, thus confirming the opinion expressed that the escape of gas was from the main. The Provost-Fiscal has obtained a warrant authorising a skilled person to take possession of the main-pipes, with the view of having them thoroughly examined.

Bilston Gaslight and Coke Company.

The Annual General Meeting of the Company was held on Monday, the 3rd inst., at the Offices, Bilston, Mr. J. Hall in the chair.

The Secretary and Manager (Mr. J. S. Brown) having read the notice convening the meeting, the following report and statement of accounts were submitted:—

The Directors present to the Shareholders their 15th annual report, together with statement of accounts.

The net amount shown is profit of £3239 12s. 6d., which, with £1126 12s. 7d., brought forward from last account, makes a total of £4366 5s. 1d. The Directors propose to appropriate this amount as follows:—

	£ s. d.
Half-year's dividend of 4s. per share, paid Aug. 1, 1880	2400 0 0
" " " payable Feb. 1, 1881	2400 0 0
Subscriber interest	1 5 0
Reserve fund	1000 0 0
Carry to next year's account	565 0 1
Total	£4366 5 1

The Directors have much pleasure in reporting a favourable result for the year to the end of the district, and a satisfactory increase in the sales of gas. It will gratify the shareholders to state that the special attention which has been given to the distributing plant has resulted in a considerable reduction in the amount unaccounted for, which is now 6·4 per cent. of the total make, as against 8·2 per cent. last year. The Directors have determined to allow a discount of 2 per cent. to all gas accounts paid quarterly. This discount will cause a reduction in the receipts from the Public Lamps, and will involve a reduction of nearly 2l. per 100l lost of gas, or about 240l. in the income of the Company, but it is hoped that this will be more than recouped by the saving.

The Directors who retire by rotation are Messrs. Silvester, H. Edwards, W. E. Colmore, and P. Bullock. They are eligible, and offer themselves for re-election. The Auditors also retire, and offer themselves for re-election.

Dr.	*Trade Account for the Year ending Sept. 30, 1880.*	Cr.	
To cost of stock, Sept. 30, 1879		£3,638	0 0

" Amount required for depreciation	3,235	13	5
" Balance, profit	4,366	5	1
	£16,778	16	3

The Chairman, in moving the adoption of the report, said he thought the Shareholders would agree with him in regarding it as a very satisfactory one. The profit realized had been the largest in the history of the undertaking, and the Directors had been able to recommend a good and steady increase. The heavy expenditure had been incurred in completing the alterations and improvements in the Company's distributing plant, and this expenditure had been judiciously made as contented to think was proved by the fact that the increase in the sales for the year, amounting to upwards of 8 millions cubic feet, had been entirely lost by the saving effected in the unaccounted for gas, which was now 6·4 per cent. against 8·2 per cent. last year. The Directors, however, hoped to effect greater economy in this direction, though in a minimg district like theirs the waste of gas from leakage must necessarily be greater than between two towns, adjoining. During the year the Directors had met a claim for compensation for damage arising out of the explosion of gas at Bilston, but, in consequence of the Company's Act not giving them the liability of the mains, regulating the matter, with a view to determine the liability of the Company, they had resisted the claim, and were practically responsible for the accident, but that it would be difficult to establish their responsibility, and had elected to compromise the matter by paying what they considered a reasonable compensation (£200), rather than involve themselves in costly litigation, the issue of which might be doubtful. As these special items of expenditure would not have to be incurred in the future, they considered the Shareholders to participate in the improved results which, from the advantageous position of the works, and by good management, they were able to secure. The Directors therefore hoped to be able, during the ensuing year, to recommend some addition to the rate of dividend which was then paid.

The report was unanimously adopted, and a resolution passed authorising the payment of a dividend of 8 per cent. for the year.

The retiring Directors and Auditors were then re-elected, and votes of thanks having been accorded to the Directors and Officers of the Company, the proceedings closed.

The Dudley Gas Company and the Corporation.

At the Meeting of the Dudley Town Council on Tuesday last—the Mayor (Alderman Wainwright) in the chair—the subject of the relations existing between the Corporation and the Dudley Gas Company was brought before the Council by the Chairman, who said he had prepared to make a communication to the Council upon the gas question. As for back as the month of June last a case was stated to the Council in the form of a petition, and the greater part of that petition was then signed. The petition was to the effect that the Council should take steps to obtain the powers which would enable the Corporation to become possessed of the gas works. A statement should be made to the Council, and, to the Mayor himself, during the interval which had elapsed, he had carefully read the Company's Bill, and at the first blush it seemed to involve a most tortuous and mysterious piece of business, and a mere matter of arrangement between the Company and the Corporation. The Bill had been framed expressly for the purpose of

MAKING GAS FROM PETROLEUM.

The question "how shall we obtain cheap light" is one of the most important problems of the day. Nature has done her part in solving the question by furnishing us material, in what appears to be an inexhaustible supply, in crude form, for making light. Gas men have known for years that they could make a cheaper and better gas out of oil than coal, and the name of oil gas has been so frequently misused, and applied to so many different compounds that the real oil gas has been almost lost sight of among the numerous claimants to reputation under that name. There is only one true oil gas, and that does not differ from ordinary coal or rosin gas in any essential particular, except in containing a much larger percentage of fixed illuminating, and a much smaller proportion of non-illuminating elements. This difference in amount of light contained, very largely favors the oil gas. Many have found that the transformation of petroleum into something in the form of gas, and remembling it enough to be called gas, is easy, as they could not well fail to produce either gas or vapor. The trouble has been to produce a fixed gas, with regularity and certainty, and to do this well, and so thoroughly, that the great difficulties in the operation, viz.: smoking, condensing, and depositing of tar and other obstructions in the apparatus and its connections, should be avoided, and at the same time keep the apparatus within such simple form as to be within the easy comprehension and power of management of ordinary intelligent labor.

Modern science and ingenuity have perfected an apparatus by which petroleum is made to yield a beautiful illuminating gas, at small cost, and by this process the gas is so thoroughly fixed, as to enable it to be sent through miles of street mains, in all kinds of weather, with but little, if any, condensation or loss of illuminating power. Gradually, but surely, petroleum is taking the place of coal in the manufacture of gas, and with the use of petroleum comes economy in labor and expense and a much greater brilliancy of illuminating power. It is conceded by all well informed gas manufacturers that oil gas works will make a safe, cheap and brilliant light, as free from smoke, and much freer from other impurities than the best coal gas. The gas is perfectly adapted to all kinds of use, either for public or private illumination, and for heating and cooking.

A burner, consuming one foot of oil gas per hour, gives a light equal to sixteen sperm candles. The best coal gas gives but sixteen candles from a burner consuming five feet per hour. In using gas, the maximum of light is obtained by using the proper sized burner. The average medium burner for coal gas is five cubic feet per hour; the medium burner for petroleum gas is one cubic foot per hour. In regard to quality, petroleum gas is pure; it does not contain any sulphur or ammonia, and therefore, requires no purifying. It is also very rich gas, being eighty candle power, while common coal gas is only from twelve to sixteen candle-power. Owing to its higher specific gravity, it burns much more slowly than coal gas, and is, therefore, more economical. The higher the specific gravity of a gas, the more economical it is for the consumer, other things being equal, and the higher the candle-power, the less gas has to be consumed to obtain the same amount of light, so one cubic foot of petroleum gas will give as much light as five feet of coal gas. Oil gas, when well made, is safe and reliable under any circumstances that coal gas is, and under some that coal gas is not. For instance, it requires a larger and more perfect admixture of air to make it explosive; is free from poisonous constituents, and does not deteriorate under extreme cold or pressure, as coal gas does.

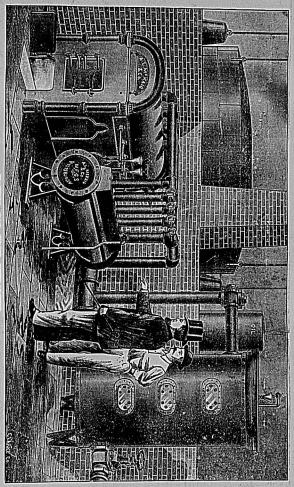
We herewith present an illustration of the National Gas Works, manufactured by A. L. McKaig & Co., of Pittsburg, Pa., with a brief description of their mode of operation.

The petroleum comes from a reservoir extending along the range of the four retorts of the furnace and thence it flows regulated by stop-cocks, into four funnels, each capping an iron supply pipe, which descends vertically and then passes horizontally into a side opening of a retort.

The gas is made in an iron retort kept at an elevated and uniform temperature, and into which petroleum flows in a steady stream.

The retort is made of cast iron, resembling in shape a flattened glass flask, with its upper opening or mouth, for the escape of the gas generated, and with openings on the narrow sides of the retort, towards the bottom, one for the inflow of the petroleum, and the opposite one for the cleaning of the retort.

The retorts are set, upright, side by side, touching only along the edge of two flanges cast on the sides of each retort like the sloping sides of the letter A, and the flanges being about one inch and a quarter wide, making a space of two and a half inches between the retorts. Through this space the current of heated air, rising from the fire below the retorts, is directed by the flanges to the middle of the top of the encasing wall, whence it is deflected sidewards and downwards to the flues in the fire tiles running around the lower sides of the retort casing; and from one end of the united flues it passes into the chimney. Four such retorts are arranged side by side over a single furnace, each retort having its exit gas tube, and the four tubes passing into a single conductor. Around the outside of the upper cylindric opening, or mouth of a retort, is a little cylinder of three inches depth, and the space of half an inch between the two cylinders contains metallic lead, which, when the retorts are in action, is heated above 612 degrees, the melting point. The melted lead acts as a seal to the exit gas pipe, which is thrust into it, excluding the outer air and preventing the escape of the gas within a pressure of over two inches of mercury.



MAKING GAS FROM PETROLEUM.

THE ENCOURAGEMENT OF GAS CONSUMPTION.

SECOND ARTICLE.

We noticed last week, under the above heading, certain causes specially operative at the present time in directing attention to the important question of extending the uses and the consumption of gas. We return to the subject in order to mention some of the ways by which this generally desired object may be attained. Last week the advantages that would accrue to gas makers from the pursuit of the policy advocated were incidentally dealt with; and we may to-day be permitted shortly to revert to this topic.

It may be stated broadly that the profits arising from any growing business will increase in a greater ratio than the gross returns; because, at least in the great majority of instances, it is more economical to manufacture on a large than on a small scale. What is true generally is true in the case with which we are interested; an increased consumption of gas enables a Gas Company to reduce the selling price, and a reciprocating action is set up, the reduced price causing a further increase of consumption. Thus the cause and effect continue to act and react, to the mutual advantage of user and producer. This is the case with old and new Companies alike. With the latter the effect is due partly to the more effective occupation of the plant, and partly to the diminished proportion which many charges of a more or less fixed character bear to the larger rental; with the former the more economical construction of the works required to meet the larger demand is chiefly to be credited with the lessened cost of the additional supply. In such works the advantages of improvements in manufacture, tending to cheaper production, would be equally applicable to old business and to new, and they do account for much of the steady reduction apparent in the cost price of gas. But the new business is not weighted with the heavy capital charges which attach to the old, and for this reason is proportionately more valuable. Let us suppose the case of a town where the price of gas is 3s. 6d. per thousand cubic feet, that price including, say, 1s. 2d. per thousand cubic feet for interest or dividend. This is a proportion not unusual, and most of our readers will be able to supply themselves, from their own experience, with an illustration very near it. Now, such a charge for dividend is no longer necessary with the lessened cost of much of the apparatus employed, more definite knowledge on the part of engineers of exactly what and how much plant they need to provide, and also the reduced charge at which, under the operation of the auction clauses, the necessary money is raised. In most towns of even moderate size, where ordinary maximum dividends are paid, new business can be met by an expenditure of capital which will not involve a greater burden than eight-pence per thousand feet, and sometimes materially less. Here, then, is a difference of sixpence per thousand feet—a saving equal, let us say, to the payment of very nearly the whole of the labour employed in the production of gas and its delivery into the holders. This may be regarded as so much premium to the producers upon new business. In the ordinary case of a consumption doubling in eight or ten years, it alone would effect a reduction in price of threepence per thousand feet over the whole district within the same period.

Such an advantage as this, and others which will suggest themselves—as, for instance, the greater economy of fuel in large as compared with small works, the profit to be derived from the treatment of residual products, &c.—applies to an increase of business obtained on the ordinary lines where the vastly greater proportion of the gas is used for lighting purposes, and its consumption limited to the hours between sunset and midnight. It has with many people become rather the fashion lately to decry the invention of the gas inventor when gas has ceased to be the great illuminating agent—when, in fact, that honourable vocation has been assumed by another, and gas is relegated to the still useful, but much less ornamental purposes of heating, cooking, and the like. Some Chairmen of Gas Companies have contemplated this change "with a light heart," which may have been as real as it looked. It is, however, more from those "good-natured friends" who want to administer a pill and at the same time take credit for a sugar-plum, that we receive most of this kind of encouragement or consolation, as the case may be; and we feel under no oppressive weight of obligation to them in return for it. It will be the commencement of a bad time for gas makers when they have to find other outlets for their chief product, not for the sake of increasing their returns, but to make up for losses sustained in their, at present, most important and useful field.

While we say this with all possible emphasis, we yield to none in the earnestness of our desire to see each of the uses of gas cultivated to the utmost, and our expectation as well as hope is that the percentage of the total quantity of gas made which will in future be used for purposes other than lighting will rapidly increase. We have already referred to the lessened charge upon the gas for dividend on capital required to meet ordinary extension of business, and pointed out that it is by no means trivial. But when considering a development of this kind, where the demand would be chiefly in the daytime, and to that extent would call for barely any increase upon one-half of the capital employed—that sunk in gasholders and distributing plant—the economy in dividend charge is still further augmented. Added to this there would be further saving in leakage and the proportionate charges for distribution, management, collection, &c., all combining to make a day consumption of much more value to a Gas Company than an addition of the same rental value obtained from ordinary lighting sources. It would be palpably erroneous to say that it is more profitable to supply gas in the daytime for working an engine or cooking a dinner than to supply an equal quantity at night for purposes of illumination. Yet at the same time there is much to recommend the idea of charging a lower price for gas used for the former and like purposes. Gas *light* is at present an indispensable necessary in our towns, and consumers have no choice as to those from whom they will buy. Gas-engines, on the other hand, will only meet with acceptance as they are able, in comparison with steam-engines, to develop points of economy or other advantage, and similarly gas stoves as against ranges heated with coal or coke.

We believe we are not over-estimating the advantage of this day consumption "found," as it were, and added on to the work of a Gas Company, at one shilling per thousand feet. If, therefore, the obtaining of this business will enable the Company to produce more cheaply, it is not unreasonable that some inducement should be offered to secure it; and a reduction in price of, say, sixpence per thousand feet would offer such inducement, while leaving a balance to be applied in cheapening the cost of gas for lighting purposes. On this point the experience of the little Danish town of Nakskov, as told in the Journal,* eighteen months ago, is instructive. A differential price has been there instituted, with the result that in 1878 forty-eight per cent. of all the gas sold was for cooking and heating purposes, while in the summer quarters the proportion used for this purpose exceeded rather considerably that for lighting. The laying on of special services to stoves would somewhat reduce the economy in capital expenditure, but it would be amply repaid, and would have further and great advantage on the score of and would have further and great advantage on the score of efficiency. Very much can be done to popularise and extend the use of gas for these subsidiary purposes, without necessarily reducing its price. Gas Companies and Gas Committees should put off, at least in this direction, the monopolist, and put on the trader, taking their wares to the consumer rather than waiting for him to be enlightened, in some accidental or extraneous manner, as to their value, and so come unsolicited to buy. We have offered no slighted praise to those who have sought to do this by opening exhibitions of gas apparatus, and to others, more numerous, who have adopted—some for many years past, others quite recently—the plan of selling or letting on hire stoves for heating and cooking. Good as those efforts have been, they are yet wanting in permanence or completeness. The best model hitherto furnished is that of the Paris Gas Company, which may once more be commended to our readers. The exhibitions should be *permanent*; the consumer should be invited to see the best apparatus for the purpose he needs, and to know, on the authority of the Gas Company, at what cost the work required can be done; and experiments should be made for the purpose of weeding out the unsuitable and inoffensive appliances, which cause dissatisfaction to the consumer, and discredit to the Company, and of bringing into prominence those that are really excellent. Another point of still greater importance is that the stoves or other apparatus, when fixed, should not be lost sight of by the supplier. Not only should the user be instructed how to keep his stove in proper order, but his consumption of gas should be watched, and assistance given to keep it within proper bounds. The excellent stoves read at the last of the Cork Gas Company, in his papers read at the last two meetings of the British Association of Gas Managers, well illustrate the importance and advantage of such attention. The first obligation which has to be met is that of instructing the public as to the great advantages to be derived from gas; and, while we are grateful for such help as is

THE ACTUAL COST OF MAKING ILLUMINATING GAS.

An investigation is going on in Philadelphia touching the management of the city gas trust, the gas works being owned by the city and operated by official trustees. A recent witness before the investigating committee was Mr. E. S. T. Kennedy, expert of the New York Mutual Gaslight Company. Mr. Kennedy said that this company manufactured last year 721,000,000 cubic feet of gas, 20 per cent of which was from wood, 20 per cent from Youghiogheny coal, and 40 per cent from naphtha. During the year the amount of gas got from a ton of coal (2,240 lb.) was 15,000 cubic feet.

The gas averaged 27 candle power, and the price charged was $2.25 per 1,000 cubic feet.

The present process with coal, wood, and naphtha was introduced in August, 1878. It deposits no lampblack, and no heavy oil beyond about 1 per cent, and that is so heavy that it is used to great advantage as a fuel in the works. To enrich coal gas, Mr. Kennedy said the method was to add a certain percentage of cannel coal to the common coal.

The gas is entirely free from smoke, and does not blacken a ceiling unless within three feet of the flame, when it scorches. With 120 miles of pipe the loss by leakage is about 8 per cent; it is called "unaccounted-for gas," and the amount of it is determined by deducting from the amount registered in the station meter at the works, the gas consumed in the public lamps, in the offices and works, and the amount of gas paid for by consumers. The average power of the gas from coal alone is about 16 candles.

In the Mutual Works there are three separate departments: for coal, wood, and naphtha. In the coal gas department the coal is brought into the retort room, and is charged into the retorts every four hours. That charge will weigh from 215 to 220 pounds. The retorts are set six to a bench, and in drawing the coal one-half of a bench is opened every two hours. As the gas comes off it ascends through a stand pipe to a hydraulic main, which receives a portion of the tarry vapors; the gas then passes off, is cooled, and goes through a double purifying process. It is then measured and stored in the holders. The labor is subdivided, so that there is an average of ninety-one one hundredths of a man to a bench. The average production of coke on a ton of coal is 70 per cent of the original weight of the coal, or a long ton of 2,240 pounds ought to produce 1,600 pounds of coke, or thirty-five bushels. That is the average and ordinary amount produced to-day by the Mutual Gaslight Company.

The average production of gas tar and ammoniacal liquor is 12 or 14 gallons per long ton. The product of ammoniacal liquor varies, some companies producing as low as 15 gallons and others as high as 40; the average would be about 30. The present price of coke is between 8 and 9 cents a bushel; from 2 to 2½ cents a gallon for tar, and about 1 cent a gallon for ammoniacal liquor.

A double system of purification is employed by the Mutual Company. First, with an iron mixture, and afterward with oxyde-shell lime. There are two principal impurities to handle—sulphuretted hydrogen and carbonic acid. The lime is used to remove the latter. After it becomes the roughly charged it is treated to a process of Dr. Wilkinson, the result of which is a lime that does one-third more work than any lime that can be bought, and at one-half the cost of the new lime. The same quantity of lime has been used one hundred and fifty times, and the chemist of the company thinks it will go on forever. There is no depreciation in quantity or quality. They have been using this process for two years without any increase of the lime.

On the following day, after Mr. Kennedy had inspected the plant and processes employed at the Philadelphia gas-works, he took the stand again. In reply to the question: "What does it cost to manufacture gas?" Mr. Kennedy said:

"The average cost of gas per 1,000 cubic feet in the gas-holder is 65 cents; that does not include the cost of distribution. That I consider a fair average price based upon present prices of material and labor. I say 65 cents; it may be a cent or two more or less. I will undertake the management of your gas-works and produce coal gas at the present prices of coal for 65 cents in the holder. My calculation is based upon 16 candle gas."

In reply to the question, "What does it cost your company to put gas in the holders under your processes?" Mr. Kennedy replied: "Less than 50 cents a thousand." The Mutual Company expect eventually, he said further on, to manufacture from wood and naphtha exclusively, when the cost would be from 35 to 40 cents.

SUFFOCATED BY GAS.

[BY TELEGRAPH TO THE HERALD.]

HARTFORD, CONN., August 3, 1881.

That gas should be turned out and not blown out might well be made an item of public school study in the rural districts. G. A. Thompson, a sixth grader from the little country town of Wilcox Station, was found dead at the McDonough House, Middletown, on Tuesday night. In the morning a strong smell of gas filled the room and corridors and adjoining. The hotel people forced an entrance into the room, and found all the windows closed and the gas burning. The boy was dressed in his clothes, and had probably been dead several hours. There was nothing pointing to suicidal intent, and the coroner's verdict was that the deceased came to his death by the visitation of the ordinary visitation of the gas.

Gas Cooking Experiment in England.

The experiment of cooking and heating by gas seems to be making more headway in England than in this country. According to an English journal nearly three hundred gas cooking stoves have been placed in operation during the past six months in Birmingham alone, and there is more or less progress in the same direction in other British cities and towns. One reason why the experiment is so much watched with so much success in Birmingham is that the gas there is controlled by the city government and is cheaper than in some other parts of the Kingdom. This probably accounts for the fact that so little is being done in this way here. The price of gas is too high, and many householders cannot afford to use it for lighting, much less for heating purposes. The use of gas in this way is a very practical question in England, particularly in London, with its dense volume of smoke almost constantly overhanging it. The argument is advanced that if gas could be substituted one good result would be to materially improve the atmosphere of the British metropolis.

LUCK, A NOVEL LIGHT BUOY.

SUCCESSFUL TRIAL OF THE SIGNAL—A STRANGE FLAME IN ALL WEATHERS.

A pleasant crowd, consisting some fifty or sixty gentlemen, went down the bay last night to near Sandy Hook on the fast steamer Sandy Hook for the purpose of seeing one of the new lighted buoys, which is stationed near the old Scotland lightship. The weather was simply delightful. The absence of moonlight served to throw luster into relief the rays of the illuminated buoy, which was found dancing at its number on the surface of as smooth a sea as the eye could wish to behold. The buoy is arranged to serve as a recipient of gas, which is under a pressure of six or seven atmospheres. It is built without rivets, and is surmounted by a diamond lantern, the arrangement of which is such that, while a sufficiency of air is admitted to keep the flame alive or water can enter, the waves are prevented from doing so. The water can, it is claimed, extinguish the light. As the buoy is so constructed that particles of salt will not adhere to it, it is claimed that the mysterious thing the light might be smeared by brinish deposits on it. The surface of the gas which is to illuminate the buoy is 1,000 candles, which is considerably far above or that used for years back on German and English railroads for signaling the passing trains. An attempt to explain the principle of the buoy, or how it works, would be puzzling at the best or how it can burn many days. The buoy light is intended to burn day and night. The buoys used in Europe are made to burn oil, and have to be filled every twenty-four hours. It can be made to burn for the long season of 240 cubic feet daily, such, therefore, the buoy will require to be filled but once in ten days. The buoy also utilizes the sea water. It is refilled at certain intervals by means of a tender. This is accomplished by the use of a hose pipe. The sea water is carried under pressure of the steam, and is forced into the buoy by means of a valve under a flange, all of no more complexity, indeed, than the valves of the tender. For a number of years in Germany, Holland, France, Russia and other countries, has sought where the buoys which will achieve full of attaining success. Some of the buoys in Europe are fitted with a lighthouse, it was found bobbing up and down unpleasant. It was, in effect, a lamp attached to a buoy, or a buoy attached to a lamp. The light was such that which the buoy must always be upward, and as to where the surface of the water as its lighthouse five feet. The light put from the buoy recently for a considerable number of days past. A number of gentlemen interested in popular lines of improvement in lighting apparatus were present, among them an Essex ward Meyers, Superintendent of the Fall River Line, W. H. Tarrant, J. Hall Pleasants, Captain Hall, of the Sandy Hook lighthouse Service, Samuel Wolf known artist and many friends of this science for protecting American waters from disaster. The Sandy Hook reached gas from after eleven o'clock.

American Gas Light Association.

OFFICE AMERICAN GAS LIGHT ASSOCIATION,
142 CHAMBERS STREET, NEW YORK.

To the Members of the Association:

The Ninth Annual Meeting of the American Gas Light Association will be held in Boston, on Wednesday, Oct. 12th, and continue for three days.

Members of the Association are earnestly requested to prepare papers upon the many topics of general interest, to be read at that meeting. The Secretary counts upon the active co-operation of the members in his efforts to render the meeting of marked value.

WM. HENRY WHITE,
Secretary.

THE CENSUS OF THE GAS INDUSTRY.

Most of the returns from the gas companies have been made, but there is still a number of companies that have not complied with the request of the special agent, and delay sending in their statements. It is consequently impossible to complete the compilation as the few returns due prevent it.

We would, therefore, respectfully and urgently request the companies not yet having attended to this matter to give it early attention.

ASSOCIATIONS FOR THE ADVANCEMENT OF GAS LIGHTING.

It is not many years since it was generally, but not universally, considered one of the fundamental principles of the gas industry to so carry on the operations of a company that no one, outside the management, should know how, or with what results, the manufacture and distribution were conducted. If an improvement was contemplated, or in use, it was for the benefit of the company introducing it, not for others; if others wanted to progress it must be done at their own risk, and from their own experience, assisted, more or less, by the comparatively scant literature referring to the gas lighting of the past. It was not difficult to find the gas manager of the old school who considered that his methods were the only true ones, and that his knowledge included the whole domain of the science and art of the industry. He remained satisfied in his convictions because there was little mutual confidence between manufacturers, and the opportunities for intelligent investigation, comparison and contradiction were few, or impossible.

Wasteful working, extravagant expenditure, ill-designed plant, large losses by leakage, were permitted in those days, when comparative statements of working results could hardly be obtained. Moreover our present great competitor kerosene was then selling at five or six times its present price, and an extra charge to the consumer may, in some cases, have been necessarily made to return dividends that might have been obtained by the savings resulting from improved working.

The need of a change was apparent to the more intelligent and progressive and, on December 15, 1863, twenty-four engineers or managers of gas works met in Manchester, and formed the British Association of Gas Managers. The need of this movement, and its success, are attested by the results, as to-day the number of members of all classes in that Association is upwards of seven hundred, and its influence is most widely extended. Not only so but, largely from the influence and effectiveness of the parent Association, kindred associations, with like objects in view, are vigorously growing in the United Kingdom, America, France and Germany.

It would seem that no question could exist that highly beneficial results have arisen from the association and intercommunication of intelligent men specially interested in the common welfare of a most important industry. Still there are a few who think otherwise, and consider the old times of high profits, when the outsiders and closed doors to have been preferable. Happily, the many do not sympathize with this class, and think it will be a fortunate day when such influences are wiped out. It is undoubtedly true that not all of the improvements made in late years are directly traceable to the influence of the meetings and members of the various associations; but many of them are, and, moreover, many ideas, considered practicable by their imaginers, have been proved otherwise when subjected to the combined intelligence of men who had experimented on similar lines, and their demonstrations have, in many cases, been productive of savings to those intending like experiments.

While the Associations have accomplished, up to the present, excellent results, it would seem that there is still room for great improvements in the methods of conducting the meetings, adding to their interest, compelling the attendance of those hitherto negligent, and to the permanent organization and work of the bodies or committees between meetings. The larger associations meet annually, and are dependent almost entirely upon the good will and interest of a few active members in the possession of power to be

Note on Magnetism (continuation).—By P. M. Gaugain.—Pure. Nov. 24 '78.—" When an armature of soft iron is fitted against the polar faces of a horseshoe magnet, the magnetisation is increased throughout the whole extent of the magnet. This seems to render the theory incompatible that the phenomenon results from magnetic matter which becomes condensed in the neighbourhood of the poles. It may be explained thus, by adopting Ampère's theory:—The action of the magnet is to impress a rotary movement on the molecules of the armature placed near its surface, and causes them (the molecules) to approach more or less the magnetic inclination. The armature, now become a magnet, reacts in its turn upon the horse-shoe, to the increase of the original magnetism. It will be probably impossible to establish, from the actual state of our knowledge, the mathematical law which regulates such mutual actions; but it may be very well conceived how they should augment the magnetisation throughout the whole length of the horse-shoe. Suppose the armature to be composed of bars, applied to the polar faces, to placed at a certain distance from the poles, as *m m*, perpendicular to the branches of the horse-shoe. Then the magnetisation is found to have increased in that part between *m m* and the keel, whilst it is decreased elsewhere. This may be regarded as the consequence of another fact, viz., that if a straight magnet and a bar of soft iron are arranged so that their axes cross at right angles, towards the middle of the iron bar, the latter becomes magnetic, and a consequent point—a double pole—is formed in that portion which is opposite to the pole of the magnet. Reciprocally, if two bar magnets be placed following one another, with their similar poles together, and upon their line of contact a bar of soft iron be placed perpendicularly to the common direction of the magnets, it is very clear that the two magnets will tend to impart the same magnetisation, and that therefore the position will augment the magnetism of the magnets (facts sufficiently attested by *recording* the conditions of the experiment). Each of the branches of the horse-shoe magnet may be considered as formed by the joining of two magnetic bars whose poles of contrary name touch at a point conformably to the line *m m*. And as the bar inclined between this line and the keel is more strongly magnetised than that position between it and the poles, it follows, from what has just been said, that the application of an armature on the line *m m* should increase the magnetisation on the keel side and diminish it on its polar side. On attaching an armature to the polar faces of a strongly magnetised iron horse-shoe magnet, and on plunking it off several times, the magnetisation is diminished throughout the whole length of the magnet; but the decrease is very small, and seems to be solely due to molecular shaking. But when this plunking off of the armature takes place at a distance more or less remote from the poles, then the permanent modifications produced are much more complicated. To illustrate, let the armature be put first on a determined line *o o*; after the armature is wrenched off a diminution of magnetic intensity is noticed throughout the whole length of the magnet; but if the wrenches are continued on the same line a limit of decrease in magnetisation will soon be observed. Then if we place the armature on another line, *n' n'*, situated at a certain distance from the first, a further magnetic decrease may be obtained, subject also to a limit. The same process may be carried on several times, but the decrease will only be continued to a definite limit; for on reaching a certain limit the wrenches effected on a definite line, though they be continue more or less for a week, will not augment between the poles that limit, will not slightly augment the magnetism of the keel. Lastly, it is found that when magnetisation has been reduced to a very low limit, further plunkings off of the armature do not sensibly alter the magnetic condition on either one or the other side of the line."

Some Experiments on the Effects of Magnetism on the Electric Discharge through a rarefied Gas, when it *takes place in the Production of the Light of the Magnet.*—MM. Auguste De la Rive and Edouard Sarasin.—This research (conducted shortly before the death of De la Rive) is a continuation of a previous one, described in the *Archives for 1871* (tome xli.). The authors here employed the electric current in columnar form, causing only one pole to act on the discharge; the tube (Geissler tube or large bell), in which the discharge took place, resting on the top of the column. The effect on the discharge was observed in a portion of the current derived into a galvanometer at some distance, beyond the magnet's influence. A Geissler tube containing nitrogen or hydrogen at low pressure (about 1 m.m.) traversed by the discharge from a Ruhmkorff machine, presents round the negative electrode a beautiful thin sureole extending to the side of the tube; beyond this a long dark interval, and thence to the positive electrode, striæ wide apart. The magnet quite changes this; the negative pole being set opposite the sureole, the latter, of about 2 c.m. length, and complete, the whole tube, is now transformed into a cylinder only 8 or 9 m.m. diameter, very luminous, extending to the positive electrode, across the interval previously occupied by the dark space, and the striated positive jet with a large ball or balloon, the same effect was had; the large spherical sureole was transformed into a narrow thin jet of great brightness. This negative jet is always produced in the continuation of the axis of the electric current, on whose positive electrode is a ring situated in the same horizontal plane as the negative electrode. With higher pressure the negative jet becomes shorter. The magnet notably augments the intensity of the current. The intensity of discharge transmitted by the Geissler tube may even be unaugured by the action of an electro-magnet sufficiently powerful. The effect in hydrogen is more marked than in air; greater in a more (electrically) conductive than in a less conductive tube. The effect is instantaneous, and disappears with the magnet's immediate action; there is scarcely any change in the appearance and intensity of the discharge. If several connected Geissler tubes are placed similarly (with negative poles below) on the top of the magnet, the action on the intensity of the current passing through all of them is simply greater. But if, in place of one or several of the tubes under direct influence of the magnet, three in one semicentre in the circuit quite beyond this influence, the action of the magnet on the intensity of the current is almost wholly annihilated, though the modifications of the light are still distinct. It would thus appear that there is a peculiarly strong resistance presented at the negative electrode, and that this is overcome by the action of the magnet.

Sill Journal May 15, 74

An Investigation with reference to Bar-Magnetism.—H. Hoh.—A number of steel bars were treated thus: (1). Each was heated to redness, and then cooled within a bath; a layer of negative (to the magnetic moment was determined, and they were put in dilute muriatic acid; after remaining in it about twenty-four hours the moment of the bars (now become lighter through solution) was again determined. The bars presented a rough surface, and the dark mass (called by the author carburet of iron) had at the ends an appearance of threads parallel to the length, the iron rises lying round, like a liquid about a solid body. The numerical results are tabulated, and the following are the author's conclusions—(1). The amount of magnetic moment of a steel bar, with reference to its quality, depends on the structure of the iron and the connected structure of the carburet of iron. (2). The magnetic moment for the unit weight (= 1 milligram) increases by removal of magnetised iron, decreases by removal of unmagnetised iron, and by that of the particles of carburet of iron remaining behind after solution of the iron are magnetisable, and receive permanent magnetism. (3). The carbon permanent magnets may be obtained from the remains of dissolved iron masses, if these remaining particles are now magnetised. The author further gives some results of observation as to the magnetic quality of several kinds of mineral graphite.

Ally Journal Dec 1. 75

MAGNETISM OF STEEL.

As Influenced by its Carbon and its Hardness.

For the measurement of the magnetism which different varieties of steel are capable of receiving according to the carbon they contain and their degree of hardness, M. Trève (*Comptes Rendus*, abstracted by Stanislaus Jaquelain) had fifteen steel rods prepared, which he grouped into five sets of three each. Each group had a varying proportion of carbon, viz., A 0·050 per cent.; B 0·130; C 0·290; D 0·636, and E 0·750 per cent. The rods in each group received a different hardening: No. 1 was heated up to 765 deg. C. and hardened in water of 10 deg.; No. 2 was heated to 800 deg., and hardened in water of 100 deg.; No. 3 was heated up to 776 deg., and hardened in oil at 10 deg. The rods were magnetized to saturation, and their magnetism measured. The results of these measurements are given in a table, from which we make the following deductions.

Rod A, with hardening No. 1, gave the highest magnetism, viz., forty-seven; with hardening No. 2, the magnetism measured forty-four; with No. 3, it measured forty-three. A comparison of rods A and E, both at hardness No. 1, show the great influence of the carbon, since, while the magnetism of A was forty-seven, that of E was only thirteen. The influence of the hardening is small when the proportion of carbon is large, but becomes more manifest as the proportion of carbon decreases. The numbers also show with precision the influence of the proportion of the contained carbon; the magnetism rising with it, as shown by the following table:—

A,	47	B,	45	C,	42
A,	44	B,	39	C,	30
A,	43	B,	37	C,	37

D,	33·5	E,	13
D,	22	E,	10
D,	29	E,	12

M. Trève has constructed curves according to these values, showing these results more plainly. A comparison of these curves with the curves of elasticity of these steels shows that as the carbon gives steel its elasticity, it lessens upon it also its magnetic capacity.

[illegible] for submarine light.

Researches on Magnetic Rotatory Polarization.—M. H. Becquerel.—Since Faraday's discovery, the phenomenon of magnetic rotatory polarization has been the subject of numerous researches. It has been remarked that bodies strongly refractive have generally also a great magnetic rotatory power; but the exceptions to this rule have hitherto prevented any connection between these two physical attributes from being established. The author finds in his experiments that many bodies which present a regular increase of rotation as the index of refraction augments. The exceptions observed may be attributed either to the effects of lamellar polarization, as in the diamond and garnet; or to the presence of magnetic bodies; or, lastly, to unknown causes.—

EXPERIMENTS UPON THE RAPIDITY OF MAGNETISATION AND DEMAGNETISATION OF IRON AND STEEL.

By M. Dufrêne.

In prosecuting my investigations with electro-magnets and their employment in registering very rapid phenomena, I was led to enquire what was the influence of the nature of the iron in the electro-magnet upon the processes of magnetisation and demagnetisation. With this view, I employed a registering apparatus in which the pieces of iron forming the electro-magnet were movable, all the other parts, such as the coils, armature, pointer, &c., remaining fixed. I then measured the duration of the processes of magnetisation and demagnetisation, by means of the method described in my first memoir, with Jamin upon electric chronographs.

The movable portion of the electro-magnet, which I inverted successively in the apparatus rails, was formed by two cores of 2 millimetres in diameter and 12 millimetres in length. The coils, through which the current was passed, consisted of 14 metres of wire, one-fifth of a millimetre in diameter. The battery used was one Bunsen cell as modified by M. Deleuvier. The different kinds of iron tried were the ordinary iron of commerce, the specially soft telegraphic iron, malleable cast iron, gray cast iron, and, lastly, cast steel drawn and tempered.

The results obtained were entirely unexpected, for the soft iron, the ordinary iron, the malleable cast iron, and *even the tempered steel* gave, very nearly, the same results for the times of magnetisation and demagnetisation, that is to say, duration of demagnetisation, 0·00025; duration of magnetisation (approximately), 0·00150 of a second.

The gray cast iron gave still better results, for the duration of the latter was found to be only 0·00100 of a second instead of 0·00150 of a second. The last result is interesting, for it would allow the greatest possible rapidity to be attained in the transmission of signals.

The final result is, that with my present registering apparatus, which will shortly be described, perfectly clear signals can be obtained, succeeding each other at intervals of one-three-hundred-and-fiftieth of a second, no matter what kind of iron is used for the electro-magnets, and at intervals of one-five-hundredth of a second when gray cast iron is employed. It should be carefully observed that I do not here speak of *signals following each other in regular succession* at intervals of a three-hundredth-and-fiftieth or a five-hundredth of a second, so as to form an equi-distant series. In the latter case a number of signals much greater than 350 or 500 per second could be transmitted.

I am inclined to believe that the superiority of the cast iron is due to its molecular structure, and not to the amount of carbon contained in it. It is therefore my intention, with the new iron and steel *not yet forged*, which I still believe to be more appropriate, to ascertain all that I have hitherto obtained. I propose, further, in a short time to treat, in another communication, of the details of my experiments, and of the application of my registering apparatus to electric chronographs specially arranged in connection with artillery.

It should be particularly noted that the times indicated above are exclusive of the time occupied by the pointer in traversing its course. This time has to be added to that occupied by the magnetisation and demagnetisation to arrive at the three-hundred-and-fiftieth or five-hundredth of a second for the *total* duration of a signal comprising the demagnetisation, the time during which the pointer is falling, the magnetisation, and lastly, the return of the pointer to its original position. These numbers have reference besides to the case where only a single battery element is used, the number of signals per second immediately increases with the intensity of the current.—*Association Scientifique.*

ON THE CONSTITUTION AND MAGNETISM OF STEEL.

The constitution of steel bars may differ on two accounts—their chemical composition, and the mechanical treatment to which they have been subjected. Chemically, steels vary according to the quantity of carbon they contain; physically, according to the degree of hardness given them, by heating and quick extinction of the heat in cold water, and by the after process of annealing.

In both directions very also the magnetic properties of steel; and numerous researches on its magnetism, as thus determined, have been published. In a recent paper to the Göttingen Society of Sciences, H. Fromme studies the question of the influence of hardening on the permanent magnetism of steel. This has often been discussed, without, however, decisive results. The observers have taken opposite sides, some attributing to hardened steel, others to annealed steel, the greater power of retaining magnetism. Thus, Müller, Plücker, and Wiedemann took the former view; Hansteen and Lamont, the latter; while Coulomb, after numerous observations, considered the question as still open.

After some researches on the magnetism of soft steel bars, M. Fromme was about to proceed to an investigation of the point, when a paper of M. Ruths (an inaugural dissertation in 1872) came into his hands, and it seemed to him of a decisive character.

M. Ruths found that the *dimensions* of the bars must be taken into account. Cylindrical bars in which the relation of the length to the thickness is greater than 30, retain in the hardened state less magnetism than when annealed in the yellow, and in the latter less than when annealed in the blue. In the manner behave also thicker bars, so long as the inducting forces are small; with greater forces the case is different; an that, in general, bars in which the ratio of the length to the thickness is less than 30, have the greater power of retention in the hardened state. "Thus with small magnetizing forces, an annealed bar always retains more magnetism than a hardened one, otherwise similar. But, since the magnetism in the hardened bars increases in greater proportion than in the annealed ones, a value of the magnetizing force is reached, at which the magnetism of the hardened bar reaches that of the annealed, and thereafter exceeds it. The coefficient magnetizing force is smaller, the thicker the bar in comparison to its length. Its value increases with increasing length and decreasing thickness, and, at a certain proportion of these two magnitudes, becomes infinitely great." It is an important confirmation of these results that the contradictions of all previous observers are fully explained, when regard is had to the dimensions of the bars. M. Fromme, however, tested the matter experimentally.

Eight steel bars of 100 mm. length, of which four (I) were 7 mm. thick, the other four (II) 2 mm. thick, were hardened in the same manner. The temperatures to which they were heated varied between 827° and 1067°. Of the bars, I_1 and II_1 were left hard, I_2 and II_2 annealed to the oxidation colour yellow, I_3 and II_3 to blue, I_4 and II_4 to disappearance of all oxidation colours. The bars were magnetized to saturation by touch, and their magnetic moment determined. The following values were obtained, and they are compared with those got from natural bars, with the same kind of magnetization:—

	Natural.		*Natural.*
I. 1.	1982 660	II. 1.	413 232
2.	1282 630	2.	288 234
3.	1218 624	3.	440 265
4.	1051 609	4.	475 257

These numbers fully confirm M. Ruths' result, at least for strong magnetising forces. It further appears, that with thin bars it makes very little difference; with thick bars a considerable difference, whether one magnetizes the steel hardened or annealed. For very small magnetising forces, on the other hand, which in practice do not come into consideration, the magnetisms of the thinner bars present, according to Ruths, greater differences. It will be perceived, however, how very unsatisfactory it is to use natural bars for magnets, for in every case the power of retention increases through the hardening.

M. Fromme seconds to M. Ruths, then, the priority in deciding this question. Quite recently M. Gaugain has communicated to the Paris Academy results which fully agree with those of Ruths.

As to the possible cause of these phenomena, M. Fromme offers the following opinion: "Determining the specific gravity of steel bars of natural, hardened, and annealed steel which I wished to use in further researches, I found no difference of specific gravity of a natural and a hardened bar considerably greater than I had anticipated, or than I found in Lamont's Handbook, and in a table of specific gravities. I therefore, myself made some experiments on bars of different dimensions.

"In hardening of a steel bar, there is an increase of volume, and so a decrease of the specific gravity; the coefficient of dilatation lies between 1/100 and 1/90. In annealing to the oxidation colour yellow, there is a contraction; the coefficient of which is 1/1040 at least; but the specific gravity rises again approximated to that of the natural state to the extent of a half. With further annealing to blue, the bar contracts further, coefficient of contraction about 1/997. It is only after heating till the disappearance of all oxidation colours (gray), that the bar reaches the specific gravity which it had before hardening.

"Hence we infer that with sudden extinction of a glowing steel bar there forms a very hard superficial layer, which cooling more quickly than the interior, restrains the latter in its contraction. Thus the interior is in a tense state, caused by the outer solid crust; the latter is very hard, the former soft. The consequence is the enlargement of volume observed."

Continued over

9

Continued

We may regard a hardened steel bar as consisting of concentric layers, whose hardness quickly diminishes from without inwards, ultimately reaching a soft heart. In slow heating or gradually higher temperatures, the molecules again arrange themselves regularly, and it might be supposed that with the annealing temperature at which the specific gravity before hardening is reached again, the molecular state of bar is also the same again. The magnetic behaviour, however, contradicts this. The much greater magnetism of the grey bars compared with that of the red indicates a crystalline arrangement of the molecules different from that of the natural state.

"Now I have found that steel bars of different thickness, otherwise alike, hardened in the same manner, show a different decrease of the specific gravity, the thin ones a greater, the thick ones a less. It may probably be inferred, that hardened and annealed steel bars of different thickness show a different magnetic behaviour, because the proportion of the outer harder part to the inner softer part is different.

"I conceive the process of magnetisation of a hardened steel bar thus: In each individual layer the separating force excites a remanent magnetism, the amount of which continuously decreases from without inwards. But from the remanent magnetism of each layer is subtracted the opposite induced magnetism which is excited by the remanent of all the other layers, and the amount of which increases from without inwards. The proportion of these two parts to each other is determined for the amount of the resulting magnetism coming outwards; it further determines whether a bar takes more magnetism in the hard or in the annealed state. Thus the greater or less value of the remanent magnetism of a bar also finds its explanation, when we consider not only the laws of the remanent, but also those of the temporary induced magnetism.

"Without proceeding to further establishment of this hypothesis, which I wish to test by further experiments, I will only refer to a result of Holtz's, which, along with another of Jamin's, may serve as verification. Holtz, having dissolved in hydrochloric acid magnetised bars, both hardened and annealed, found that in the removal of the outer layers the magnetic moment of unit weight increased more in the annealed in greater proportion in the hardened than in the annealed bars.

"The explanation is easily furnished, according to my hypothesis, as follows:—In the removal of the outer hard bed, of course, most strongly magnetic layers, a considerable portion of the magnetism is also removed; and one might therefore expect rather a decrease of the magnetic moment of unit weight. That this does not occur is proof that at the same time opposing forces are removed—namely, the opposite induced magnetism. Its influence was given, that even the moment of the unit weight increases; and the increase must be less in annealed bars, because in them the inequalities of the individual layers are in part removed by annealing."

Note on Magnetism.—By M. Th. du Moncel.—Replying to M. Gangain's objection as to originalities in certain experiments, M. du Moncel says:—I have shown that magnets have two kinds of action—a *dynamic action*, or in the molecules of iron, and a *static action*, which constitutes the attractive force properly so-called. The two actions, which have a certain connection, may be produced independently one of the other, under certain conditions. The effected results—despite the hypothetical statement of which M. Gangain contests the theoretical value—are positive, and are, consequently, unrelated to dynamic action. It is a kind of reflex action exchanged between the armature and the pole acting on the armature, which has for its effect, not the depleting of the magnetism from the end of the magnet (as interpreted by M. Gangain), but the molecular induction of a greater quantity of magnetism. These result from the effect two consequences. The atomic polarities being excited to excess, the molecular currents possess more energy, and the magnetic solenoid acts with greater intensity. The polarities determining the attraction finding themselves displaced or assailed more or less by the reflex action of the armature, all the atomic polarities in the different parts of the magnet are obliged to displace themselves in the same manner in order to preserve their equilibrium, from which results a general subdivision of the exterior polarities of the magnet. Consequent upon these curious consequences of magnetic molecularities is the retardation which occurs on the current of demagnetisation in a cloud magnetic system, when the voltaic current succeeding the system is interrupted. This effect is analogous to that remarked in electric transmission on submarine cables. In these transmissions there exists a dynamic action, which is related to the current transmitted, and a static action, which is represented by the condensation produced between the insulating envelope of the cable. Now there are actions which exist simultaneously give rise to contrary effects, and these by retrogressive influence retard the rapidity of the electric development which has produced them.

MAGNETISATION OF STEEL TUBES.—According to further researches of M. J. M. Gaugain, when a system of steel jars formed of two parts enclosed with different degrees of coercitive force is submitted to the magnetising action of a feeble electric current, the part which possesses the least coercitive force is always that which takes the strongest magnetisation, whether it take the form of a core or a tube. This result is analogous to those formerly obtained with plain bars, annealed or tempered.

Electrical Review, July 8, 1882.

SPECIFIC GRAVITY AND MAGNETISM OF IRON.

By corrosion of magnetised steel bars with nitric acid, and fresh determination of the magnetic moment, M. Holz found that the moment was become greater, per *unit of mass* of the undissolved of the soluble iron; and that, therefore, the insoluble carbonated iron appears to be the bearer of the magnetic coercive force. The closely related question of how pure iron behaves with regard to magnetic properties, forms the subject of a second investigation by M. Holz in a recent number of *Poggendorff's Annalen*.

Perfectly pure iron, free from carbon and all admixtures met with in ordinary iron, M. Holz prepared by electrolysis of an iron salt solution, according to the method described by Klein and Jacobi. He obtained in this way four shining and strong plates of the purest iron, which formed the material of a large series of experiments.

It was necessary, however, first to ascertain what influence gases occluded by the iron in electrolysis might have upon the magnetic moment. M. Holz did so by first magnetising the galvanic iron, then determining the magnetic moment; then keeping the iron in vacuo till no gas bubbles came from it, and then determining the magnetic moment anew. This was found to be only very slightly increased. The collection of the galvanometer rose from 4178·7 to 4179·5, and M. Holz concluded that the occluded gases have no considerable influence on the magnetic moment.

From three plates small bars were now prepared, magnetised to saturation by a coil traversed by the current from several Bunsen elements, and their moment was then determined. Thereupon the bars were annealed and subjected to the same process. These experiments gave approximately to observe the following properties of galvanoplastic iron (which are somewhat divergent from those hitherto known).

On annealing in the gas flame, there was deposited over the bar an envelope of oxide, which could easily be split off, and quickly became separated if the red-hot iron was allowed to fall into water. The iron then appeared brilliantly white, like platinum, and possessed elasticity almost equal to that of steel. The magnetic moment of the bar was not at all diminished by annealing, but, on the contrary, somewhat increased. The specific gravity of the iron was also increased, and that considerably. Before annealing it was 7·8, and after annealing 7·9. The increase in the specific gravity is, therefore, 1·3 per cent. This result is remarkable, as it is known that in the annealing of ordinary iron, which is accompanied by a considerable increase of carbon and its compounds. The change which occurs through annealing of electrolytic iron is accordingly only a change of density and the texture of the metal, considered therewith; and in order to determine this entire molecular change in pure iron with reference to its density, with sufficient accuracy, I have merely to ascertain the specific gravity for each molecular state. The specific gravity of the electrolytic iron before annealing, and the same after annealing, must yield perfectly determinate results as to the molecular expansion and contraction of all particles subjected to the annealing."

M. Holz gives his determination of the magnetic moment and specific gravity of various bars of galvanoplastic iron (see preceding table), and, it is shown that in annealing, the moment increases with increase of density of the iron bars; but the decrease of density is greater than the moments increase. Annealing has this, it reiterates to magnetism, an opposite action on galvanoplastic iron to that it has on steel. Both actions, however, stand in intimate connection with the specific gravity, as appears from the following review of the results:—

The values obtained in the foregoing experiments suffice to prove that through the change of the specific gravity in iron, as in steel bars, the coercive force is considerably altered. The opposite results of pure iron and of steel correspond to like causes.

In Gaugain-Holtz iron regulates, through annealing, a *greater* specific gravity; the molecules are more compressed, the intervals become smaller, and the permanent magnetic moment diminishes about half.

In steel bars, by annealing and hardening, acquire a *less* specific weight; the molecules are further apart (if in addition the mean of all distances of the molecules is not somewhat lessened), the intervals are, in arithmetical mean, greater, and the magnetic moment is considerably increased.

M. Wiedemann has shown, by his extensive experiments upon the influence of magnetisation on torsion, that the permanent magnetism decreases through torsion, the compressing in consequence increases through distortion; and thus twisted iron bars untwist on being magnetised. These facts are explained by the author here found between density and the magnetic force of iron. Torsion causes, in fact, by the distortion of the magnetism, a decrease, owing to the increase of the specific gravity. Through detension, the molecules are separated; the magnetism will, therefore, increase. Hence it follows, that if the magnetism of iron bars by magnetism and, therefore

Rapidity of Magnetisation and Demagnetisation of Iron, Cast-iron, and Steel.—M. Dupuy.—The tell-tale machine used in researches, of which the following is the results, will be fully described in a later number of this journal.—"The pieces of iron in it composing the electro-magnet are removable; all the other pieces, such as coils, armature, &c., remaining intact, so as to give evidence of the influence of the metal composing the electro-magnet. The metallic rod used in the electro-magnets, which I call the instrument for magnetising bodies, was 12 of two cones 6 m/m. in diameter, and 12 m/m. in length. The exciting coils contained 14 metres of wire #2 m/m. in diameter. The battery used consisted of one Bunsen element modified by M. Dulaurier. Lastly, the varieties of iron experimented upon were the ordinary iron of commerce, the soft iron of telegraphy, malleable and grey cast-iron, and drawn and tempered steel. The results obtained were quite unexpected for soft iron, ordinary iron, malleable cast-iron, and even tempered steel, as they gave almost precisely the same readings, viz.:—

	Second.
Duration of the phase of demagnetisation	0·0003
" " magnetisation (ap-	0·0030
proximately)..	

Grey cast-iron gave still better results, since duration of magnetisation was reduced to about $\frac{1}{1000}$th of a second.' This last metal, therefore, is that which will enable us (according to the author) to attain the greatest possible rapidity in the transmission of signals.

Simple Way of Finding the Pole of a Bar Magnet.—M. F. Müller.—A magnetised sewing needle, between two pieces of cork, is placed horizontally on water, and allowed to place itself in the magnetic meridian. A pointed iron wire is then brought in that position, towards either of the ends of the needle (both ends possessing the constant of all forces goes versâ-vicâ in proportion as the iron wire is more carefully brought closer till it touch the magnet, constant taking place in the beginning of the approximation. To mark that fact point, the point (pencil) is precisely directed in all parts. Any indication of deflection from the point is always found.

Elect News Oct. 15.'74

Notes

M. GAUGAIN has lately undertaken experiments with a view to ascertain the influence of changes of temperature on the magnetisation of steel bars, and has obtained curious results. He found that, when certain bars were magnetised at a high temperature and cooled, their magnetism entirely disappeared and then changed sign; so that if a bar had been magnetised when hot in a certain direction it was found to be magnetised in the opposite direction after returning to the ordinary temperature. When heated afresh the inverse magnetism, which is always very feeble, vanished, and the primitive magnetism reappeared. The same change of sign is reproduced when the bar is again cooled. The specimens of steel with which these experiments were made were all of Sheffield manufacture. With other bars changes of intensity of magnetism were observed, but no changes of sign. M. Gaugain does not give any very satisfactory explanation of these phenomena.

Tel. Journ Nov 15. '74

MAGNETIC PROPERTIES OF NICKEL AND COBALT.—M. Hankel finds that with feeble currents the magnetic power of nickel is equal to that of soft iron; but with strong currents it is comparatively feeble. The magnetic power of cobalt with both strong and feeble currents is much less than that of nickel and soft iron.

MAGNETIC PROPERTY OF HYDROGENIUM.—It is known that palladium is feebly magnetic, and that hydrogenium is feebly diamagnetic, and when the late Professor Graham succeeded in "occluding" hydrogen and palladium, he believed that the resulting alloy would be at least less magnetic than before, but to his surprise, he found it much more magnetic. M. Blondlot has inquired into the matter, and found results in all cases opposed to those of Graham. He finds that palladium charged with hydrogen is much less magnetic that when in the pure state. It is thought that Graham's materials have been impure.

ON THE ACTION OF HEAT IN MAGNETIZATION.

BY L. PAVÉ.

It has long been known that the magnetic state of a steel bar changes with the temperature. Coulomb, Hankel, and other physicists have studied the very complex laws of the dissipation of magnetic intensity; and the most marked consequence resulting from their experiments is, that by raising the temperature of steel to a certain point we cause it to lose definitely the magnetism it has received.

M. Jamin has recently demonstrated "that steel is capable of receiving considerable magnetization at a temperature at which it loses almost entirely that which is received when cold, while the magnetism of a bar magnetized when hot diminishes very rapidly as it is a very short time almost completely disappears.

We have investigated the variations of magnetic intensity by the method of Van Rees, which permits a speedy determination of the total quantity of free magnetism in a bar.

If a helix, formed of a few turns of copper wire wound round the bar, be slid quickly from the middle to a distance at which its influence is no longer sensible, the initial deflection of a galvanometer-needle, produced by the very feeble induced current resulting from the movement, measures sensibly the total quantity of free magnetism of the bar, we are assured that the earth's action is not sufficient to give an induced current that could disturb the result.

We operated on bars previously annealed, and cooled slowly, so that we could regard the changes of state as absolutely temporary, and the variations of temper did not complicate the phenomenon.

The bar to be examined is suspended horizontally to a copper rod, above a tube pierced with a series of apertures forming gas-jets close enough to heat the bar in a manner sensibly uniform throughout its length. This arrangement permits the magnetising-coil to be introduced without the bar ceasing, even when inside, to be under the action

Telegraphic Journal July 29 1875

performed by the engines; but the steam-engine is by no means the only thermic motor employed in the industrial arts. Electro-magnetic engines may also be regarded as thermal machines, deriving their motor force from the heat developed by the solution of the zinc in each cell of the battery, and transmitted to the engine by means of the current. The experiments of Professor Page have shown, in the most satisfactory manner, that it is at the expense of a certain quantity of this heat that an electro-magnetic engine produces mechanical work; and in measuring the work performed upon Gramme's machine, I had no knowledge of Van Rees's labours; they are not mentioned in any French work, and I do not think I am far wrong in saying that M. Blondlot was the first to bring them into notice in this country. From him I am led to understand that the various methods I used had been employed for a long time, which rests of less important modification, by various German physicists—Messrs. Lenz, Jacobi, Van Rees, and Riefsthal. I do not, therefore, claim priority.

The method I employed to determine the curves of magnetic intensities is described in my paper on Gramme's machine,* and consists in marking the bar into equal parts—a centimetre, for instance. I then moved an annular conductor from one extremity of the bar to the other, moving it only over one of the marked portions at a time, and noting the existing corresponding in each spots so traversed. The curve was drawn by taking the measured bar-lengths for the abscissæ, and the corresponding readings for the ordinates. Now, undoubtedly, it is not evident that the intensity measured by this plan is proportional to the ordinary magnetic strength as measured by Coulomb's oscillating method; but I have experimentally proved that this proportionality does exist so long as we leave on one side the parts of the bar bordering on the extremities. As to the statement that I have admitted, between the curve of the intensities and the curve of the demagnetisation, it evidently results from the mode of constructing the two curves. If Van Rees and myself have been led to use the same experimental means, we have been guided by different theoretical considerations. Starting from the same premises, With Van Rees, the induction current represents what he calls the free magnetism, *i.e.* the sum of the molecular elements belonging to the part of the bar upon which the helix is placed. With me, the induction current is that of demagnetisation, *i.e.* the current which would be obtained in the given position of the helix if the magnetism of the bar were destroyed. According to Ampère's views, which I have adopted, this current gives the measure of the solenoidal current. In other words, if we imagine a solenoid of variable strength, which possesses all the properties of the bar, the current of demagnetisation corresponding to a given point of the bar represents the strength of the current which causes the corresponding portion of the equivalent solenoid.

Electrician & Mechanic July 1 1875

Relation of Temporary Magnetism to Magnetising Force, and its Bearings on the Reciprocal Action of Metallic Particles.—M. Blondlot.—The nature of the experiments was briefly this.—Fine powdered masses of the magnetic metals, chemically prepared, and mixed variously with anglicaceous earth, were enclosed in glass tubes, corked at both ends, when brought to a certain density, would float on water, when forced down out of a magnetising spiral. A small steel magnet with mirror, was hung a little way off the end of the coil, and above its level. The deflection by the coil was compensated by a simple circuit on the other side, which received the same current. The deflecting action of the magnetised bars was thus brought into prominence. Each bar was subjected to currents of different strength, and the rendered magnetism examined. *Inter alia*, it appears that by mixing a non-magnetic substance with iron, the magnetic nature of nickel or cobalt may be imparted; and similarly, to nickel, the magnetic nature of cobalt (diffregarding the absolute weight of the metal). The phenomena of temporary magnetism are affected in the same way, when one increases the dimensions in direction of the magnetising force at cost of the other dimensions, as they are when one separates the small particles of the magnet from each other. The metal diluted as described presents more favourable conditions for magnetisation than massive metal. Bars of different density, with corresponding differences of which, however, with increasing magnetisation, and, on saturation, being reached, quite disappear. The entire reciprocal action decreases with increasing magnetisation. In reverse, the course of magnetisation in soft magnetisable metallic bodies depends both on the form and the density of the magnet, and this dependence is to be explained by the reciprocal action of the magnetic molecules.

The Engineering & Mining Journal Oct 23 1875

Magnetic Properties of Nickel and Cobalt.—M. A. Ditlfs, says the *Electrician*, has made some fresh experiments on the magnetic properties of nickel and cobalt, the specimens being obtained by an electro-chemical process, the currents employed being of sufficient intensity to render the metals very hard. Having divided the two into bars of nearly equal dimensions, some of them were left in the hard state, others were annealed, and again some of them were left hard. All of them were magnetized in the same time and by the same way, and measured by means of a set the same time and by the same way, and measured by means of a magnetometer. After being left for 36 and 72 hours, they were again remagnetized. The found the their magnetic properties increase, and consequently, with increasing magnetization, and, on saturation, being reached, quite disappear. The entire reciprocal action decreases with increasing magnetization. In reverse, the course of magnetization in soft magnetisable metallic bodies depends both on the form and the density of the magnet, and this dependence is to be explained by the reciprocal action of the magnetic molecules.

"question, is the coefficient of self-induction of a coil constant, independent of the current, or does it vary with the current? In short, is the coil "electrical" or "magnetical"?

It consists in inserting the magnet between two very short coils of conducting wire united to a galvanometer, and observing the throw when the coil from x to x', and measuring the deflection produced by the induction current. According to Faraday and Lenz, this deflection depends simply on the loss of magnetic force intercepted by the coil, and which are bounded by x and x'; it is thus proportional to the quantity of magnetism comprised between x and x', and is independent of the form of the coil provided the latter be sufficiently tight against the steel. M. Gaugain adopted this plan without modification. Recently M. Blondlot rigorously proved that Van Rees method is only exact for a single case: that in which the magnet is very long, and the coil is rapidly transferred free from the middle line to an extremity, and thence to an infinite distance. In this case the deflection measures M the whole of the magnetism, in its values, M_1, are given in the third column of the table.

On the other hand, let us call A the true value of the ordinate at the commencement; we shall obtain a second valuation of the total magnetism by measuring the expression $y \, d \, x$ *from axis to infinity*: and, as this valuation will not be related to the same unit as the preceding one, we will express it by the product of M with a constant a

$$Ma = \int_0^\infty y \, dx = c \int_x^\infty \frac{A}{x^2} \, dx$$

whence

$$\frac{A}{x} = M \, l \, k$$

The values of $M \log k$ are shown in the fourth column of the table, and are very sensibly constant. Hence it follows that the true value A of the ordinate at the commencement is constant for the same steel, whatever may be its degree of temper. The coefficient A_0, which had been found by the parabolic method, is a function of the conductibility, and its increase by annealing proceeds only from increase of conductibility.

We must now find the relation of A_1 to A or $f(\theta)$. I said that A_1 should be equal to $\frac{A}{\mu}$. Indeed, $\frac{1}{\mu}$ expresses the coefficient of conductibility in a bisted magnet, and $\frac{A}{\mu}$ will represent the superficial coefficient in all the directions around a point on the plane of a magnet; and observed laterally A_1 will be proportional to this coefficient, and consequently equal to $\frac{A}{\mu}$. Whence $A = A_1 \mu$.

I have already found this quantity to be constant, and we now see that it expresses the true ordinate at the extremity of the bar. Whence it follows that the expression for the true ordinate y at any point whatsoever will be

$$y = A_1 k^{\frac{1}{x}} = A \, k^{-x} = A \, l^{-x}$$

that of the observed ordinate being

$$y_1 = A_1 \, k^{-x} = A \, k^{-(x+a)}$$

To classify the steels in a magnetic point of view it will then be necessary to transform them into long plates with a thickness of one millimetre. Let A_1 and k be measured; A_1 will be the true ordinate, and it will represent the magnetic power of the steel; it will depend simply on the chemical composition of the steel; and it cannot be changed, neither by the process of annealing nor by temper.

The second constant k is at the disposition of the constructor; it depends on temper, and diminishes by the process of annealing.

The attractive force developed at the extremity of the bar is proportional to y^2, whence $\left(\frac{A}{\mu}\right)^2$. For the same steel this force increases with the annual, and diminishes with the temper.

The height of the true magnetic curve at the extremity of the bar is invariable and equal to A; but the measured height by "trial of contact" is $\frac{A}{\mu^2}$, and increases with process of annealing.

In proportion as k decreases by anneal the magnetic curve lengthens. The steel used should therefore be longer the more it is annealed; otherwise it cannot contain the whole of the magnetism it is capable of. Such was the case with No. 12 in the table.

The quantity of total magnetism $\frac{A}{l \, k}$ increases with the anneal; the quantity measured by "trial of contact" increases more rapidly still and is $\frac{A}{\mu \, l \, k}$.

The conclusions to be learnt from these experiments and reasonings are that *to make magnets which shall excercise great* CONTACT-ACTIONS *we must use annealed steels of very great lengths; but if we desire* DISTANT-ACTIONS, *we must use short and strongly tempered steels.*

SPECIFIC GRAVITY AND MAGNETISM OF IRON.

By corrosion of magnetised steel bars with nitric acid, and fresh determination of the magnetic moment, M. Holz found that the moment was become greater, per unit of mass, after removal of the soluble iron; and that, therefore, the insoluble carbonised iron appears to be the bearer of the magnetic current. The closely related question of how pure iron behaves in regard to magnetic properties, forms the subject of a second investigation by M. Holz in a recent number of *Poggendorff's Annalen*.

Perfectly pure iron, free from carbon and all admixtures met with in ordinary iron, M. Holz prepared by electrolysis of an iron salt solution, according to the method described by Klein and Jacobi. He obtained in this way four shining and strong plates of the purest iron, which formed the material of a large series of experiments.

It was necessary, however, first to ascertain what influence grains occluded by the iron in electrolysis might have upon the magnetic moment. M. Holz did so by first magnetising the galvanic iron, then determining the magnetic moment; then keeping the iron in vacuo till no gas bubbles came from it, and then determining the magnetic moment anew. This was found to be only very slightly changed. The deflection of the galvanometer rose from 67·75 to 67·85; and M. Holz concluded that the occluded gases have no considerable influence on the magnetic moment.

From these plates small bars were then prepared, magnetised as saturatedly as a coil traversed by the current from several Bunsen elements, and their moment was then determined. Thereafter, the same bars were annealed and subjected to the same process. These experiments gave opportunity to observe the following properties of galvanoplastic iron (which are somewhat divergent from those hitherto known).

On annealing in the gas flame, there was deposited over the bar an envelope of oxide, which could easily be split off, and quickly became separated if the red-hot iron was allowed to fall into water. The iron then appeared brilliantly white, like platinum, and possessed electricity in no small degree. The extraordinary hardness of iron acquired, through annealing, such softness that it could be cut out with shears. This degree of softness remained in the iron even when it was quickly cooled; but the original hardness did not return perceptible, even when it was brought red-hot into an ice mixture.[1] On measuring the expansion that the annealed iron had a hardness 2 to 3, while the hardness of the annealed was between 5 and 6, and other quick-steels are reminded at this.

The magnetic moment of the galvanoplastic iron was considerably lower after annealing than before it. Still more remarkable was the disappearance of magnetic force of the annealed iron. One bar lost in five days over half its moment; this fell from 47 to 23, and direct experiment showed that this was not caused by changes of temperature. "On the other hand," says M. Holz, "the most intelligible shaking had no influence; it was found that the deflection of the magnetic mirror was reduced several degrees when the annealed iron lay in a tube. . . . By throwing the bar three times on the ground, I removed four in the whole of the permanent magnetism; a steel bar of the same size was brought, by six times stronger throwing, from 72 to 35·72; and in the last two throws, no further change of the moment took place."

It is generally known that the ordinary soft iron has only very little power of retaining magnetism that the annealed; but the relations of the coercive force to the changed molecular conditions of *one and the same iron* have not hitherto been investigated. "The phenomena of ordinary wrought-iron," M. Holz says, "and those of steel, are, in the molecular changes of these through annealing and hardening, subjected to various conditions; the parts of the bound carbon present experience a different expansion from those of the free or unbound; and both of these, again, not the same as those of the pure iron present. Much more simple is the process in annelectrolytic iron bar; annealing changes the position of the iron particles, without requiring a considerable influence of carbon and its compounds. The change which occurs through annealing of electrolytic iron is accordingly only a change of density and the texture of the metal connected therewith; and in order to determine this entire molecular change in pure iron with reference to its density, with sufficient accuracy, I have merely to ascertain the specific gravity for each molecular state. The specific gravity of the electrolytic iron before annealing was found to be 7·8443, afterwards 7·8744; therefore the determinate results as to the magnetic and density connection of all particles subjected to the annealing."

M. Holz gives his determination of the magnetic moment and specific gravity of various bars of galvanoplastic iron and ordinary steel; and it is shown that in annealing, the moments decrease with increase of density of the iron bars; but the density of the next bars decreases and the moments increase. Annealing has thus, in reference to magnetism, an opposite action on galvanic iron to what it has on steel. Both actions, however, stand in intimate connection with the specific gravity, as appears from the following *resume* of the results:—

The values obtained in the foregoing experiments suffice to prove that through the change of the specific gravity in iron, as in most bars, the coercive force is considerably altered. The opposite results of pure iron and of steel correspond to the causes.

2. Galvanoplastic iron requires, through annealing, a greater specific gravity in order that its more compressed, the relation between annelled and the permanent magnetic moment diminishes about half.

3. Steel bars, by annealing and hardening, acquire a less specific weight; the molecules are further apart (if the arithmetic mean of all distances of the peripheral constituents be hereby expressed), the intervals are, in arithmetical mean, become greater, and the magnetic moment is considerably increased.

M. Wiedemann has shown, by his extensive experiments upon the influence of magnetisation on torsion, that the permanent magnetism decreases through torsion, the temporary magnetism increases through detorsion; and that twisted iron bars unwind on being magnetised. These facts are explained by the relation here found between density and the magnetic force of iron. Torsion condenses the bar; the magnetism must, therefore, decrease, and the case is the inverse of the specific gravity through detorsion, the molecules are separated; the magnetism will, therefore, increase, and it follows that if the magnetism in twisted iron bars can increase, an untwisting must be indicated by detorsion.

The important herewith is the fact ascertained by Maxwell and Wertheim, that through the stretching of a hard iron bar, its temporary magnetic moment is increased. It is also generally known that steel, through hardening, acquires a less specific gravity than it had in the unhardened state; and that in the former case it has a much greater coercive force than in the latter. With reference to pure iron, I am not aware of comparative tables showing the changes of structure and of coercive force.

From the values here given, then, it may be concluded, that the magnetic coercive force is generally a function of the space formed between the molecules, and is dependent on the size of this intervallic space."

VARIATION OF SHIPS' COMPASSES.

By E. T. ROLLS, A.S.T.E.

A number of calamitous wrecks that have taken place on our shores within the last twelve months from unaccountable error in the dead reckoning, of sailors ominously call it—meaning the estimate of position by course steered, distance run, &c., without recourse to astronomical observations—hindances me to believe that the terrible score of erring compass more frequently lures the mariner to his destruction than is generally supposed. A man endeavours to make a passage he has made hundreds of times before, he steers the same courses, allows for the tides and winds, and feels confident of his whereabouts as of walking down well-known road. The weather is thick; all at once, often simultaneously with the cry of the look-out man, there is a disagreeable sibilating sensation, immediately intensified into a violent shock, and the ship is fast on a shoal that had been reckoned miles away. Vain efforts are made by reversing engines or trimming sails to get the unfortunate ship off again. But what success can be expected from such means? A moving mass of two or three thousand tons, such as a moderate size ship represents, with very slight exception, must almost invariably be immovably rigged, and if she has gone on with a "fair" wind, her chances are hopeless indeed.

It is not then a time for men to ask themselves if they got there; rather, if it may be, to find means to get away. But soon after, there is probably a formal inquiry into the disaster, and, unfortunately, then its cause can only be surmised, for all evidence has disappeared.

As most are aware, iron ships, or ships containing much iron, are swung for compass adjustment before proceeding on their voyage. They are taken to a convenient spot, moved into various positions with regard to the magnetic meridian, and the compasses compared with standards on shore. Usually the former are more or less affected by the iron surrounding them, possessing, as it always has a number of magnetic poles indiscriminately charged, sometimes aiding, sometimes neutralising each other, the result, of course, affecting the compass proportionately with its magnitude, and deflecting the needles from the proper position, which have to be restored by the introduction of counteracting magnets on the deck.

Now, if all these conditions were immutable, all would be well. But it has been proved, over and over again, that they may easily be disturbed. As the ship in warping out of dock, a heavy lighter being hoisted in, a slight collision with another craft—all these quite likely events in the career of a ship have been actually known to so destroy the equilibrium of magnetic forces as to render the compass the mariner's most deadly enemy, instead of the inseparable and faithful friend it should always be.

Various plans have been suggested as cures for this fearful evil, the *master aperaud* being, as a rule, directed to removing the standard compass a full tripod; but with iron lower masts this can scarcely be successful. Others have suggested the bowsprit end, and reading the card by means of a mirror and telescope. Iron bowsprits are common, and would therefore offer some of the disadvantages of the iron masts: they are frequently damaged, and, further, many steamers have none.

My plan does not aim at removing compass variation; I fear that is impossible, but simply to ascertain at *any* moment if it exists, and then to correct it. I propose to do this by providing each ship with a pair of astatic needles properly mounted, and having one end of the upper needle shaped as an indicator or pointer; the needles would be used thus:—

At the time of swinging the ship, and after the adjustments had been made, the compass card should be removed from the ship's standard compass, and replaced by the astatic needle, in such a manner that these should move freely upon the same axis that had pivoted the compass card, taking care to introduce the needles with their indicator pointing forward.

The astatic needles, apart from magnetic influence, would of course retain any position given them; but here their position will be determined by the magnetic forces surrounding them, and they will, therefore, as soon as their oscillations have ceased, assume a definite direction. Let this direction be carefully noted by recording it with a mark upon the interior of the compass—a compass, in fact, to the "Admiral's point"—and we shall have all that is required, and the compass card can be replaced. After this observations for the constancy of the compass can at any moment be made. It will simply be necessary to introduce the astatic needles as before, and note the position they assume. If it corresponds with that observed at the time of swinging, well and good; if it does not, then the conditions must have altered, and the correcting magnets should be adjusted until the combined needles have their indicator brought opposite the recorded mark, when the compass card may be returned to its place, and its correctness will be found to be restored.

POCKET COMPASSES.—We have had brought under our notice a very neat form of pocket compass which has lately been brought out by Mr. L. Casella, of 147, Hatton Garden. The instrument, which is of the usual size, is known as that of "The Unalterable True North Compass" has been given, is not painted by Mr. Symons, and its peculiarity consists in the marking of the card (which renders it extremely easy to read, even in a dull light), and in the fact of the "S" of the card being made to point to the true north instead of the magnetic north as is usual in pocket compasses. No difference, however, is made in the way the needle is used, and there have as yet been but few cases in which inconvenience has arisen from the fact not being known and appreciated. Mr. Casella's instruments are well finished and got up in a variety of convenient forms.

Correspondence.

Terrestrial Magnetism.

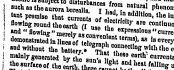
To the Editor of the Scientific American:

In your issue of August 14 appeared an interesting article on the subject of terrestrial magnetism, so-called, in which the views entertained by Humboldt, Hansteen, and Gauss were clearly outlined. During the past year, I have devoted considerable attention to the phenomena of the earth's electricity, and my experiments have demonstrated that there is no such thing as terrestrial magnetism in the sense in which the term is generally employed. To use the term terrestrial magnetism is to indicate that the earth is a magnet, whereas the force which is characterized as terrestrial magnetism stands, with relation to magnetism, precisely as the galvanic current stands with relation to an electromagnet.

I began my experiments in full view of the phenomena set forth in the article to which allusion has been made, namely: The observed declination of the magnetic needle, and its inclination, and the intensity of its action, as well as the facts that these phenomena not only vary in one place from another, but in the same place with time, and that the needle is subject to disturbances from natural phenomena, such as the aurora borealis. I had, in addition, the important premise that currents of electricity are continuously flowing round the earth (I use the expressions "currents" and "flowing" merely as convenient terms), as in every day demonstrated in lines of telegraph connecting with the earth and without the battery.* That these earth currents are mainly generated by the sun's light and heat falling upon the surface of the earth, I cannot but regard as the slightest doubt. That the electricity thus generated is of two well known forms, theretical frictional, there also can be no doubt; nor would it be difficult to estimate the enormous volumes of electricity generated in a day by the impact of the light waves upon the surface.

With these acknowledged facts and observed phenomena, in connection with the results of some experiments of my own, it became an easy matter to show that the surface of the earth is an immense electric helix, or a section of sections of helices or electric belts, whose right angles are the poles.

Taking as a basis the two facts that earth belts of electricity exist, and that their direction is east and west, we are at once brought face to face with the phenomena of deflection of a magnetized needle by the electric current, discovered by Œrsted in 1819, namely, that if a magnetized needle be placed parallel to a wire conductor, the moment an electric current is sent through the wire the needle assumes a position at right angles to the wire, or nearly so, thus:



In Fig. 1 is seen the suspended magnetized needle with its poles parallel to the wire. In Fig. 2 is seen the result when a current of electricity is sent through the wire. And here we have in miniature the cause of the direction of the currents flowing east and west; and, as in this experiment, the compass needle is beyond doubt caused to point north and south by the earth currents, which, flowing east and west, must inevitably cause the needle to assume a right angular direction, which, as we know, is north and south.

But we have not yet made sufficient progress. We have, it is true, satisfactorily accounted for the direction of the needle, but we have not accounted for the dipping of the needle, which, at the poles, is equivalent to its assuming a vertical position. Let us examine further.

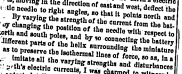
As the electric belts, surrounding the earth, and moving east and west (at least as rapidly as the diurnal revolution of the earth), must form belts or circles of less and less diameter, as we approach the poles, so at the poles we must have the effects of the ends of a helix, or coil of wire; and what are these effects from a helix in which the electric current is flowing? Perhaps I cannot better answer and illustrate than by a diagram of a helix with a compass needle suspended in various positions with respect to the longitudes of the helix.

In Fig. 3 it will be observed that, at the longitudinal center of the helix, corresponding to the earth's equator, the needle, being equally affected by both terminals of the helix, preserves a horizontal position; but that, as we approach the terminals, the needle dips and finally inclines to enter the helix. In this simple form we have all the phenomena of the direction and dip of the compass needle, as the electric current, flowing in the coils of the helix at right angles to the needle, corresponding exactly with the electric belts encircling the earth, and which flow at right angles to the poles, and produces precisely the same results.

The effects of the currents flowing in a helix, it is thus seen, are in every way the same as the effects of the electric currents encircling the earth east and west. The theory that rests in the earth of a great magnet or a series of magnets, is not only utterly improbable, in view of the phenomena observed, as it renders the phenomena impossible; but it is utterly and wholly superfluous. Since we have in the electric earth belts ample force, and a force which we know to be one of the greatest of practical students of natural philosophy, will say: "The actual phenomena of terrestrial magnetism are not in very close agreement with the results which would follow from the presence of such a magnet as the earth's interior, nor do they agree well with the hypothesis of two interior magnets inclined at an angle to each other, which has also been proposed. It would rather appear that the earth's magnetism is distributed in a manner not reducible to any simple exposition." Thus the problem is abandoned in the glamour of an hypothesis, for terrestrial magnetism; yet the same author gives a diagram of the lines of equal intensity in the phenomena of the dipping needle, and these lines are from east to west, precisely as the direction of the electric earth belts, and are closely allied to the thermal lines. The thermal electric belts encircling the earth, it became apparent to me must correspond to the isothermal lines, and this has been shown to be the case.

Although satisfied with the results of my experiments, I determined to pursue the subject more thoroughly, for the purpose of demonstrating the correctness of my deductions. I accordingly took a globe, of the ordinary size, eighteen inches in diameter, and covered it with a single layer of copper wire, in a spiral running east and west with respect to the imaginary poles. When completed, it was as shown in Figs. 4 and 5.

I placed a suspended compass needle near the surface of the globe, so that, when no current was traversing the helix, the needle stood in the position shown at A. The instant a battery was applied, however, so as to give the helix precisely the direction of the earth's belts or currents, the needle assumed the position shown at B, pointing to the north and south poles of our miniature world. Thus in our miniature world, as in the miniature world, the earth's electric current, moving in the direction of east and west, deflect the needle to right angles, so that it points north and south; by varying the strength of the current from the battery, or changing the position of the needle with respect to the north and south poles, and by so connecting the battery with different parts of the helix surrounding the miniature globe, as to produce the isothermal lines of heat, so as to imitate all the varying strengths and differences of the electric currents, I was charmed to witness in the most minute details all the inclinations, declinations, and dips of the needle that we witness on the earth, due to the irregularities of the electric belts in various localities.



The numerous electric disturbances. Perhaps I cannot more clearly than by a quotation, not only the fact that these disturbances of the needle are due to the electric belts, but that these electric belts are continuous, and are of long periods of time, there are minute fluctuations perceptible. To a certain extent, these are dependent on the varying position of the sun; but over and above all regular periodic changes, there is a large amount of irregular fluctuations which are invariably connected with exhibitions of aurora borealis. They are nearly the same at stations many miles apart, and they affect the direction and amount of horizontal much more than of a force" in the magnetic needle.

As we approach the poles of our miniature globe with the helix, it gradually loses its horizontal direction, dipping more and more, just as we observe when we approach the poles of the earth, until we reach one of the poles, when it becomes vertical and tends to plunge into, and to one side of, the helix, as indicated in Fig. 6.

The problem is clear enough when we recall to mind that, as we travel northward upon the earth from the equatorial electric belt, the north pole of the needle inclines downward at the rate of about 1° for 1° of latitude, until we reach the north magnetic pole, latitude 70° 5′ N., longitude 96° 46′ W., at which point the needle points directly down to the earth.

Of the many interesting details of the phenomena observed in my experiments, it is impossible to treat in the space of a single article. At some future time I hope to present the facts more in detail.

What we have learned and what we now know, so far as human knowledge based upon practical experiments can extend, may be summed up as follows:

That the earth is not a great magnet, but that the phenomena of the magnetic needle are due to the electric earth currents, which flow at right angles to the needle;

These are, in brief, the bases of the argument:

1. No placing of magnets in the earth can account for the variations of the magnetic needle.

2. Even if, by a cumbersome and overdrawn hypothesis, magnets could be placed in the earth to produce the effects observed at different places, the variations would still be unaccounted for, for the reason that such magnets would be permanent and without fluctuation.

3. The magnetic theory is utterly superfluous, for the reason that the electric belts surrounding the earth, which we know exist, could not exist without causing the magnetic needle to point north and south.

4. These electric belts, being thermic and frictional, must vary in localities, and accordingly in the situation of the sun with respect to the earth. This we know to be the case, for we not only find the thermic belts of equal intensity, as exhibited in the direction of the needle, closely allied to the isothermal lines, but we find that the needle's perturbations are dependent upon the situation of the sun and auroral displays.

5. The electric belts, not only theoretically, but by actual practical experiment, as we have seen, satisfactorily account for all the observed phenomena.

W. B. HAWKINS.

Washington, D. C.

[1877. MAUSER'S COMPANY, *D. Baker, Boston, Ct.*—dated 28th April, 1875.

The invention relates, first, to the breech in which the cartridge is placed, and which is provided with a receiver employed in connection with a movable breech-block, and with a hammer and a lever which operates the latter, and which is pivoted to the receiver. Secondly, to the peculiar construction of the breech-block, which is provided with a central recess, in which the hammer-lever is pivoted, and with a lateral recess, in which the hammer moves. Thirdly, to the peculiar construction of the hammer and lever, which are provided with a projection and a recess, by which they are locked together. Fourthly, to the peculiar construction of the hammer-lever, which is provided with a projection, which is engaged by the sear, and with a recess, which receives the projection of the hammer. Fifthly, to the peculiar construction of the sear, which is provided with a projection, which engages with the hammer-lever, and with a projection, which engages with the sear-notch. Sixthly, to the peculiar construction of the sear-notch, which is formed through the upper side of the lever, and which is provided with a projection, which engages with the projection of the sear. Seventhly, to the peculiar construction of the lever, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Eighthly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Ninthly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Tenthly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Eleventhly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Twelfthly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Thirteenthly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Fourteenthly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Fifteenthly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Sixteenthly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Seventeenthly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Eighteenthly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Nineteenthly, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch. Twentieth, to the peculiar construction of the sear-spring, which is provided with a projection, which engages with the projection of the sear, and with a projection, which engages with the sear-notch.]

The Chinese authorities are only now about to commence mining operations in the very locality referred to in an ancient Chinese history, some 2000 years old, as being the spot where the loadstone was first discovered in China.

19

THE ATMOSPHERE AND MARINERS' COMPASS.

[VOL. 5.—A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY" (letter 910, p. 46) has misunderstood me on the above subject. I will, therefore, try once more to make it clear. If, how takes two bolts and a nut to make a screw. If, as best we can from all other bolts, there is a centre of gravity and centre of inertia, there will be in each bolt a centre of gravity or inertia. The centre of gravity would be exactly, irrespective of the axis round which, each bolt may be turned. But if the matter is introduced into the question of centres of gravity and corresponding centres of inertia, how, if we connect the two globes with a thin wire, the subscriptions respecting the centre of gravity and centre of inertia in each is very little impaired, although we have introduced into the air and make them serve round a common axis, we have the new centre of the matter with which we have connected, this centre of gravity and centre of inertia differ very much in their axis. The same results would be arrived at by bringing the globes near together. However, practically it would be impossible to construct one

THE LOAN COLLECTION OF SCIENTIFIC APPARATUS, SOUTH KENSINGTON, LONDON.

NATURAL MAGNETS.

On the natural magnets we may notice a large one—the largest at present known—from the Taylor Museum, Haarlem; the weight of this magnet with its armature is 2 cwt., and it is capable of supporting a load of over 2 cwt.; also a Siberian loadstone used by Faraday, and from which he first obtained the induction spark. Large permanent steel batteries are contributed by Dr. Guthrie and the Taylor Museum.

MAGNETIC NEEDLES.

There is a number of modern and historical objects—one from the Naval Museum at Greenwich, with 8-inch needle; meeting on friction wheels, said to have been used by Captain Cooke in his voyages round the world; others similar, but with the needles resting on agate plane; a mariner's compass of Sir James Ross, that at present in use at the Kew Observatory, and another constructed by Dent. Models of needles of various lengths may be employed. Of the ordinary compasses we need say little; here are seen the various forms now in use in H.M.'s ships, standard compasses with four needles, steering compasses with two needles, liquid compass—the compass-box being filled with a mixture of water and alcohol—and compasses for boats, sledges, etc. There is another form of compass-card, however, which should be noticed—namely, that mounted by Sir William Thomson, of which four examples are exhibited. In this instrument the cards have on two sections, each about 2 inches long, placed parallel to each other and on either side of the centre. The whole of the weight, light, is supported by a sapphire cup on a very fine needle being mounted in the middle, and weights with magnets on only 44 grains, that is, only $\frac{1}{10}$ the weight of the Admiralty compass of the same dimensions and period of oscillation. In these compasses there are as many as eight needles fixed symmetrically with regard to the centre. The object of this form of card is to obviate the errors in a certain definition of the error usually introduced by the masses of soft iron which are employed for correcting the deviation of the compass, for with this subject we may notice a model lent by the thermal Diplographical Department illustrating the method of correcting the deviation of the compass in iron ships.

(*To be continued.*)

ILE'S DIFFERENTIAL COMPASS. 76

At the meeting of the Institute, in December last, a model of the working parts of this instrument was exhibited and explained. This compass is intended to obviate any necessity for alteration of the magnetic condition of the iron, either as used in the construction of the vessel or in the cargo, and to enable a mariner to ascertain true bearing by making due compensation.

Its principal difference from the ordinary ship's compass consists in its having two needles suspended in the usual manner, and placed one above the other at such distances as to remain under uniform mutual influences. These needles are counterpoised so as to rest upon agate planes in magnetic—preferably aluminium brass rumbers. The upper one are fastened a brass rumber, the lower one are fastened, about 2 in. long, placed parallel with the body of the needle and the line upon all is one direction. As usual, a magnet lends north and south, and the whole needle will settle in that direction.

The lower needle is composed of soft iron, and magnets of the same materials and dimensions, but with the magnets are fastened to the strip crosswise with the line parallel to the needle, and as all these magnets are placed similarly in one direction, will point east and west. The needles are so placed with respect to order to determine the magnetic force evenly through their length and thus cause them to be equally influenced in position and compensation.

It is evident that if there be no local attraction, the two needles will be parallel to each other in all right angles to the line; but if local attraction does exist, it will be detected by the intervention of the lower needle, toward it at an acute angle; the amount of deflection of each needle depending on the position and strength of the local attraction.

Compensation for true bearing is effected by using the compass point of a fixed object, magnet in either acute angle when placed on any line, and as the compensator can restore 90° when in the opposite, reliable result with the direction of the disturbing cause, the "error" is determined by using the bar magnet in combination with a steel table to be constructed at the factory and to accompany each compass. The position of the bar magnet for obtaining true compensation into been in the ship's bearing, when it will need to be determined there.

MAGNETIC INSTRUMENTS.

In magnetism pure, the Taylor Institution at Haarlem contributes one of the largest natural magnets in the world; and M. Jamin has sent over one of his, by which he demonstrates the greater holding power obtained when the magnet is built up of fine lamina. In terrestrial magnetism are historical dip circles and elliptical recording instruments, as well as many useful for magnetic surveys. Dr. Vogel, of the Sun Observa-

To. 33. AUGUST 12, 1876.

tory, of Berlin, has allowed his complete magnetic equipment, made by Adie, to remain in this country during the Exhibition, and it is now being erected near the Inglefinnan. The subtle laboratory results of Ampère on the attractive and repulsive influence of voltaic currents upon themselves when passing through metallic conductors in the same or in opposite directions; the delicate elaboration by themself in 1820 of the directive influence upon a suspended magnetic needle of voltaic currents passed in a direction parallel to its axis; the development of this by Gauss and Weber in 1833; the work of Sesemanning in 1820, who first used currents from the Voltaic pile for telegraphic purposes; of Steinheil, who discovered, in 1838, the practicability of using the earth as the return circuit; of Seebeck, of Berlin, in 1821, on thermo-electric currents; and the labors and discoveries of Oersted and Wheatstone as regards magneto-electricity, and the laws that regularise the transmission of electric currents through metallic conductors, with their practical application to the transmission of intelligence to distant parts, will be fully shown. The chief interest of collection is this department, as in others, culminates in the original apparatus.

Among the most interesting of the original apparatus of Faraday, which he employed in his electromagnetic researches in the magnetic and diamagnetic condition of gases, and in his researches upon the polarity of diamagnetic force, are of great interest. The series of voltaic current generators comprise, among others, the original elements which were employed by Daniell, Wollaston, Sturgeon, and Grove in their researches. Some of the earlier forms of the magneto-electric machines by Wheatstone are contributed from the physical apparatus collection belonging to King's College, London. From the same collection is the original apparatus by which Wheatstone determined the velocity and duration of the electric spark by means of a rapidly revolving mirror, and the elongation of the electric spark disentangled through a wire half a mile in length, giving an estimated velocity of 288,000 miles in a second. A wonderful series, illustrating the evolution of the electrometer, contributed by Sir William Thomson, must not be passed over.

MAGNETIZATION OF TUBES OF STEEL. 78

By J. M. GAUGAIN.

THE variations of magnetism produced under the influence of heat in a solid bar of steel do not differ from those produced under the same influence in a system composed of a tube and a nucleus. Both appear to depend on the inverse magnetism developed by the mutual reaction of the concentric layers, whether of the bar or of the system.

MAGNETIC CAPACITY. 77

By M. THEVE and DUBOSCQ.

LET a horse-shoe magnet, of any length, be covered on one face with a varnish, or, better, a film of glass. If on the neutral part we place a cylinder of soft iron, we shall see this move towards the poles, which it will reach in a time which is, naturally, a function of the weight of the cylinder, and of the coercitive force of the magnet. The magnetic attraction, then, is here exerted not merely in the limited field which has been assigned to it, but over the whole extent of the magnet.

Thus we have a new way of estimating the magnetic force by the *mechanical* work it does. The product of the weight of the movable body by the space passed through, divided by the time, will be the exact measure of this magnetic force. If we determine this force, e. g., for three large and three small magnets, similar in form and weight, and containing respectively 9·200, 9·200, and 1 per cent. of carbon, we can see how it may perhaps be possible to determine the unit of magnetic force, the "*magnetic*," and to fix its equivalence in kilogrammetres.

We have made great efforts to determine the magnetic conductivity of steels in relation to their proportion of carbon; but the want of a rigorous mode of estimation of magnetic forces has always stopped us. The phenomenon described will fill the gap, and helps us to reach the desired end. We will, however, indicate here the plan we have followed.

If we take 1·2 g. a steel bar, with 1 per cent. of carbon, of our first Crusot series, its coercitive force is found approximately 47 with the compass. We now enclose it in coils, like an ordinary electro-magnet, giving the coils the proportions of Jamin's coils, which, we established by M. du Moncel for obtaining maximum magnetic force; and pass a very strong current. The magnet becomes given 47, has 84". If 47 coils were absolute numbers, we might say that the magnet A. has 47 of permanent magnetism, but can take 84 in the temporary. The 84 would represent the magnetic capacity of the magnet with 1 per cent. But, the maximum capacity of magnetism, that is, the difference between 84 and 47 would give the magnetic conductivity.

Take now B., the sixteen steel of the series, with 0·200 per cent. of carbon. Its coercitive force is 38. If we allow to it the same coils as to A., which are identical in form and weight, we get 69 for the magnetic capacity. The difference between 69 and 38 will be the magnetic conductivity of steel with 0·200 per cent. of carbon.

We proceed in the same way with D., C., and D., and have obtained the following table:—

	Magnetic force.	Magnetic capacity.
A.	47	84
B.	38	69
C.	42·5	67
D.	32·5	62
E.	19	69

The magnetic capacity of a soft piece of iron, the same in form and weight, was 77.

The importance of finding a mode of rigorous measurement of the magnetic force.—*Comptes Rendus.*

The Earth's Magnetic Force.—Captain F. J. Evans, Hydrographer to the Admiralty, read a paper before the Geographical Society, on the 13th inst., on the determination of the Earth's Magnetic Force at the Sea Surface. He said that the value of the magnetic force of the terrestrial magnet governs all the mariner's compass, and noted the discoveries which they had conveyed to the minds of theorists of the magnetic forces in different parts of the earth. The first discovery was that the magnetic force was not constant with the variation of the latitude and longitude, as was assumed in which was absolutely necessary for safe navigation, in no region of the globe—like smaller—this variation was worthy, and in the other—the Atlantic and Pacific Oceans—the variation proceeded to be almost uniformly, and, in fact, quite, particularly in the Pacific Ocean. As a matter of fact, the magnetic condition of the globe was already varying, but in what manner and to what real was wanting. Accurate and many observations were accordingly undertaken. It was taken to be the magnetic discoveries made during the voyage of the Challenger. Further researches the various facts and hypotheses concerning magnetic phenomena, and how these were to be explained. The question was how was to be interpreted them? Whichever way we look at the matter, the facts were undoubtedly of the secular change, we find marvellous complexity and mystery; lines of time and lines are of known, being curves in form likewise as further and further back in the solution. The formula of Hadley, the Astronomer Royal, and Gauss, the more recent hypothesis of the silent men, of the day, all fail to solve the mystery."

FLOW OF ELECTRICITY. 22

Mr. Lodge briefly described a model which he has designed to illustrate flow of electricity, &c., which is fully explained in a paper in the *Philosophical Magazine* for November, and he showed how similar considerations can be applied in the case of thermo-electric currents. The model in its simplest form consists of an endless cord passing over four pulleys, and on one side of the square thus formed it passes through a series of buttons held in their positions by rigid rods or elastic strings, according as they represent bodies of a conducting or non-conducting substance. When considered in connection with thermo-electricity, the buttons are assumed to oscillate on the cord, and if they move in one direction with greater velocity than in the other, the cord will tend to move in the former direction. Now, at a junction of copper and iron, since the metals have different atomic weights, and their kinetic energies are equal, the velocities of the atoms on each side of the junction, and an unsymmetrical oscillation of the molecules must ensue, analogous to that assumed by Sir Benjamin Brodie in Crookes' radiometer, and the cord, or electric current, will advance when two junctions are made. The most convenient way to have observed experimentally the true given difference of temperature the maximum thermo-electric current is obtained when one of the junctions is at 280° C., and beyond this point the current diminishes. The addition of a third bar W. Thomson has shown that the conductivity of iron by electricity; that is, if we have a circuit composed of copper and iron, and one of the junctions be at a high temperature, the current in passing from hot to cold in the iron, or from cold to hot in the copper, absorbs heat. This fact was experimentally illustrated by Mr. Lodge. A strip of tin plate is symmetrically bent, so as to nearly touch the two faces of a thermopile, and is heated at the bend by steam passing through a brass tube on one side from end of the thermopile, and kept cold by a current of water on the other side. As the arrangement is symmetrical, no current is found to pass through the thermopile, but when a powerful voltaic current passes through the strip of tin plate the deflection of the needle is observed in accordance with the above law.

The Steam-Magnet.—M. Benoît Thevenot states that when a current of steam is sent under pressure through a coil of insulated copper wire, through which a small iron cylinder, the latter becomes strongly magnetic. This is a very convenient arrangement for producing powerful electro-magnets, and the writer has applied during the winter to warm the steam current passes through the tube.

Manufacture of Cast-iron Magnets.—M. Jordan publishes some details of a process he has just patented for manufacturing magnets of cast iron. He melts soft metal, very slightly carburetted in crucibles, and runs it into moulds; adding from 10 to 15 per cent. of steel filings, according to the degree of carbonation, to improve the quality of the cast iron. He obtains the best by adding to the iron, when melted in the crucible, from 1 to 1·75 per cent. of nickel and 9 to 10 thousandths of copper, or a per cent. of tin and 50 thousandths of copper. The addition of the copper and tin to the iron facilitates tempering of the compositions (*sic* interpreted) heat. The cast-iron magnets are then annealed, especially of the tin, care be reduced without detriment to the quality of the result by tempering at a higher temperature as their properties is decreased. The best result of all is obtained by tempering just cast iron, at as high a temperature as can possibly be attained, short of reaching a degree of heat which would melt it, above the moulded pieces, or escape from the liability of fracture. *Telegraph Journal.*

or terrestrial objects without being impeded by the quadrantal correctors.

6. Improvements in the method of correcting the compass by observation of the sun, moon, or stars, on a detached azimuth circle.

SIR W. THOMSON'S MARINERS' COMPASS.

IT is well known that ships' compasses are not altogether so satisfactory as mariners and others could wish, and only too frequently fatal defects have existed, more or less directly, the loss of the finest and best-found vessels—a small error, easily made, in the process of adjusting a compass, upsets the most carefully-made observations and calculations; hence Sir W. Thomson has endeavoured to devise, and we believe an improved compass and improved means for ascertaining and correcting its errors. His object has been to obtain—

1. With smaller needles than in compasses hitherto in practical use as long a period of free oscillation as is absolutely working well at sea.

2. Smallness of frictional error.

3. Improved gimbals for supporting the compass bowl to give sufficient steadiness, and to bowl a greater freedom to take up as nearly as possible the true level.

4. Practical methods for applying corrections for the quadrantal semicircular and heeling errors.

5. An improved appliance to the compass for taking magnetic azimuths of sun or stars

FIG. 1

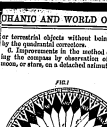


FIG. 2

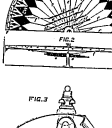

FIG. 3

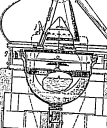

FIG. 4

Sir W. Thomson showed that longnesses of period of free oscillation is favourable for steadiness. It follows from these considerations that it is possible to obtain as large a moment of inertia as possible, with as light a compass bowl, magnets, and frame, as may be.

The improved compass consists of a light aluminium cup with a central cap of agate, or other substance sufficiently hard material for the compass to rest on, and a rim of aluminium from about 4in. to 12in. or more in diameter, according to the size of the compass. The compass card is by preference constructed with an even number of leaves in the rim (16 being preferred for the largest size of compass card), and the central boss has the same number of radii as the circumference. The rim and boss are connected together, as may be, by 32 fine silk threads, c, which form, as it were, 32 spokes. Those silk threads cross, or are knotted, so as to retain them in the holes both of the boss and the rim, after which they are cemented thereto by shellac or other adhesive substance. The compass card is partly supported by these threads, c, directly, and partly by the rim, f, as shown at Figures 1 and 2. Two or more small magnets, d, of which eight are employed in the compass shown at Figures 1 and 2, having their corresponding ends tied together by silk threads, c, of equal lengths, so that the magnets may be as nearly parallel as possible, are attached to the rim by means of fine silk threads, f, as shown.

The following method is said for giving an equal tension to each of the threads between the boss and the rim:—When connecting the boss and rim together, and so as to get the boss to a truly central position, the boss is fixed immediately over the centre of the fine wire ring, the diameter referred to. Each of the 32 threads is then passed outwards through a hole in the rim, where one end is retained by a knot on the inside of the rim, then upwards and over the wire ring, and to its corresponding hole in the boss. Each thread is then threaded through the hole, and then back and finally outwards over the fixed ring above-mentioned, and downwards with a weight attached to it to stretch it with proper force. The rim is then worked about until its boss is truly central, and concentric with the graduated ring. The threads are then passed up to the boss, after which they are drawn through the holes in the boss a sufficient distance, and again connected and the holes sealed up, and again the compass is then obtained while quite steady, extremely light, and yet having large moles of gyration, has very small frictional error with small enough oscillation period to give a very long period of free vibration. For instance, in one of the compasses of this kind, 3in. in diameter, having eight needles of 8mm. 5in. to 6in. long, weighs in all 178 grains, and in this compass has a period of free vibration of 18 seconds, and extremely small frictional error as also has error of the true position of less than one quarter degree.

The third improvement is to swing the gimbals in knife-edges instead of on pivots or journals, as is now generally done, and to adjust the position by the use of a very obvious oil or other liquid contained in the bowl, A, of the compass, fig. 3. The object of this improvement is to give greater freedom to the compass to assume a horizontal position, and to minimise sensibly the use at sea the vibrations of the case due to the motion of the ship are also lessened by the action between the cylindrical journals on which the gimbals are swung and the knife-edges or bearings which they are supported. In consequence of this friction the compass comes rest of itself with a very low level position. With the use of knife edges the compass can also settle truly level position, by the energy-destroying power of the rubbing action at the knife edges on the plane or bearing surfaces fig. W. Thomson employs the level, connected according to the plan, this bottom forming the roof of the bowl, which is then filled with liquid; thus, when there is any motion of the bowl energy is consumed by the frictional or viscous action of the liquid.

The correctors for the quadrantal error are founded on the principle first given by the Astronomer Royal. They consist of iron balls placed in brass fixed in pillars of the binnacle. The semicircular error is corrected by steel magnets according to the general principle also

Steadiness of the compass at sea in stormy weather has hitherto been obtained by making the compass card and needles large and heavy, and sometimes also by adding weights to the compass card. The addition of weights is detrimental, by increasing the frictional error, the needles thereby to make the compass follow the motion of the ship when she moves in azimuth. In a mathematical paper communicated to the British Association in 1874,

first given by the Astronomer Royal. The varying adjustment of the correction required for variation in the ship's sub-permanent magnetism and magnetism induced by the vertical component of the earth's magnetic force is effected in the following manner:—At P, Q, fig. 3, are two similar correctors, one for the fore-and-aft focus and the other for the thwart-ship focus.

Each corrector consists of two bar magnets, O, O, in a vertical vertical, a common horizontal axis, which passes through one of their ends. One of these, the magnet O, is a compound magnet, consisting of two bars rigidly connected parallel to each other, with their poles similarly formed, and with a space between them through which the other magnet, H, passes. The magnet, H, is of a strength equal to the sum of the strength of the two bars of the compound magnet, O, a small piece which is easily fulfilled with sufficient accuracy by making it also a compound magnet of the two said close beside one another with similar poles. The magnets, O, of the two outer bars, G, constitute control magnet. H, has such a spur-wheel at its end, diameter rigidly attached to its inner end. These spur-wheels both revolve round the common horizontal axis, one of them being placed loosely thereon, and they are connected together by means of other spur-wheels in such a manner that when set in motion they turn in opposite directions. The poles of the outer or split magnet, O, and that of the central one, H, at the common axis, are of contrary names, and so, of course, also are the poles remote from the axis. The latter will be called the "serviceable poles," or simply "the poles" for brevity. A circular dial, N, fig. 3, with degrees marked on the outer edge, is arranged concentrically with the common axis of the magnets to indicate the angle of deflection of the magnets from the vertical, and there is a clasp, G, attached to one of the outer bars, G, so that when they have been deflected to any required degree they may be firmly fixed in that position. The spur-wheels attached to the magnets are so connected together that when the two outer bars, G, are vertical the ship being supposed to be upright) the central magnet, H, is also vertical and between the two bars of the compound magnet, O, and when the compound magnet is deflected through any angle on either side of the vertical the central one is deflected through twice that angle, but on the opposite side of the vertical, as shown by the dotted lines at Fig. 3. The correctors are so placed that the vertical line connecting them at a distance is zero, because the split magnet, O, is then at right angles to the central one, and the poles of opposite names are contiguous to each other. The horizontal axis round which the magnets turn for the fore-and-aft corrector, R, is thwartship, and for the thwart-ship corrector, P, S, is fore-and-aft. The correctors, as shown at S and P, are placed one over the other, and both under the compass, as that in their zero position the middle line of each corrector is vertically under the centre of the compass (the ship being supposed to be upright).

If the ship's magnetic force is to starboard the magnets, O, O, of the thwart-ship corrector, P, are turned from the vertical position in such a direction as to bring their serviceable north and south poles to the port and starboard sides respectively; or if the ship's force is to port the correctors are turned in the opposite directions. Similarly if the fore-and-aft component is bowed the magnets of the fore-and-aft corrector, S, are turned so as to bring their north and south poles aft and forward respectively. The spur-wheels may be dispensed with and the magnet of the pair constituting either corrector may be moved by the other pair of the said clamped there simply by hand. Or a single corrector, connected according to the above description, and having sides an eccentric adjustment, and having its two magnets of unequal length, may be used, and is preferable on the ground of simplicity, but is not quite so easily used when the correction is to be readjusted frequently.

When there is a greater amount of error to be corrected than can be conveniently done by the continuously adjustable correctors, auxiliary correcting permanent magnets are used as shown at T, Fig. 3. These magnets are made by preference of steel wire, or round rod steel, hardened, and soldered in brass tubes to project that these from east and from adjacent or from close contiguity with other magnets, and might alter the strength of their magnetism. These magnets are made in pairs of equal strength, and with ends so adapted that when out of use they are to be placed in a box so fitted that they cannot be set into it except with dissimilar poles together. This may be easily effected by making one end of each to the magnet round and the other end square.

For correcting the heeling error, the binnacle contains an upright with a V-groove forming a proper groundwood clamp Q, fig. 4, for holding firmly at the proper height a magnet, R, in a vertical position centrally below the lower of the two pairs of adjustable semicircular correctors.

The fifth improvement consists of a convex half lens placed over the compass between the outer circumference and the centre, with its axis directed to the graduated circumference of the compass card, and its centre at a distance from the division slightly exceeding the radius of the divided circle. This half lens is shown at L, Fig. 3. Another is the lens, i, there is a plane mirror, j, for observing the image of the sun, whose azimuth is required, mounted upon a horizontal axis coinciding with the diameter of the lens, i, and mirror, j, are placed on a frame mounted on a projecting arm, k, for the observer, when looking on the mirror, this frame round its vertical axis, until the mirror, j, and lens, i, are fairly opposite to the object. He then places his eye above the compass and a little between the centre and the graduated ring until the image of the object reflected from the mirror's axis upon a division on the compass card seen through the lens. The point on the compass card where the object is seen will be the bearing of the object. This appliance is called the azimuth mirror. It is provided with a spirit level to show whether the case and level are properly balanced.

The sixth improvement relates to a detached azimuth circle, to be used for finding the azimuth directly by observations of the sun, moon, or other bright enough planet or star, for the purpose of ascertaining from time to time the error of the compass, varying from this with the alterations in the ship's magnetism. It consists of a horizontal detached circle circle supported on gimbals having an inner circle also mounted in a horizontal plane at right angles to the axis of movement of the outer circle. The gimbals of both the inner and outer circle are, as in the case of those of the compass, supported on knife edges. The rim of the inner circle is graduated to degrees, and may also be marked with points of the compass, and this circle carries on a horizontal axis pivoted on it a portion of a hollow spherical surface. This surface is marked with a great circle corresponding to the equator, and with circles corresponding to degrees of declination, as far as 20 degrees on each side of the equator. These declination circles are divided into spaces corresponding to four minutes of arc of time at the rate of a degree to a quarter to five minutes, which divisions are numbered in hours and minutes, the points to which the declination circles are cut by a plane perpendicular to the above mentioned horizontal axis being reckoned as noon. A lens placed with the centre at the centre of the spherical surface is pivoted on a frame so that its axis may be directed to select between the extreme declination circles of the spherical surface. To use the instrument, turn the spherical surface round on its pivots until its equatorial circle is inclined to the vertical at an angle equal to the latitude of the place, then turn the whole round horizontally until the image of the sun or other heavenly body is seen in the lens, and on a point on the equatorial circle. This point corresponds to the apparent solar time, as to the meridian of the body observed, and to the declination of the body at the time. The lens is to be turned about on its vertical until the image is well defined. The effects of refraction and parallax are sufficiently corrected for all practical purposes by bringing, as nearly as may be judged by eye, the centre of the images into the same azimuth with the proper time point of the

proper declination circle. When the instrument is correct and well levelled, the image of the centre of the sun will be seen always below the proper point by the amount of refraction; the centre of the moon's image will be seen above the proper point by the excess of her parallax above refraction.

To avoid expense in the construction, and confusion in the use of the instrument, Sir W. Thomson has divided a geometrical slide which, with other details, avoids the necessity for so many circles and divisions. In the illustrations Fig. 1 shows one-half of the face of the declination card, the segments of which are connected by gunmetal strips underneath the inner circle, which by tongues folded down and attached to the slide on the outer ends. Fig. 2 is a transverse section through the card and centring disc, and needles. Fig. 3 is a sectional elevation of the compass and its box, as placed on board a vessel.

[9603.]—Variation of Compass.—The following are the observations of the magnetic elements (of variation and inclination) at Kew Observatory for eleven years, ending with 1875. As W. F. Ivory surmises, the present variation, or declination as it is more properly called, is about 19° W.

Year.	Declination or Variation West.	Inclination or Dip.	Horizontal tion.	intensity.
1865	20 55	66 7		2820
1866	20 49	66 51		2811
1867	20 45	66 38		2844
1868	20 35	66 7		2846
1869	20 25	66 1		2852
1870	20 18	67 05		2837
1871	20 11	67 04		2850
1872	20 0	67 04		2860
1873	19 57	67 31		2827
1874	19 52	67 10		2861
1875	19 46	67 48		2805

—Artificial Perpetual Motion.

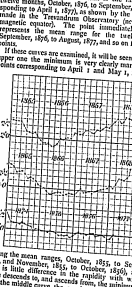
(see reference to "Hare's" question, respecting the variation of the compass, bk. [9607], p. 615, let me first note that the deviation in the direction of any magnetic needle to which its suspension is exactly counterpoised with that element which has been assumed as the constant period.

That "Hare's" question necessarily implies that he suppose there is a constant variation between these two phenomena, but that it is not quite clear in me whether he supposes so or not. Quite clear in me that the variation of the magnetic meridian is a constant, and, therefore, apparently for its period some 300 years. In 1580 the needle at the north at Greenwich pointed due north, and in 1657 the needle at Paris so pointed, having previously, and subsequently, like the north. Hence 1657 both needles have returned to the first authority or nearly so, year by year; and finally the two needles have ten real true. In this the stations westerly deviation had been attained as Paris, but the Greenwich needle had been attained deflected westwards until March, 1818, when it reached the extreme limit of its western deviation. Both needles have since been travelling eastwards, that is, returning towards true north. The greatest westerly deviation attained at Paris was 22° 30′, to about 22°, whereas at Paris it is 19 (historical) westerly deviation attained at London the greatest westerly deviation attained at Greenwich 24° 41′ 30″ (Airy). Again, the inclination or dip of the needle was when it was first carefully observed, about 1576, 71° 50′ (Norman), and in 1720 (Graham), 74° 30′. In 1780 (Cavendish), 72° 30′. In 1827 (Hansteen), 70° 21′. In 1865 (Sabine), 70° 21′. In 1876 (Ivory), 67° 48′. Now, if the needle is the northern, the tongue of the needle's deflected by magnetic (the Earth), may be easily by suppose that the Earth, may be easily by suppose that the Earth, may be [illegible] at Greenwich of London in 1576, may be [illegible] at the North Pole, and has in the travelled round between the west of such a space 300 years. See do article of mine in the Standard of January, 1875. There is more information [illegible] with the work's magnificent [illegible] article of my "Light Sleeves for Leisure Hours."

ever, been studied. The accompanying diagram will show this for the last three minima.

If we suppose that the mean diurnal movement of the magnetic needle is determined for each month, we obtain the amount of the oscillation or range; the mean of the ranges thus found for twelve successive months is represented by a point in the curves; thus the last point in the lowest curve represents the mean of the ranges for the twelve months, October, 1876, to September, 1877 (corresponding to April 1, 1877, as shown by the observations made in the Trevandrum Observatory *specially* on the magnetic *equinox*). The point immediately preceding represents the mean range for the twelve months, September, 1876, to August, 1877, and so on for the other points.

If these curves are examined, it will be seen, that in the upper one the minimum is very clearly marked by two points corresponding to April 1 and May 1, 1876 (repre-



senting the mean ranges, October, 1875, to September, 1876, and November, 1875, to October, 1876), and that there is little difference in the rapidity with which the curve descends on, and ascends from, the minimum.

In the middle curve the epoch of minimum is by no means so distinctly marked; the minimum is, as by no eye, not the point for January 1, 1876, but the point for the ninth following that of a minute of arc) higher. In this curve the change of ranges in the diurnal oscillation is quite insignificant from November 1, 1874, to April 1, 1877, an interval of three years and five months. If this result is confirmed by other observations, as I believe will be the case, no such constant state of the earth's magnetic action will have been observed since the last years of the eighteenth century.

The observations of sun-spots, even if they give as accurate a measure of the intensity of the cause as that obtained from the movements of our magnets, cannot be observed with the same continuity, nor be measured with the same precision; but I have little doubt they will confirm generally the result shown in the last curve, as they have in preceding cases.

With regard to the aurora borealis, the appearances seem to have been very rare during the last two winters. In the report by Capt. Sir G. Nares, on the Arctic expedition, he says that in the winter of 1875-76, "Light flashes of aurora were occasionally seen on various bearings, but most frequently passing through the south; none were of sufficient brilliancy to call for notice. The phenomena may be said to have been insignificant in the extreme, and, as far as we could discover, were totally unconnected with any magnetic or electric disturbance" (NATURE, vol. xv. p. 58).

In the twelve months including September, 1875, and August, 1876, including the epoch of minimum disturbance and of several frequency, I observed in the south of Scotland on last, 55° 35') thirty appearances of the aurora, and from September, 1876, till the end of 1876 forty-nine appearances were observed at this single station.[1] Making every allowance for the continuous watch over the magnetic instruments at the Makerstoun Observatory during these years, the difference between Capt. Sir G. Nares' result, in so high latitude, in 1875-76, and that for the south of Scotland, is very distinct. I ought to add, with reference to the apparent want of connection of the faint auroral appearances with the magnetic disturbance noticed by Sir G. Nares, that several of the auroras observed by me were of the very faintest kind, mere "traces," as I have termed them, which I could never have remarked had I not been the sky with the greatest attention. Again, in no case have I seen the faintest trace of an aurora without finding at the same time a corresponding irregularity in the movement of the force or declination magnets.

I am unacquainted with any observations of the aurora made in the British Isles during the last two winters; I believe that no scientific institution exists in this country which makes the look-out for auroras throughout the night a definite portion of its work, and that all our knowledge of this phenomenon appears to be left to the chances of some one being out, at the hour of a display, sufficiently bright to attract his attention who will take the trouble to communicate his observation to a public journal.

JOHN ALLAN BROUN

P.S.—I have to thank Mr. A. Buchan for kindly furnishing me with a note of the auroras seen at the stations of the Scottish Meteorological Society during the year 1876. These amounted to forty-two in number, twenty-six in the first half and sixteen in the second half of the year. The greater part were seen in the most northerly stations, including the Orkney, Shetlands, and Faröe Islands; nine only having been seen south of the Forth. I cannot, however, compare the total result from the hundred stations of the Society with that from the single scientific station of Makerstoun in 1844, since much depends on the nature of the watch kept in each case. It is, however, gratifying to find so much attention given at the stations of that highly useful association, the Scottish Meteorological Society, to the observation of this phenomenon.

December 31, 1877

[1] "General Results of the Makerstoun Observations," by Isaac Pitman, Esq. See Edin. Trans., vol. xxvii. p. 1.

[2] I do not understand the expression of "equivalent light," which he uses as synonymous with the number of the aurora, which he considered a spectrum of some solar origin. Auroras, vol. xv. p. 226. The spectrum must have been common and brilliant in the dark days of September and October before dawn (about five o'clock), when I frequently saw the aurora in the south-east. In the two years, however, it is very rarely seen in the south or south-west at Makerstoun: every fifth night during which observations were made, on an average of many years, and only once in the month at 9 P.M. I would be glad to know of nearly three hours such as I remember during the latter part of 1844, and what with a bright or brilliant aurora in the south-east, and a fine display in the north, I was unable to sleep for excitement. I have, of course, seen many auroras since, both with other observers in Ireland and Scotland, and I had therefore formed a high standard. I would be most important, especially as made so frequently at the epoch of minima.

ON COMPASS ADJUSTMENT IN IRON SHIPS[1]

II.

AN important objection was made to me some years ago by Capt. Evans against the use of compass-card corrections in the Navy, that they would prevent the taking of bearings by the pelorus-and-sooth arrangement, which forms part of the *Admiralty* standard compass. The azimuth mirror (Fig. 5) applied to the compass before you was designed to obviate that objection. By its use even bar shifting bearings of objects on the horizon is not interfered with by the plate corrections, the quadrantal corrections, even if their highest points rise as high as five inches above the glass of the compass-bowl. It is founded on the principal of the camera lucida. The observer when taking a bearing turns the instrument round in vertical axis until the object and line see fairly opposite to the object. He then looks through the lens at the degree divisions of the compass-card, and turns the mirror round its horizontal axis till he brings the image of the object to fall on the card. He then reads directly on the card the compass bearing of the object. Besides fulfilling the purpose for which it was originally designed, to allow bearings to be taken without interference from the quadrantal corrections, the azimuth mirror has a great advantage in not requiring any adjustment of the sights to suit the altitude of the object, as in the pelorus-and-sooth the line is brought to exactly cover the object. The focal length of the lens in the azimuth mirror which I use is only 2·4 per cent. longer than the radius of the circle of the compass-card used, and thus, by an elementary optical principle, it follows that two objects a degree asunder on the horizon will, by their images seen in the azimuth mirror, cover a space of 1·024 of the divided circle of the compass-card however high the objects are above the horizon. The instrument round its vertical axis through one degree will only alter the apparent bearing of an object on the horizon by 1°. Thus it is not necessary to adjust it exactly to the direct position for the bearing of any particular object. If it be designedly put even as much as 4° away on either side of the direct position, the error on the bearing would hardly amount to half a degree. If the instrument were to be used solely for taking bearings of objects on the horizon, the focal length of the lens should be made exactly equal to the radius of the circle, and thus even the small error of 1·2° in the bearing for one degree of error in the setting would be avoided. But one of the most important uses of the azimuth instrument is to get a correct bearing by means of the azimuth instrument at sea is to correct the bearings of sun or stars at altitudes of 15° or 20° or 60° above the horizon. The actual focal length is chosen to suit an altitude of 25°, or thereabouts (this being the angle whose natural secant is 1·1), for those objects whose altitudes are

[1] Report of paper read to the Royal United Service Institution, February 15, 1878, by Archibald Smith, M.A., LL.D., Trin. Coll. Camb., Professor of Physics in the University of Glasgow, and Fellow of St. Peter's College, Cambridge. Revised by the Author. The Council of the R.U.S.I. have kindly permitted it to be published by W. Thomson's Copper Engraver, and have printed it on the use of the illustrations.—ED.] Continued from p. 322.

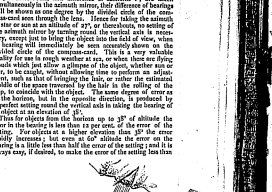


FIG. 5.

a degree by turning the instrument so that the red point, which you see below the lens, shall point within a degree of the position marked on the circle of the compass-card by the image of the object.

But taking star azimuths the azimuth mirror has the great advantage over the prism compass, with its lens invisible hair, that the image of the star is thrown directly on the illuminated scale of the compass-card. The degree of illumination may be made less or more, according to fairness or brilliance of the object, by holding a timesaie lamp in the hand at a greater or less distance, and letting its light shine on the portion of the compass-card circle seen through the lens. Indeed, with the azimuth mirror it is easier to take the bearing of a star somewhat bright star by night than of the sun by day: the sun is seen as a fine point on the illuminated compass-card, and it is easy to read off the position laterally by estimation to the tenth of a degree; whereas, as well as the most accurate of all, however, is the sun when bright enough and high enough above the horizon to give a good shadow on the compass-card. For this purpose is the small silk thread which you see, attached to the framework of the azimuth mirror in such a position that when the instrument is properly placed on the glass of the compass-bowl, the thread is perpendicular to the glass and through the central bearing-point of the compass.

Another advantage of the azimuth mirror particularly important for taking bearings at sea when there is much motion, is

level of the platinum wire. By aid of a totally reflecting prism, like that of the polarimetric scientific apparatus, with one side convex, the user of the instrument looking downwards sees where the black line on the cut of the prism is exactly level with the zero on the glass plate. This mode of sighting has proved very accurate, is very quick and quickly used, and it is so sensitive that with the finer motion and magnetic power of the instrument in it shows easily a variation of vertical force corresponding to 1 on the card's vertical force in this locality. The accompanying printed instructions for the adjustment of my compass circles is sufficient detail the way of using it for correcting the heeling error.

In the instrument before you there is a divided paper circle in the bottom of the box to serve as a "dumb card," to be used with the azimuth mirror when there may be occasion for the use of a non-magnetic azimuth instrument. This appliance has nothing to do with the dipping needle, and is introduced because, while adding little or nothing to the cumbersomness of the instrument, it saves the adjuster the necessity for carrying a separate azimuth instrument with him.

(To be continued.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—From the University Calendar for 1878 we learn that the Undergraduates, who were last year 3,500, have now risen to 3,650, while the members of Convocation have increased from 4,870 to 5,006. During the year 300 have taken the degree of Master of Arts, and 456 that of Bachelor of Arts. The number of matriculations, which in 1868 was 370, and which in 1876 was 650, rose in 1877 to 770. But this increase was due to the number of candidates for a musical degree. The list of members of Congregation—that is, of the legislative body of resident members of Convocation—has increased, but only slightly. In 1876 they numbered 314; in 1877, 322. But the proportion between clergymen and laymen has considerably changed during the year. In 1876 there were 160 clergymen and 154 laymen; in 1877 the laymen have risen to 154, and the clergymen have fallen to 168. Of the whole body of Fellows (exclusive of Christ Church, resident and non-resident, there are at present 192 laymen and 110 clergymen.

CAMBRIDGE.—The Council of the Senate having had under consideration a letter from Prof. Hughes, Woodwardian Professor of Geology, representing the need for additional assistance, propose that an assistant be appointed, with a stipend of 200*l.* per annum, whose duties shall be to assist the Professor in the arrangement and care of the geological collections, to give such instruction and demonstration as may be required, and to assist students generally out of the museum. It is proposed to vest the appointment in the Professor, with the consent of the Vice-Chancellor.

EDINBURGH.—A site has been secured in Chambers Street, close to the University, for the erection of a new school of medicine. The extra-academical teachers, on the spot formerly occupied by Surgeon's Square, so long the scene of the demonstrations and practice of eminent extra-mural lecturers.

TAUNTON COLLEGE SCHOOL.—A testimonial, edited by Smith and Beck, with other valuable appendices, has been presented to Mr. Rev. W. Tuckwell by his assistant-masters in the Taunton College School, as an expression of their personal sympathy and their recognition of the services rendered by him in the higher education.

TRIESTE.—January 20 was a red letter day for a number of professors in Prussian universities, no less than fifteen receiving orders of different ranks from the Emperor William.

DARMSTADT.—On May 1 the Royal Polytechnic Institution at Dresden will celebrate the fiftieth anniversary of its foundation. Originally confined to the narrowest limits, the Institution has rapidly developed, and is now one of the most frequented polytechnic schools of Germany.

GREIFSWALD.—The attendance on the university shows a decrease as compared with the past summer. The students number 43 in the theological faculty, 73 in the legal, 126 in the philosophical, and 228 in the medical. The corps of professors and privat-docents is at present 60. A library of 60,000 volumes, well equipped laboratories and collections, and ample reverium place Greifswald on a par with most German universities, but for a number of years it has failed singularly to compare in point of attendance with many poorer centres of study.

THORNTON.—The university shows at present the highest winter attendance since its foundation. The students are divided as follows: Theology (evangelical), 215, (catholic), 108; law, 256; natural sciences and medicine, 222; philosophy, 145.

MÜNSTER.—Prof. R. Sturm, of the Darmstadt Polytechnic, has been appointed to the chair of mathematics, rendered vacant by the late death of Prof. Heis. The number of students at present is 312.

BERLIN.—Prof. Schweckener, of Tübingen, has received a call to Berlin to fill the second professorship for History lately created at the University.

VIENNA.—In the lately presented educational budget of Austria the sum of 50,000*l.* is appropriated for the erection of new buildings for the Vienna University.

DORPAT.—The hitherto rigorous rule of Russian universities requiring from all instructors the possession of Russian diplomas of the doctorate, &c., has been modified in the case of Dorpat, recognition being made of foreign degrees and professorial positions.

SIENNA.—The Imperial Commission appointed to settle the long-debated question as to the University of Siena, has definitively given the university the title of Royal University, with one of the seven Universities because of its central position in Tuscany, its larger population, and extensively scholastic area, as at Omie, and the larger number of secondary schools. Several Siennese merchants have endowed the future University with considerable sums of money.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 31.—"On the Expression of the Product of any Two Legendre's Coefficients by means of a Series of Legendre's Coefficients," by Prof. J. C. Adams, F.R.S.

"Royal Society, February 14.—"On the Use of the Reflection Grating in Eclipse Photography," by J. Norman Lockyer, F.R.S.

The results obtained by the Eclipse Expedition to Siam have led us to think that, possibly, the method of using the coronal atmosphere as a circular slit, suggested by Prof. Young and myself, for the Indian eclipse of 1871, might be applied under very favourable conditions, if the prism or train of prisms hitherto employed were replaced by one of those reflection gratings with which the generosity of Mr. Rutherfurd has endowed so many of our observers.

To test this notion I have made some experiments with a grating, which I owe to Mr. Rutherfurd's kindness, containing 17,280 lines to the inch. The results of these observations I propose the honour of laying before the Royal Society.

In front of the lens of an ordinary electric lamp, which lens was adjusted to throw a parallel beam, I have introduced a circular aperture, cut in cardboard, forming an almost complete ring, the breadth of the aperture in thirteen diameters, the breadth of the ring about one-fifth. This was my artificial eclipse.

At a distance from the lens equal to twice its focus, I mounted a 3½ inch Cooke telescope, of five-feet focus. As I bought, from distance about of this focus I placed Mr. Rutherfurd's grating, and, where the first solar spectrum fell, I placed a focussing screen. To adjust for sharp focus, in the first instance, the grating was so inclined to the axis of the telescope that the image of the ring reflected by the silver surface adjacent to the grating was thrown on to the screen. This done, the grating was placed at right angles to the axis, and the spectrum of the circular slit, illuminated by sodium vapour and carbon vapour, photographed for the first, second, and third orders on one slit. The third order spectrum, showing the coquidite rings due to the carbon vapour fairings was produced in forty-two seconds. The first order spectrum, also adjusted to the Society, was produced in the same period of time, and was very much over-exposed; it is, however, I think not expecting too much that we should be able to take a photograph of the eclipse, in the third order, in one minute; but let us make it less. Similarly, we may hope for a photograph of the second order in two minutes, and if in, I

in the western suburbs of London, and perhaps also in other parts. Two remedies are recommended for warding off the insects; one by scattering amongst the plants some pulverised gas-lime, and the other by watering with the liquid from pig-sties. The clouded yellow butterfly (*Colias edusa*) was, it seems, "the great appearance of the year," and was first seen near Dumfries early in June, and across the south of England it was generally observable from June till October. The frequent death of the larvæ when feeding on various clovers and trefoils is mentioned as a point of interest relatively to its permanent settlement, as also the great difference in the quantity of the sexes noticed at various stations which may be followed by coincident variety of appearance next year. The report is published by Mr. T. F. Newnam, Botolph Lane, Eastcheap, from whom we believe copies may be obtained. Every information on the subject will also be supplied on application to the Rev. T. A. Preston, The Grove, Marlborough, Wilts, E. A. Fitch, Esq., Malden, Essex, or Miss E. A. Ormerod, Dunster Lodge, Spring Grove, Isleworth.

THE St. Petersburg University has addressed a note to the Ministry of Public Instruction requesting that the necessary steps be taken for the preservation of any valuable manuscripts which may be found in the Turkish towns occupied by Russian troops. Valuable manuscripts were preserved in this way from destruction in the War of 1829, and important manuscripts have already been discovered in the museums of Tiflous.

A SMALL Japanese "line" book comes to us in the shape of a report by the department of Public Hygiene on some of the mineral waters of the country and the uses to which they may be put. Japan seems to contain a great variety of such waters.

At the meeting of the Musical Association on February 4 a paper was read by Mr. D. J. Blaikley, "respecting a Point in the Theory of Bass Instruments." The necessary difference between such instruments and contact tubes was pointed out, and a new experimental method for determining the positions of the nodal points in tubes, especially applicable to such as are of varying section, was shown. As an instance may be given a conical tube open at both ends and of the pitch C 512 vib. The node is nearer the small than the large end of the tube, and by sliding one end in water and holding a fork of the pitch of the tube over the other, the exact position of the node is shown by the level of the water when the tube is giving its maximum resonance.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Lieut.-Col. Fielden; a Grivet Monkey (*Cercopithecus griseo-viridis*) from North-eastAbbissinia, presented by Mr. E. H. Lockley; a Banded's Night Heron (*Nycticorax gardeni*) from South America, presented by Mr. Henry Batrell; three Chimpanzees (*Troglodytes niger*) from West Africa, deposited; a Black-faced Spider Monkey (*Ateles ater*) from East Peru, a Collared Peccary (*Dicotyles torquatus*) from South America, a Globose Curassow (*Crax globicera*) from Central America, a Black-footed Penguin (*Spheniscus demersus*) from West Africa, a Harp Parrakeet (*Pezoporus wallicus*), purchased.

ON COMPASS ADJUSTMENT IN IRON SHIPS[1]

I.—*New Form of Marine Azimuth and Steering Compass with Adjuncts for the complete Application of the Astronomer-Royal's Principles of Correction for Iron Ships.*

THIRTY-EIGHT years ago the Astronomer-Royal showed how the errors of the compass, depending on the disturbing experienced from the iron of the ship, may be perfectly corrected by magnets and soft iron placed in the neighbourhood of the binnacle. Partial applications of his method have since been made use of in merchant steamers, and within the last ten years have become universal not only in the merchant service, but in the navies of this and other countries. The compass and the binnacles before you are designed to thoroughly carry out in practical navigation the Astronomer-Royal's principles. The general drawback to the complete and accurate realisation of plan for carrying out these principles heretofore, has been the great size of the needles in the ordinary compass which renders one important part of the correction, the correction of the quadrantal error for all latitudes by means of soft iron placed on the two sides of the binnacle, practically unattainable; and which limits, and sometimes paralyses, the other, the other chief part of the correction, or that which is performed by means of magnets placed in the neighbourhood of the compass. Five years ago my attention was directed to the subject through my having been called upon by the Royal Society Committee on Standards, and by Admiral Archibald Smith, with an account of his adaptation of one of the mariner's compass and ships' magnetism, and I therefore endeavored to make trial compasses with much smaller needles than any previously in use; but it was only after three years of very varied trials, in the laboratory and workshop, and at sea, that I succeeded in producing a mariner's compass with the qualities necessary for thoroughly satisfactory working in all ventilers and all seas, and in every class of ship, and/yet with small enough needles for the perfect application of the Astronomer-Royal's method of correction for iron ships. The needles small enough which I selected, partly by experiment at sea in my own yacht, and partly by dynamical theory analogous to that of Fourie with reference to the rolling of ships, was that steadiness of the compass at sea was to be obtained not by heaviness of needles or of compass-card, or of added weights, but by largeness of vibrational period[1] of the compass, however this largeness is obtained. This, if the addition of weight to the compass-card improves it in respect to steadiness at sea, it is not because of the additional friction on the bearing-point that this improvement is obtained; on the contrary, dulness of the compass-card, or heaviness of needles, is always accompanied by less friction at the point of support. The secret of the wonderful changes of the ship's head, then it would be were the point perfectly free and frictionless, supposing for the moment this to be possible. It is by increasing the vibrational period that the addition of weight gives steadiness to the compass; while, on the other hand, the increase of friction on the bearing-point is both injurious in respect to steadiness, and detrimental in blunting it or breaking it down, and boring into the cup, and so producing sluggishness, after a short time of use. If weight is, however, to be added to produce steadiness, the plane to add it would be at the very circumference of the card. My conclusion was that no weight is in any case to be added, beyond that which is necessary for supporting the needle; and that small enough needles to admit of the complete application of the Astronomer-Royal's principles of correction, the length of period required for steadiness at sea is to be obtained, without sacrificing freedom from frictional error, by giving a large diameter to the compass card, and by throwing by its outer edge as nearly as possible the whole mass of light weight which is required for steadiness.

In the compass before you (Fig. 1), it is these principles which are carried out. The compass-card is a thin rim of aluminium, and the two needles are thirty-two inches or four copper wires stretched from the rim to a small central boss of aluminium, sixteen wires to a needle, as it were, of the wheel. The needles of thin strong paper, and all the central parts of it are cut away, leaving only enough of it to allow conveniently the poles and degree-divisions of the compass. The central boss consists of a thin disc of aluminium, with a hole in its centre, which rests on the projecting lip of a small aluminium inverted cup mounted with a sapphire cup, which rests on a fixed iridium point (Figs. 2 and 3).

Eight small needles from 3½ inches to 2 inches long, made of thin steel wire, and weighing in all fifty-four grains, are fixed like the steps of a rope ladder on two parallel silk threads, and slung from the aluminium rim by four silk threads or four copper wires through a pin in the centre of the small pair of needles.

The weight of the central boss, aluminium cup, and sapphire

[1] Report of paper read by the Royal Naval Service Institution, February 19 by Sir Wm. Thomson, LL.D., F.R.S., F.R.S.E., Professor of Natural Philosophy in the University of Glasgow, and Fellow of St. Peter's College, Cambridge. Reached by the Author, 11th October 1877. Read by Fleet-Engineer H. T. Denny, R.N. Printed by permission of the Council of the Institution. Illustrated by Diagrams.

[1] The vibrational period, or the period (as it may be called for brevity) of a compass, is the time it takes to perform a complete vibration to and fro when deflected horizontally through any angle not exceeding 5° or 6°, and left to itself to vibrate freely.

Reproduced by permission of the Council of the Royal Naval Service Institution.

Terrestrial Magnetism.

To the Editor of the Scientific American:

Allow me to offer you the details and results of some experiments which I made recently, and which, so far as I have been able to ascertain, are original.

By way of introductory remark, I may say that about twenty years since, in a work entitled "Key to the Geology of the Globe," I endeavored to show that the trends and main mountain ranges of our continents bear a direct relation to certain phases of the ecliptic, being usually secondaries, or, in other words, at right angles to the sun's apparent path at the solstices, then forming angles respectively of about 23° or thereby with the meridians. These trends therefore correspond in the main to the position assumed by the needle at its extreme easterly east and west elongation, as far as we can judge from the magnetic observations made at Paris since 1580. The magnetic phenomena are now generally supposed to result from the effect of strong thermo-electric currents passing from east to west, between the tropics, along the apparent path of the sun.

As solar energy is some of its manifestations appeared to me, by reasons from the earth's interior on its exterior crust, to have an intimate connection with dynamical geology, and hence possessed great interest for me, I have, during the twenty years above alluded to, been devoting such time as I could spare from my collegiate duties to terrestrial magnetism in connection with physiographic and dynamical geology.

Just before the Buffalo meeting of the A. A. A. S., I had sent in the title of a paper which I had prepared, and intended to read, on this subject; but in consequence of a sunstroke I received I had to withdraw it. Since then, having recovered sufficiently to engage in some original experiments etc communications, to be followed probably by two more, to the Indianapolis *Daily Journal*. Inasmuch, however, as that journal may probably fail to reach some scientific men who might find an interest in these results, I offer you the following synopsis of the more recent experiments and results:

Using a delicate galvanometer, accurately adjusted, and the necessary amount of insulated fine copper wire for making the attachments, and being kindly aided by Mr. Brown-Wyllie, of the physical department, we drove iron rods of ⅝ inch diameter six feet into the ground. On the upper end of these I had had good sized eyes formed at the blacksmith's shop, so that with a round wooden lever inserted in the eye, and a few blocks as a fulcrum, we could take the rods up, in order to drive them again elsewhere. Sometimes these rods were driven due east and west of each other, at other times due north and south, at from 100 to 300 feet apart, while the insulated wires, finely stitched respectively to the two rods, were brought through the open windows of the museum, where, as that is under my charge, the galvanometer could be undisturbed. Being carried previously, by deflected by a known current (as for instance, from the carbon pole of the potassium bichromate battery) connected with a given binding screw, we could then be quite certain as to the direction of the so-called current transmitted from the iron rod or other material along either wire.

In this way we experimented at different hours of the day, and during varying weather on different days; we also attached one wire sometimes to an iron oil tank sunk six or eight feet under ground in the campus, at other times we formed wire connection with a water tank having a cast iron collar. We also sometimes connected one wire with the lightning rods or metallic gutters and spouts, and occasionally another wire from the underground tank, while the other was attached to an iron column above ground in the museum. The results of these experiments may be thus summed up:

1. Whenever both wires connected with underground objects north and south of each other, the current was invariably from south to north and usually strong, making a deflection of the needle, after breaking and connecting a few times, of at least 50°.

2. When the rods were east and west of each other the current was from the west, but comparatively weak, as high, however, sometimes as 45°.

3. When we experimented with a long cast iron fence, even in reader, placing the galvanometer and its wires in that central space (in which rose the connection with the earth's crust was made only by the stone pillars to which

the iron pillars of the fence were riveted), then the result showed currents from the south.

4. But when we brought one wire from an underground metallic source, and the other from a metal pillar, stove, fence, or the like above ground, then the current, as far as yet tried, was from the atmosphere to the earth.

The above experiments would seem to justify the conclusion that those electrical currents in the earth's crust are due to the thermal difference between countries southward of us, such as Mexico and Central America, and our portion of Indiana, or regions northerly from us.

It would be interesting to repeat those experiments here, as I shall do if health permits, during the summer, there having all been made in January and February of this year. And, as we are here *west* of the agonic line, it would be interesting also to repeat them in some of our eastern cities which are situated *east* of said agonic line. If the currents then should be found to come from the southeast, occasioned probably by the great heat in northern South America, the variation or declination of the needle would then appear to cause said needle to assume a position parallel to the so-called currents. The magnetic needle does often undoubtedly assume that relation to a weak current transmitted along a single wire, although when the current is strong, as in the solenoid, the needle places itself at right angles to the current.

One more suggestive thought before I close: In stellar electricity, the nonconducting glass of the Leyden jar enables that peculiar mode of motion to accumulate on the surface of the gold leaf within the jar when charged. A much somewhat similar mold the molecules of steel may, perhaps, explain the reason why *pure iron* easily receives and easily parts with that mode of motion, or form of energy termed magnetism, while steel, in which molecules of carbon, comparatively non-conductors, are interposed between the molecules of iron, retains its magnetism.

In the case of the Leyden jar, if we connect the pent up motive molecules of gold leaf with the outside foil by a conductor, we have a rapid transference of motion; but if no conductor is presented, the motion remains bottled up, so to speak, just as with other modes of motion (first vital, then chemical action and heat) derived remotely from the sun, there is energy bounded up in the stick of firewood or lump of coal, to be converted, under certain circumstances, into the artificial heat necessary to maintain normal nervous energy (probably another form of motion) during periods of great climatic cold.

[illegible] the same way, perhaps, magnetism remains dammed up by the carbon, until, by the proximity or contact of a conductor, we render practicable the transference or propagation of the motion. Of course, besides the magnetism which we can induce by proximity of magnetized bodies, the earth's inductive action is always operative on all iron vessels, giving them, while they remain in certain fixed positions, the properties of a magnet; and if of steel they soon become *permanently* magnetic. By running a sewing needle through a short cork, and using the former as a pivot for a delicate magnetic needle, the above phenomena can be readily observed in all permanently placed stoves, hinges, locks, etc., even in iron tinned cups piled on each other and subsequently detached, thus first forming a long magnet and then a number of smaller magnets. The magnetism, or polarity, *here and of your stove*, especially if it is of a round or cannon form, uniformly attract the south end of your needle, while the upper part of the stove, hinge, tin cup, etc., as invariably attracts the *north* or marked end of your needle. Should new facts present themselves, I may perhaps offer a statement of them in a future communication.

Very respectfully yours,

RICHARD OWEN,
Professor Natural Science.

Indiana State University, Bloomington, Ind., Feb. 8, 1878.

[We have since received a later communication from Professor Owen, dated February 11, 1878, in which he states that he has been able to repeat these experiments a number of times and in a variety of ways, during four additional days. The results were the same, except that the amount of deflection varied; being, however, usually from 28° to 30°. He of Paris, described in the Scientific American of February 2d, although the results obtained by the French physicist, in his experiments with the galvanometer and water tank, were given to the public previous to his own, still he even believes himself to be the first to indicate the direction of the current in the earth's crust.]

Eastward Progress of Terrestrial Magnetism

As the progress of weather eastwards is one of the subjects now engaging attention, while the possible connection between meteorological and magnetical phenomena is another, we are led to ask if there be no traces of an eastward progress in certain of the phenomena of terrestrial magnetism.

I cannot yet affirm that such is the case, but it may interest your readers to know that, as far as a preliminary investigation goes, there are some indications of such a progress when we compare together the Declination-ranges at Kew and at Trevandrum. It will, however, require a more thorough discussion before the fact can be considered as at all established.

Manchester, May 4 B. STEWART

(SEQUEL.)—Magnetizing.—Place the magnets on a board parallel to each other, and at a distance apart equal to the length of the magnets, the poles of pure horseshoe magnet. Across these poles lay a piece of soft iron, two bits of soft iron, so as to form a rectangle. Secure this in the board. Then place the large magnet on them, the poles not one on each material [illegible] other. The effect is always about to the other end. Then lift it off, and repeat the process. Then reverse the magnet, occasionally reversing the magnets over.—F. E. FLOYD.

MAGNETIC FIGURES.

To the Editor of the Chemical News.

SIR,—In your last issue you published the report of a meeting of the Physical Society held on Saturday June last. In that report it is stated that Mr. S. P. Thompson exhibited a series of "magnetic figures produced by electrodynamic solenoids." These figures are produced by laying upon glass plates the curves obtained by the use of iron filings scattered in a magnetic field. There are probably few who deliver courses of lectures upon electricity and magnetism who have failed to make use of some such simple device for showing the nature of a magnetic field in that now dignified by the term "magnetic figures illustrating electrodynamic relations." But the very device used has also been employed. As a lecture upon the "Telephone" which was delivered at the United Trade and Mining Schools in April last, I exhibited some of these figures upon the screen, and described the method of preparing the plates which resulted in exactly similar to that now employed by Prof. Thompson. I have also used this figure to illustrate various other lines drawn on the 29 figures which were traced in a similar manner, now in the Physical Cabinet at that Institution, and have been either extensively used, both in my own and other classes.

One of Prof. Thompson's students was present at this lecture, and a full report appeared in the Bristol papers.

ERNEST H. COOK.

Ilfracombe, July 4, 1876.

INTERNAL MAGNETISM.—M. J.M. Gaugain, from experiments upon steel tubes and anchil, concludes that the changes of magnetism which are produced, under the influence of heat, in a solid steel bar, do not differ from those which are produced under the same influence, in a system composed of a tube and a nucleus. Both seem to depend on the inverse magnetism developed by the mutual reaction of consecutive layers, either of the bar or of the system.

surrounded by an atmosphere containing sufficient hydrogen sulphide, the opposite effect occurs. Now the needle, when strongly electrified, turns from copper to iron; when oxidized, from iron to copper. The conclusion to be drawn from these facts appears to be that the electrical behaviour of metals in metallic contact is, if not entirely, due to the difference of their affinities for one of the elements of such compound gases as may be in the atmosphere surrounding them. This would be entirely analogous to their behaviour in electrolytes containing these same elements, *e.g.* iron is positive to copper in an oxidizing electrolyte such as water, because of the affinity of oxygen for iron being greater than for copper, while iron is negative to copper in potassium sulphide solution, because of the affinity of sulphur being greater for copper than for iron. J. HAWKS

Ebenezery House, Belfast

Solar Halo

THE following was noticed at Bordeaux on April 4, at 11 A.M.:—1. A well-defined and very complete circumzenithal circle (86° in diameter), of a brilliant white light, passing through the sun. 2. An iridescent circle, larger than the first, and resting it at two points 60° distant from the sun. The second circle showed more especially the red rays on its concavity (*i.e.* towards the sun), except at the parhelia, where it was bright iridescent. Near the western parhelion the brilliancy of the mock sun was quite insufferable to naked eyes.

The morning was very warm, but the night had been very cold. E. DURUTE

FLOATING MAGNETS

THE extract from the *American Journal of Science* describing experiments with floating magnets by Mr. Alfred M. Mayer to illustrate the equilibrium of mutually-repellent molecules each independently attracted towards a fixed centre, which appeared in NATURE, vol. xvii. p. 487, must have interested many readers.

It has interested me particularly because the mode of experimenting there described, with a slight modification, gives a perfect mechanical illustration (easily realised with satisfactory enough approximation) of the kinetic equilibrium of groups of columnar vortices revolving in circles round their common centre of gravity, which formed the subject of a communication I had made to the Royal Society of Edinburgh on the previous Monday. In Mr. Mayer's problem the horizontal resultant repulsion between any two of the needles varies according to a definite law of their mutual distance readily complicated function of their mutual distance readily calculable if the distribution of magnetism in each needle were accurately known. Suppose the distributions to be precisely similar in all the bars and in each to be accomplishing to the following law:—Let the intensity of magnetisation be rigorously uniform throughout a very large portion, *c*, in the whole length of the bar (Fig. 1), and let it vary uniformly from C and D to the two ends A and B. The bar will act as if for its magnetism were substituted ideal magnetic matter, or polarity, as it may be called, uniformly distributed through the end portions CA and DB; the whole quantity in D B to be equal in amount and opposite in kind to that of C A. For example, suppose true northern polarity in A B and true southern in B D. The lengths of C A and D B need not be equal. Let now A′C′D′B′ be another bar with an exactly similar distribution of magnetism to that of A C D B, and let the two bars be held parallel to one another. The mutual repulsion will vary inversely as the distance, if the distance be sufficiently small in comparison with B B′ or C A, and if each of these be infinitely small in comparison with C D. If the bar A′B′ of a powerful bar-magnet be held in a true south pole S of a powerful bar-magnet be held in a line midway between B A and A′ A, at a distance from the ends B and B′ infinitely great in comparison with B B′, and comparable with the length of each needle, the horizontal component of its effect on each magnet will be a force varying directly as its distance from the central axis. Under these conditions Mr. Mayer's experiments will show configurations of equilibrium of two, or three, or four, or any multitude of ideal points in a plane, repelling one another with forces inversely as the mutual distances, and each independently attracted towards a fixed centre with a force varying directly as the distance. This, as I showed in my communication to the Royal Society of Edinburgh, is the configuration of the group of points in which a multitude of straight columnar vortices with infinitely small cores is cut by a plane perpendicular to the columns; the centre of inertia of a group of ideal particles of equal mass placed at these points being the fixed centre in the static analogue.

The consideration of stability referred to by Mr. Mayer has occupied me much in the numerical problem, and it is remarkable that the criterion of stability or instability is identical in the static and kinetic problems. In the static problem it is of course that the potential energy of the mutual forces between the particles, together with that of the attraction towards a fixed centre is less for the configuration of stable equilibrium than for any configuration differing infinitely little from it. The potential energy of the attractive force in a function of distance from the central axis, diminishing as the distance increases, and the statement of the criterion may be conveniently modified to the following:—

For a given value of this function the mutual potential energy of the atoms must be a minimum for stable equilibrium. When, as supposed above, the attractive force varies directly as the distance its potential energy is:—

$$C - \frac{1}{2}\alpha r^2$$

where C, α denote constants, and $2r^2$ the sum of the squares of the distances of all the particles from the attractive centre. And when the law of force between the particles is the inverse distance, their mutual potential energy is equal to—

$$K - k \log. (D\,D'\,D'' \ldots)$$

where K, k denote constants, and D, D′, D″, &c., denote the mutual distances between the particles. Thus the condition of stable equilibrium becomes that the product of the mutual distances between the particles must be a true

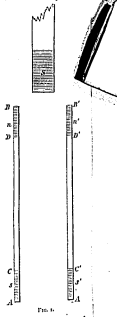

FIG. 1.

minimum for a given value of the sum of the squares of their distances from the attractive centre. A deduction from this condition must be that the centre of gravity of the particles must be the attractive centre. Now the condition of kinetic equilibrium of a group of vortex columns, that is to say the condition that they may revolve in circles round their common centre of inertia is, as proved in my communication to the Royal Society of Edin-

EXPERIMENTS WITH FLOATING AND SUSPENDED MAGNETS, ILLUSTRATING THE ACTION OF ATOMIC FORCES, THE MOLECULAR STRUCTURE OF MATTER, ALLOTROPY, ISOMERISM, AND THE KINETIC THEORY OF GASES.

By ALFRED M. MAYER.

I HAVE recently devised a series of new experiments which are so easy to make and so well adapted to illustrate the action of atomic forces and the molecular structure of matter, that I think a description of these experiments will be acceptable to all those who are interested in the study or teaching of science.

Any portion of matter, whether solid, liquid, or gaseous, is forced into a smaller volume when subjected to pressure (in other words, matter is compressible), and when this pressure is removed, the matter expands into its original volume. This shows two things: first, that the matter of which the body is formed does not really fill all the space which the body appears to occupy; and, secondly, that in the body is a force which, acting from within outward, resists the outward pressure and expands the body to its original volume when this pressure is removed.

There are several instances where a volume of one liquid when mixed with an equal volume of another liquid does not form a mixture of two volumes, but their combined volume is considerably less than the sum of their separate volumes. Thus, when one mixes one volume of water with an equal volume of alcohol, their combined volume is less than the sum of the volumes of the water and alcohol before the mixture. These experiments show that the spaces which the volumes of water and alcohol appeared to fill were not really filled with water and alcohol matter, but that vacant spaces (vacuola) existed in these liquids. In other words, these liquids are porous, like the ether. This shrinkage of the mixed alcohol and water is all the more remarkable when we remember that each additional atmospheric pressure on water lessens its volume only by the $\frac{1}{22000}$th part.

These phenomena of compressibility and porosity, which we have just described, may be explained by supposing that all matter is built up of very minute parts, and that these parts do not touch, but are kept asunder by the action of two forces which exactly balance one another. One of these forces is a constant attraction which tends to bring these minute parts together; the other is a force of repulsion which constantly tends to separate them.

There are two laws in chemistry which lie at the foundations of that science, and which cannot well be explained except by the assumption that matter is really formed of these minute parts, and, also, that the minute parts have definite and constant forms, volumes, and weights. The volumes and weights, and probably the forms, differ with the different kinds of matter. These minute parts are called *atoms*. These atoms are assumed to be ruled by forces of attraction and repulsion, so that when these two forces exactly balance, the atoms will be separated and arranged in a geometric manner around some central point. Such a combination of atoms is called a *molecule*. A molecule may be defined as the smallest portion of any kind of substance which can have the chemical properties of the substance, while an atom is defined as the smallest particle of elementary matter which can enter into the composition of a molecule. Thus a molecule of water may be supposed to be formed of two atoms of hydrogen and one of oxygen. This is the smallest mass of these two atoms which can form water, for if one of these atoms should be removed from the molecule, the molecule would break up into hydrogen and oxygen.

The first of the two laws of chemistry, above referred to, is this: The same body is invariably composed of the same elements united in the same proportions. Thus, water, no matter how formed, is composed of one part by weight of hydrogen united to eight parts by weight of oxygen; and carbon dioxide, whether formed by a burning candle, by the combustion of carbon in oxygen, or by breathing, is always formed of six parts by weight of carbon united to sixteen parts by weight of oxygen. This law is readily explained by the suppositions we have made as to the existence of atoms and the structure and nature of molecules. For, since the molecule of the same matter is always formed of the same number (or weight) of atoms, and since masses of matter are made up of combinations of many molecules, it follows that these masses of matter will have the same proportions by weight of the same elementary atoms as compose the molecules.

The second law is this: When an element unites with another in different proportions, the higher proportions are invariably multiples of the lowest. This nitrogen and oxygen show and form the following five different compounds:

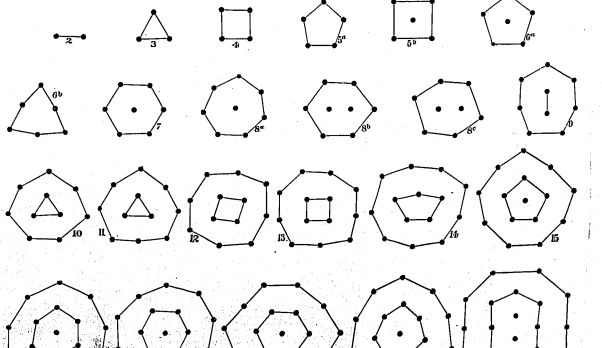
1. Nitrogen monoxide contains 28 of nitrogen and 16 parts of oxygen.
2. Nitrogen dioxide contains 28 of nitrogen and 32 parts of oxygen.
3. Nitrogen trioxide contains 28 of nitrogen and 48 parts of oxygen.
4. Nitrogen tetroxide contains 28 of nitrogen and 64 parts of oxygen.
5. Nitrogen pentoxide contains 28 of nitrogen and 80 parts of oxygen.

In this series of compounds oxygen unites in five different proportions, and if you call the lowest proportion, in the monoxide, *one*, then the proportions of oxygen in these compounds are *one, two, three, four, five*.

This second law may be explained by the supposition that, as we have stated, the molecule is a combination of atoms, and that there is always the same number of these atoms in a molecule of the same substances. Thus, in the five oxides of nitrogen mentioned, of oxygen, the molecule of nitrogen may be supposed to always consist of two atoms of nitrogen, and may be represented by **N N**.
The molecule of oxygen we may suppose formed of a single atom and may be represented thus, **O**. If this be granted, then these molecules unite as such, it follows that the various combinations of nitrogen and oxygen must take place as the second law states, and these compounds may be represented by the following table of the combinations of the symbols **N** and **O**:

Nitrogen monoxide	= **N N O**.
" dioxide	= **N N O O**.
" trioxide	= **N N O O O**.
" tetroxide	= **N N O O O O**.
" pentoxide	= **N N O O O O O**.

There is a law, known as the law of Avogadro, which states that equal volumes of gases contain equal numbers of molecules; but as atoms of different elementary substances are of different size and weights, it follows that molecules



EXPERIMENTS WITH FLOATING AND SUSPENDED MAGNETS.

REMARKABLE CHANGES IN THE EARTH'S MAGNETISM!

ONE of the most important, scientifically, of the special lectures at the Geographical Society, was that by Capt. Evans, in March last, on the subject of terrestrial magnetism. The

[From Letter of the Royal Geographical Society, March 11, by Captain F. J. Evans, R.N., R.A., Hydrographer to the Admiralty.

URE [May 16, 187

escaping portion, especially, is of high scientific importance. Capt. Evans gave a bi-chromic sketch of the course of terrestrial magnetism from the time of the discovery of the dip of the magnetic needle. After specifying further on various departments of inquiry, Capt. Evans went on to say—

"We have now passed in review the successive stages of development of our branch of knowledge, from the pregnant epoch when its principles were established by Gilbert, till the period when the well-directed assiduousness of its own and other Governments dotted the earth's surface with observatories, and furnished land and sea expeditions, specially equipped, for the determination of the magnetic elements. We have seen how, at length, the foundations for future generations to build on were laid, gaps slowly, and insensibly the symmetry discernible even surrounding the needle's daily and yearly movements, in the inconsequents to their primary centre, the sun; and how by the perseverance of states and of individuals, we are now in possession of a comparatively complete knowledge as to the distribution of magnetism over the surface of our globe, as represented by the variation and dip of the needle, and by the measure of the force connected with these component elements. But the task, from a scientific point of view, is by no means completed while we remain in ignorance of the causes of greater changes in the earth's magnetism going on from year to year, and so, probably, through all time. From a practical point of view, so far as the interests of men are concerned, the collection of records will be a never ending task, for every generation must observe and chart the magnetic elements of its time.

"The subject of secular change is then one of such great interest that the remaining portion of my address must be chiefly devoted to it. The solution of such problems must be chiefly the first, to the probable extent of future endeavours, as one of observation—the variation of the elements; secondly, to the mode, and projecting them on polar charts, as the form that the convergence of the lines of force in the north and south magnetic areas in each hemisphere. On this is to be based the question as to whether the whole globe of the earth is one great magnet, having two magnetical poles or points of attraction and repulsion, or whether it is made up of a number of such, as some of the world is governed by a number of these magnetic poles in addition to over the new magnetic poles, Halley saw, as he confessed with despair, the difficulties in the way of such a proposition, "on having heard of a certain sect having four poles," but there were the facts manifested by the needle, and he was too sagacious not to accept a phenomenon because he was too sagacious not to accept a theory which, however true, he accordingly propounded perhaps did at the time by a man of his position, he occasioned, for of genius, and may probably be, nevertheless within a hit of the truth. Halley stated independently of the external shell of the earth, which he considered as passing through the centre; but the two men believed in each other and the movements of the convergent four imaginary poles in each tion of the problem.

"Humboldt, looking at the same problem a century after Halley [1827-29], and much on the same lines, arrived at the same conclusion with regard to the four poles of attraction; and he had discovered the secular magnetic attraction of the first who seem, with the natural aid of his extensive travels, to have further, not consulted, but on his geographical position as a probable period of the variation of this element, however a step in the direction of this subject, and the general question of the conjunctions he found that the North American pole or pole traversed 1,292 years, and that the North American pole or magnetical pole, the Siberian 962 years; the pole in the Antarctic near Cape Horn, 1,304 years.[1] 2,634 years; and a secondary pole investigations on the minds of subsequent inquirers may easily be traced.

"The learned views of Sir Edward Sabine on the secular changes—enunciated in the clearest manner in 1864-72—are deserving of the highest consideration. An ardent admirer of

[1] *Untersuchungen über den Magnetismus der Erde.* Cotta'sche, 1810.

Challenger's officers;[1] at Valparaiso and Monte Video, compared with those made in preceding observers, show that within half a century the whole force has been steadily diminished one-sixth and one-seventh—that the Falkland Islands one-sixth. Further north we find at Bahia a decrease of one-fifth, in the same period of time, an equally marked diminution of one-sixth of the force. This mass of diminishing force is seen at St. Thomas, at Trinidad, at Hobson on the east; at the Cape of Good Hope there is evidence of the force decreasing.

"Such are the facts, and how are we to interpret them? Which, over way we look at the subject of the earth's magnetism and its secular changes, we find marvellous complexity and mystery; in lapse of time and increase of knowledge appear to have thrown no further and further back in the vistas of the past. The terrells of Hallley, the revolving poles of Hansteen, and the more recent hypotheses of the ablest men of the day, have failed to solve the mystery. We must not, however, be discouraged at these repulses in the great conflict for the advancement of human knowledge. The present century has been productive of keen explorers in the field of terrestrial magnetism; other centuries will have no less pressing exigency than the present; and knowing as we do that knowledge shall be increased, we may confidently anticipate that the day when duly, one of Nature's most formidable secrets, shall be revealed."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

At the annual meeting of the Convocation of the University of London on May 14, a report from the senate committee was presented with the recommendation above mines and co-operation of the colleges and medical schools affiliated to the University with each other and with the Senate, and also more direct participation by the University in the work of higher education and in the encouragement of new original work. The following resolutions were carried by large majorities after an animated debate, in which Drs. Sharpey, Payne, Hayter, Pye-Smith, and Weymouth, and Messrs. Hutton, Carey Foster, R. N. Fowler, and Finch, took part:—That this Convocation is of opinion that the admission of candidates for degrees in the faculties of the teachers of the candidates by a body independent of the course of study pursued in those institutions should be brought into closer connection with the Senate. 2. That with under the present Charter of revision, it is desirable to exercise its powers of, and from time to time call a meeting of affiliated bodies for this purpose, including in the invitation to or excluding from the University examinations for degrees, such other colleges as the Senate may in each case determine. 3. That the Senate be requested to take into consideration the question whether it would be desirable to constitute, by delegation or otherwise, a Board of Studies, consisting of such persons as it may think fit, to whom shall be referred for consideration and report all questions relating to the course of study for the examinations of the University, either in its faculties or collectively, as from time to time may arise, and that the delegates of deliberating together and of consulting with the Senate, and to make such determinations as shall be binding upon the University. That it is desirable that the University should take advantage of such opportunities as may present themselves of promoting, by the institution of University chairs or otherwise, the cultivation of such higher or less usual branches of study as can be most conveniently or more efficiently taught by a central body. 5. That it is desirable for the Senate to consider the importance of recognising independent research in the examinations for the higher degrees in such way as the Senate may approve.

M. Barbier has sent to the French Chamber of Deputies a letter, and law, in order to organise in the colony superior of France. An *école préparatoire* of medicine was established fifteen years ago.

The late Prof. Wilhelm Pütz, well known through his excellent geographical and historical hand-books, has bequeathed the

[1] This extended and carefully made series is prepared for publication; we cannot too highly estimate this valuable contribution to magnetical science.

THE PHYSICAL SOCIETY.

On Saturday, the 22nd instant, a meeting of the Physical Society was held at the Science School, South Kensington, under the presidency of Professor W. G. Adams, F.R.S.

Two papers on electrical subjects had been deposited of,

Professor Balfour Stewart, F.R.S., which exhibited a series of Magnetic Figures, illustrating Electrodynamic Induction. A copper disc, mounted like the rotatory remarks, he observed that the lines of magnetic force around a wire carrying an electric current can be shown by passing a wire through a glass plate, showing two fillings around, and tapping the plate gently. The filings may be fixed in their places. If the plate has previously been gummed to a card, by soaking the gum with steam. Such a prepared plate may be used to show the figure of the magnetic curves in the lantern. Two parallel disc currents in the same direction attract each other, and tend to set the action; or they repel if travelling in opposite directions, the repulsion being evident from the form of the curves. It was shown in the remaining numbers of the series that, in a similar way, a very large number of electrodynamic relations could be illustrated by curves produced in a similar manner. Figures were thrown upon the screen, illustrating the law of action and reverse, the attraction of a magnet into or its repulsion out of a coil, the attraction of a magnet by a coil when the current is in a certain tendency to rotation of a current and a magnet, &c. A very interesting figure was produced by a current running through a magnet lengthwise. A transverse section of the bar of iron or of a pole given under the radial lines of the magnet nor the circular lines of the current, but a series of spirals. It was argued that Faraday's conception of the lines of force leading to electric themselves supplied the means of interpreting the phenomena, and of predicting the results of new experiments.

During the course of the meeting, the President intimated that, in addition to the papers fixed to come on, there were a modified form of Professor Hughes's microphone, by Mr. Hollaer, and a combination of the *Stenotelescope* and telephone, by Mr. Varley.

Owing, however, to the number of papers before the meeting, neither of these was described. Mr. Frederick Elliott also withdrew his paper on Electrical Resistance and a Conductor under Influence.

Prof. Fitzgerald, at the close of the meeting, intimated that that was the end of the session, and adjourned the Societies.

Researches on Magnetic Rotatory Polarisation.—

M. H. Becquerel.—Since Faraday's discovery the phenomenon of magnetic rotatory polarisation has been the subject of numerous researches. It has been remarked that bodies endowed with natural rotatory power also a great magnetic rotatory power; but the exceptions to this rule have hitherto prevented any connection between these two physical relations from being established. The author finds in his experiments that the sign of the rotation a regular increase or decrease in the index of refraction augments. The exceptions observed may be attributed either to the effects of lamellar polarisation, as in the diamond and garnet; or to the presence of magnetic bodies, as in the following cases.—*Comptes Rendus*, vol. lxxx., No. 23, p. 1577.

(20352.)—Magnetic Meridian.—To raise into any desired position the variations in declination of the needle would seem to be a matter of no difficulty, and would now seem to be easily accomplished. I may tell you that the needle is never constant for any two days together, but is always varying, and that in a very irregular manner. The largest variation I have observed is 1° 30′ W., 1860, 25° W., 1865, 21° 30′ W., 1870, and 19° 30′ W., 1875, and for probability it is, I am sure, the course of the next, the two meridians will approach each other, and the compass will point due north and south. Now, the greater part of the world from the geographical meridian, and would now have the full variation from the true meridian. You are aware that the variation is almost the same at Dunbar in Scotland as at Plymouth in England, and that it is the same at Dublin as at Liverpool. Now, I am not aware that there is any difference between geographical and magnetic meridian at Dunbar, Plymouth, Dublin, or Liverpool, but at these places the variation is 20° W., 1875, and the same equal declination or any other equal form of magnetic meridian at each place, in other words, the variation is the same at Dunbar, Plymouth, Dublin, and Liverpool. Nevertheless, 2° 30′ greater difference between Greenock Glasgow, 2° 30′; Liverpool, 1° 30′; London, 1° 30′; Plymouth, 1° 30′; Dublin, 2° 30′; Dunbar, 2° 30′. All geographical meridians have a longitudinal north only. The lines on such maps are, therefore, of no use to the navigator. It is impossible to obtain any data for longitude having to give you the magnetic meridian. Such can only be obtained by observation.—W. J. Lancaster.

(20353.)—North Pole of a Magnet.—According to certain theories, the great call (as real centres of force) would be found in the earth in relation to the north pole of a bearing on the following page. The point has not action may be expressed as follows:—If does not matter —as it is of interesting bulk ways at the same instant.

(20354.)—Battery Power.—To Mr. W. J. Lancaster.—You cannot send a current through one wire in a lot without equally affecting every one of the others. What you are going wrong. Can you tell me how much you want to obtain? Then, I think, I can tell you how you can do it. Double, &c. A prepared paper can be sent to you. You must would be as satisfactory as paper that you can cut. You can suggest a better attaching you to use. Your battery is not good, and a bit of blue litmus paper will make sure you want the battery to do, and then you will be the best battery for you to have.—W. J. Lancaster.

Floating Magnets

I HAVE no intention of discussing the beautiful experiments of Prof. A. M. Mayer on floating magnets; but as a pictorially-expressed epitome of nine has appeared in NATURE, vol. xviii., p. 260, I feel bound to defend it. The mutual repulsion of the vertical floating magnets varies nearly inversely as the fourth power of the distance in great distances, and nearly inversely as the square at small distances. The horizontal attraction of the magnet, held vertically in the water, varies nearly inversely to the fourth power at very great distances. At a certain moderate distance it attains a maximum of force, and close to the centre it varies directly as the distance. It is easy to see that variations of the magnetisation of the lengths of the magnets, and of the distance of the large magnet from the surface of the water, may account for the observed results. I will consider, under different conditions, he forms of unstable equilibrium. Prof. Meyer thinks that the configurations . . . can never be stable. It is easy to see that in a form of equilibrium, and is true that any given size of hexagon will be brought into equilibrium by placing the large magnet at a suitable distance. It may, therefore, be in equilibrium when the floating magnets are on the circle of maximum attraction of the feed magnet. But, in this case, the equilibrium is stable; for work would be expended in altering in any way the position of any one of the floating magnets. If this were carried away from the others they repel it back, and it will be brought back; if it were carried across the others they repel it more, and again it will be brought back.

The nature of equilibrium where there are several degrees of freedom may be illustrated by considering a tract of country upon which water can flow. The hollows mark positions of stable equilibrium; the summits and passes (cobbles) are positions of unstable equilibrium. Then, if any one speaks of the former as more or less stable (as Prof. Meyer does of stable configurations), he may be as independent as the flows of the surface of the hollow, or to its level, or to some vague and mixed character.

It is very easy to understand why the form . . . should be difficult to produce or maintain. It is because the floating magnets are in this case at much greater distances from the centre than when they assume the form . . . Hence, the potential energy of the system is much greater in the latter form . . . of the latter. The reverse is the case with . . . and . . . and still more so with . . . and . . . , and so with greater numbers of magnets.

C. S. Pierce

THE "DIP" OF THE MAGNETIC NEEDLE.—This property of the needle was discovered by Robert Norman, about the year 1576.

39

Freeing a Magnetic Bar from the Influence of the Earth's Magnetism.—Dr. Joules' method may be well known to most readers, while that of Professor Trowbridge may not be so well known, and, therefore, we give it a place among our "Notes." An ordinary tangent galvanometer is to be constructed that the coil is free to turn about a vertical axis, and also about a horizontal one. The coil is first placed in a plane, perpendicular to the magnetic meridian; it is then turned about its horizontal axis until the component of the strength of the current acting in the horizontal plane shall be just equal and opposite to the horizontal component of the earth's magnetism. A figure can be easily constructed to assist in the illustration of this system. Draw rectangular co-ordinates x, y; draw $a\,b$ to represent strength S of current passing through galvanometer coils at the angle θ which the plane of the coil makes with a vertical plane. We have S cos $\theta = \mu_1$ in which μ_1 is the counter-balanced force of the earth's magnetism. Under these conditions, the magnetic needle is in a state of unstable equilibrium, and, if placed perpendicularly to the magnetic meridian, will vibrate through small arcs free from the action of the earth, and subject only to the attraction in the field of force in which it may be placed. A bar of soft iron placed in the vertical plane which passes through the suspension of the needle perpendicular to the magnetic meridian at a suitable distance from one of the poles of the needle, serves to bring it back to zero, just as the controlling magnet serves a similar purpose in Thomson's reflecting galvanometer.

Mist of Magnetic Storms '79.

It is surprising that an accomplished telegraphist like Mr. Mance (NATURE, vol. xix. p. 469) should rest on the necessity and advisability of expressing earth-currents in webers. It is precisely on that account necessary, as I said, to express the magnitude of an occasional current or set of currents in terms of the unit we do as if Mr. Mance's plan were adopted, that I should say, the webers, or rather, in more convenient sub-multiple, the millionth part of a millionth (the current produced by one Daniell's cell (nearly one volt), through 1,000 ohms. Currents can be reduced to this unit from any galvanometer. The tangent galvanometer is, perhaps, the simplest to use—it is that which we employ in England. Supposing for simplicity that your constant, viz., one Daniell cell through 1,000 ohms (including cell and galvanometer) gives 45°, then the tangent of any other reading will give you the current in millionths. Then, knowing the resistance of your circuit and its geographical position, you have all the data necessary to determine the elements of earth-currents.

I will not on Mr. Mance's suggestion, and being the matter before the Society of Telegraph Engineers with a view of organising a systematic mode of observation in different parts of the world.

Whitfield, March 8 W. H. Preece

Curious Facts in Magnetism.

At the meeting of the New York Academy of Sciences, February 17th, the article in the March number of *Harper's Magazine*, entitled "Gray's Magnetic Motor," was incidentally alluded to, and Prof. C. A. Seeley made the following remarks: The article claims that Mr. Gray has made a discovery of a neutral line or surface, at which the polarity of an induced magnet, while moving in the field of the inducing pole, is changed. The alleged discovery appears to be an exaggerated statement of some curious facts, which, although not new, are not commonly recognized. If a bar of iron be brought up, end on, near a magnetic pole, the bar becomes an induced magnet, but an inferior magnet quite different from what our elementary treatises seem to predict. On the first scrutiny it is a magnet without a neutral point, and only one kind of magnetism—namely, that of the inducing pole. Moreover, the single pole is pretty evenly distributed over the whole surface, so that if iron filings be sprinkled on the bar they will be attracted at all points, and completely cover it. Now if, while the bar is covered by filings, it be moved away from the inducing pole, the filings will gradually and progressively fall, beginning at the end nearest the inducing pole and continuing to some point near the middle of the bar; the filings at the remote end will generally be held permanently. When the bar is carried beyond the field of the inducing pole it is simply a weak magnet of ordinary properties—i. e., of two poles and a neutral point between them.

A plausible and simple explanation of this case is that the inducing pole holds or binds the induced magnetism of opposite name, so that it has no external influence; the two magnetisms are related to each other as are the positive and negative electricities of the Leyden jar. So if the inducing pole be N.; the B of the bar will be attracted by it and bound, while the N. of the bar becomes free, and, moving from and [illegible] moving the bar from the pole the positive electricity is retained and a part becomes residual magnetism. Now, when the neutral line passes the fine magnetism which is of opposite name, we are on Gray's neutral line. In a fantastic sense there is a change of polarity over the half of the bar analogous to the inducing pole; on the other half there is no change of pole in any sense. Experiment with a shingle nail in the place of the filings, as Dr. Gray, tying the nail to the induced neutral pole, and it may be held, except at the neutral line. Now, if one will read the magazine article with such ideas as these, he will feel pretty sure that the writer of it has used words recklessly, that Gray has not made an original discovery, and that the "neutral" line, whatever it be, has only an imagined relation to the "principle" of the motor.

The Gray Motor as a perpetual motion scheme, of course, is not worthy of serious notice from a society devoted to science. It has no more merit or novelty of construction or conception. Mr. Gray is afflicted with the very old delusion of the cut-off or shield of magnetism, which is to cut less than, when cause from it. His cut-off is a sheet of iron, which we

On the Electrical Aftercurrents of Transversely Magnetized Iron Rods.—By Prof. H. Streintz.—The experiments referred to in this paper were carried out by the author in conjunction with Dr. F. Streintz. The phenomenon was discovered by Villari, that in a rod of iron or steel through which a galvanic current has passed, when agitated after the interruption of this current, a galvanic current is again generated the same in direction as that originally conducted through the rod. He subsequently investigated some properties of these aftercurrents, and gave an explanation of the phenomenon;—namely, that the rod is transversely magnetized by the current; and if we employ the notion of molecular magnets, these arrange themselves in concentric circles around the axis of the rod. Now, if the rod be agitated after the interruption of the current, the molecular magnets obey the direction-forces which tends to mingle them again irregularly. We can here avail ourselves of the representation of the molecular magnets returning to the positions which they had before the action of the current. Now, in this return they generate in the rod an induction-current, to which Villari gives the name of "agitation-current," but which may with equal usefulness be designated as an aftercurrent. Afterwards H. Herwig studied the properties of transverse magnetism on iron tubes. The author now shows that in a very simple manner the quantity of the magnetising force can be calculated which is exerted upon the molecular magnets by the current originally conducted through the rod. Starting from Biot and Savart's theorem, that a rectilinear current of infinite length acts upon a pole of a magnet with a force inversely proportional to the perpendicular distances of the pole from the conductor, the problem is reduced to one of the plane; so that we have to calculate the action of a circular surface with uniform mass (the pole investigated had a circular cross section) upon an mass-point situated in the surface. In accordance with the laws of force previously stated, however, a circular line with uniform mass exerts no action on a point situated in the enclosed surface, while it acts on an external point in the same plane as if the mass of the circle were collected in the centre. Now by this the calculation becomes very simple, and we obtain, as the force which is exerted upon a magnetic pole situated at the distance r from the axis, $p = \frac{2\pi}{r}$, in which i has constant, and a the semidiameter of the rod. The total moment upon all the molecular magnets c. . . nd in the rod is then $R = Ki\sigma$, where R, i, and σ have the same meaning as above, and K denotes the length of the rod. The author has also investigated by experiment the properties of the aftercurrents; and in so doing he found some method which could be foreseen from the theoretical developments, and also discovered various other properties, some of them, indeed, very striking, which could not have been determined *a priori*.—*Entwicklet Absolute Wiesenchaften in Wien, math.-naturw.* 78

Magnetism of Loadstone and of Steel.—

Dr. A. L. Holz has investigated the comparatively-feeble magnetism of loadstone (Magnetic oxide of iron) and the powerful magnetism of steel. He has created stone and open glass-lenticular rod. His researches were conducted by measuring which are the following: 1. The maximum of permanent magnetism in the loadstone, for equal volumes, is about the same as that in the best steel. 2. The coercive magnetism of the loadstone is the greatest of all magnetisms of the loadstone is the greatest of all magnetisms bodies yet investigated. 3. The permanent magnetism of the loadstone is nearly zero that the maximum of the intensity of temporary magnetism which disappears after the magnetising force is removed, is less in the loadstone than in steel. Ap. 79

Magnetic Storm, May 14, 1878

At the *Bellelle Mound* of the observatory of Zi-ka-wei, near Shanghai, China, the following interesting remark occurs in the number for May, 1878 :—

"During la nuit du Mai, une seule perturbation a été enregistrée par le magnétographique; elle commença le 14, à 8h. 20m. de l'après-midi, et se termina 24 heures après; sa plus-li la différence, par extraordinaire, ne présenta pas d'oscillations dignes de remarque, mais de très-nombreuses petites oscillations comme le lithiline."

On examining the photographic trace of the Stonyhurst magnetograph I find that the only magnetic storm in May last commenced on the 14th at 6h. 40m., and lasted rather more than twenty-four hours. The longitude of Zi-ka-wei being 8h. 15m. 32s. E. of Stonyhurst, the storm began at the same time at both stations. The character of the movement was also identical, for the only disturbance at Stonyhurst from 6 A.M. until 4 P.M. was a tremulous motion of the declination and horizontal force traces.

The storm was at its height at midnight, when all the magnets were much disturbed, and the vertical force magnet was thrown completely off its balance.

It is impossible to obtain more than the roughest outline of a magnetic storm from hourly readings, but even this slight data as from Chino shows a general agreement in the declination curves during the storm at these two distant stations.

The *Monthly Record* of the Melbourne Observatory also mentions the same magnetic disturbance, which commenced there at 4 P.M. on the 14th, and lasted until 8 A.M. on the 17th. Melbourne lies 9h. 39m. 54·3s. E. of Greenwich, and therefore 1h. 24m. 10s. E. of Zi-ka-wei. We thus see that the Zi-ka-wei storm commenced 3h. 55m. Melbourne time; it was therefore simultaneous at the three observatories.

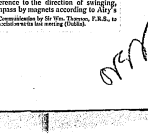
Stonyhurst Observatory, September 27 S. J. Perry

On Gaussin's Warning Regarding the Sluggishness of Ship's Magnetism.

Practical Rule and Caution

1. After steering for some time on westerly courses expect—
   1. (*a*) Westerly error if you turn to the north;
   2. (*b*) Or easterly error if you turn to the south.
2. After steering for some time on easterly courses expect—
   1. (*a*) Easterly error if you turn to north;
   2. (*b*) Or westerly error if you turn to the south.

The diagram representing case 1 (*a*) illustrates the physical explanation, N and s representing the north and



south poles of the compass card (or *true south* and *true north* poles of its needles), and the small letters, $s_1 s_2 s_3$ true southern polarity, and $n_1 n_2 n_3$ true northern polarity, induced in the port and starboard ends of deck beams and port and starboard sides of ship while steering east, and remaining for some time after she has been turned to north.

In the "Admiralty Compass Manual" Gaussin's warning is given with reference to the direction of swinging, in correcting the compass by magnets according to Airy's

* Being an abstract of a Communication by Sir Wm. Thomson, F.R.S., to Section A of the British Association at its late meeting (Dublin).

first method. In the Reports of the Liverpool Compass Committee and in Mr. Towson's "Information for Masters and Mates regarding Ship's Magnetism," instances of perplexing changes in the compass are given, and are referred to the same cause. The "sluggishness" of ship's magnetism, according to which it depends generally in part on the influence experienced some time before the time of observance, and not wholly on the influence at the time, seems to have been first definitely noticed and discussed scientifically by Sir Edward Sabine in his analysis of the results of the magnetic observations in the Antarctic and Arctic Expedition of Sir James Ross in the *Erebus* and *Terror*, in the years 1840-41.

The practical rule and caution given above is of great importance in the navigation of iron ships. The amount of the error which may be found cannot be predicted for ships in general, nor for any particular ship except after much experience and careful observation. A small effect of two or three degrees, such as that referred to in the Admiralty Manual as found in M. Caussin's experience, may be observed in the course of quietly swinging a ship by hawsers or steam-tugs. If the ship under way is steamed round on the different courses the amount of the "Caussin error" may generally be greater than if she

is hauled round by warps; but we must not be sure that it will be so, because the *choke* of the screw which enhances the magnetisation on the east or west courses may shake it out again before the observation is made on the north or south courses.

A good practical rule in correcting the compass is, after having got it quite correct on the north and south courses, correct just half the error which is found after that on the south and north course, in the regular swinging of the ship.

The warning at the head of this article is particularly important for ships of war after firing guns when on easterly or westerly courses; if the compass is then changed to north or south, and particularly if, after the firing, the change of course is effected under canvas, without the shaking of the ship's magnetism produced by the engines and screw.

The warning is also very important for ships steaming through the Mediterranean eastwards or westwards, and then turning south through the Suez Canal or north round Cape St. Vincent; and for ships steaming eastwards from America and then turning northwards or southwards into St. George's Channel.

NICKEL COMPASS NEEDLES.

Joseph Wharton has sent to the French Academy a marine compass with a nickel needle, constructed nearly after Sir William Thomson's model. Four similar compasses have been placed on Bordeau cruisers. It is proposed that the fifth should be put on a French ship for comparison with steel needles.—*Comptes Rendus.* [illegible]

Magnetic Storm of May 14, 15

The magnetic storm of May 14, 15, which was observed simultaneously in England, Chili, and Australia, and which made itself felt in the telegraph wires of Paris and Italy, was also perfectly observed in America. Mr. G. F. Kingston, director of the government observatory at Toronto, Canada, has kindly forwarded to me a tracing of his magnetograms, and I find that all the principal inflexions of the declination, as well as of the components of the intensity, bear a striking resemblance to those recorded at the Stonyhurst observatory. The correspondence between the two vertical force curves on May 14 is very remarkable for such distant stations. Comparing the times of the principal minimas in the V.F. curve, and of the chief maximum of the declination, we have the following results in Toronto mean time:—

	Principal V.F. min.	Secondary V.F. min.	Decl. max.
	h.m.	h.m.	h.m.
Toronto Observatory ...	6 17 ...	4 0 ...	6 39
Stonyhurst Observatory	6 42 ...	4 20 ...	6 54
	0 25 ...	0 20 ...	0 15

The disturbing force would there appear to have been felt somewhat earlier in Canada than in Europe.

The extent of the extreme oscillation of the V.F. magnet cannot be compared, as that at Stonyhurst was too sensitive, and was excessively thrown off its bearings; but the rapid movement of the declination needle immediately preceding the maximum was almost identical in England and in Canada, the Stonyhurst curves showing a rise of 38 30′ in less than twenty minutes, and that of Toronto an increase of 37 53′ in the same time.

It is important to note that I have used the terms maximum and minimum in reference to increase and decrease of ordinate, but it so happens that an increase of ordinate signifies a decrease of H.F. and V.F., and also of W. declination in the Toronto curves, which it shows an increase of all these elements in the magnetograms of Stonyhurst.

S. J. Perry

Stonyhurst Observatory, December 28, 1878

— — ongnetic Storm, may 14, 1878

I am inclined to think that Mr. Mance's observations (vol. xlv. p. 148) upon the earth currents observed at Barcelona have been incorrectly reported. To agree with the observations in China, Stonyhurst, Greenwich, and Hawsterhaven, they should have commenced at A.M. on May 15, and terminated at 5 P.M. on the same day (Barcelona mean time).

It is a pity that short times do not record these currents in absolute units. To say that the current was equal to one Daniell cell means nothing unless the resistances present are also given. If an earth current is observed to exist in a cable it is easy to reproduce the current upon the same galvanometer with a known resistance and a known electromotive force, and then to express its value in ohms or millionohms. Thus if at Kurrachee the deflection through a total resistance of 125 ohms, then the current would be equal to $\frac{E}{125}$, or 5 millionohms, a magnitude which every electrician would understand. Moreover, if the length, resistance, and general direction of the cable or wire were given, as well as the direction of the current itself, the difference of potential of the earth at the two ends would be known. This if the cable were 246 Se per mile, then in the above case

$$E = \frac{\text{Se}\Omega}{1230}$$

$$E = 5^{\text{Se}}/_{246} \text{ volts},$$

which is the difference of potential at the two ends.

If simultaneous observations were made in this way at numerous stations on the earth's surface, we should be able to plot out the distribution of potential on the globe, and arrive at some better knowledge of the cause of earth-currents than we have at present.

December 20 W. H. Preece

A DELICATE MAGNETIC NEEDLE.

[3333]—A. Perry has constructed a delicate magnetic needle suspended by a method new to me, and as it is so sensitive I think that a description of the principle may not be uninteresting to those who have never previously tried such an arrangement. The needle may be made as follows:

Take a piece of fine wire, well magnetised, and covered all over with a thin coat of tin by means of gravity by a light covering through which one tiny hole is made, just large enough for the insertion of the point of another needle. A second needle is magnetised, and the point is placed in the hole just mentioned. On touching the middle portion of the first needle the magnetism in the point of the second needle is reversed. If the second needle is held vertically, the first will point north and south, and will have a few vibrations to a local place. The whole arrangement resembles a letter T, the vertical needle being held in the hand or fixed in a horizontal piece of ebonite.

The horizontal needle loses from the other if not carefully handled, but at the same time it becomes very sensitive to small local errors in the vertical. On resting it from top to bottom of all the vertical iron bars within reach, the needle has proved these bars to be temporary magnets by influence of the earth's magnetism. One end of the needle oscillated before the upper half of each bar trial, but the other end of the needle attended before the lower half of the bar. The bars were then placed in the opposite way, so that the ends had been turned up and down in front of the upright permanent magnet. On testing with other needles, differently suspended, they pointed with either extremity to the whole length of the vertical iron bar, and hence it is evident that the bars were magnetic through the inductive action of the earth.

The light needle was found to be reversed by means of the horizontal needle to present its skyward.

[3331.]—Variation of the Compass.—In plotting colliery or other plans with surveys made with the magnetic needle, I have often first great attention should be given to the time of the magnetic meridian, as the accuracy of the survey depends. Plan observations being made of the variation with which it was plotted, and of all subsequent surveys made, the error at that original variation. The changes of the compass with the magnetic needle possesses of various kinds, and the knowledge of variations of the compass—sufficient differently disregarded to allow extensive workings to be a very large error. "T. P." must therefore allow for the difference of 5° 31′ in plotting surveys made now with the 1878 variation. For the 1st of July, 1878, the variation is 19° 31′ W.

[3334.]—Variation of the Compass.—Can any reader who desires the true north and south at any colliery must observe the variation of this year or at whatever time for such course to be added if west, or deducted if east of Greenwich. 3. Have a true meridian line, and observe it as a datum. When properly adjusted, the statements for observed to the selected meridian line, and the variation. When the compass has become quite steady read off the number of degrees between the north point, as the compass, and the 360° of the circle. Should the needle pass to your plan which are still to be found, it is the variation required. Carefully note on the plan the angle which the alignment of the two points makes with the meridian north on the plan. Then observe the angle which the said two points make on the land with the true north, and the difference will be the variation. The difference of the said angles, one of the old plan, the other of recent observation, will show how much the magnetic north has varied (or is supposed to have varied) since 1793, the date of the old plan. Thus, in the old plan, the angle which the two points made with the north point was 20° 30′ east, which will give a new angle showing the true north as the old plan. For example, the magnetic variation now observed is 19° 45′ west of north. Then the angle which the two points make with the true N. is 20° 30′ + 19° 45′ = 40° 15′. The alignment between two known points answers on the ground to 39° 30′ from the magnetic north marked thereon. But on remeasurement on the land it measures, say, 21° 25′. Then the difference, 21° 25′ from 39° 30′ = 2° 5′, is the error of the alignment of those two points from the magnetic north. Then, as the angle which the two points made with the old plan was 20° 30′ east of true north, we have 21° 25′ − 20° 30′ = 55′, the angle which the true north must be plotted to the new 360 west of the alignment. I know this is clear enough for "J. P." [illegible] Dewar.

CURIOUS FACTS IN MAGNETISM.

At the meeting of the New York Academy of Sciences February 17th, the article in the March number of *Harper's Magazine*, entitled "Gary's Magnetic Mouse," was incidentally alluded to, and Prof. C. A. Seely made the following remarks: The article claims that Mr. Gary has made a discovery of a neutral line or surface, at which the polarity of an induced magnet, while moving in the field of the inducing pole, is changed. The alleged discovery appears to be an exaggerated statement of some curious facts, which, although not new, are not commonly recognized. If a bar of iron be brought up, end on, near a magnetic pole, the bar becomes an induced magnet, but an induced magnet quite different from what our elementary treatises seem to predict. On the first scrutiny it is a magnet without a neutral point, and only one kind of magnetism—namely, that of the inducing pole. Moreover, the single pole is pretty evenly distributed over the whole surface, so that if iron filings be sprinkled on the bar they will be attracted at all points and completely cover it. Now, if while the bar is covered by filings it be moved away from the inducing pole, the filings will gradually and progressively fall, beginning at the end nearest the inducing pole and continuing to some point near the middle of the bar; the filings at the more distant end will generally be held persistently. When the bar is carried beyond the field of the inducing pole it is simply a weak magnet of ordinary properties—*i. e.*, of two poles and a neutral point between them.

A plausible and simple explanation of this case is that the inducing pole holds the lines of the induced magnetism of opposite name, so that it has no external influence; the two magnetisms are reluctant to each other as are the positive and negative electricities of the Leyden jar. Let the inducing pole be N.; the S. of the bar will be attracted by it and bound, while the N. of the bar becomes abnormally free and active. On moving the bar from the pole the bound magnetism is reduced and a part becomes residual magnetism. Now when the residual balances the free magnetism which is of opposite name, we are on Gary's neutral line. In a restricted sense there is a change of polarity over the half of the bar contiguous to the inducing pole; the other half there is no change of pole in any sense. Experiment with a shingle nail in the place of the filings, *A la* Gary, bring the nail to the induced bound pole, and it may be held, except at the neutral line, where if one will read the magazine article with such ideas as these he will feel pretty sure that the writer of it has used words recklessly, that Gary has not made an original discovery, and that the "neutral" line, wherever it be, has only an imagined relation to the "principle" of the motor.

The Gary Motor as a perpetual motion scheme, of course, is not worthy of serious notice from a society devoted to science. It has no noteworthy variety of construction or conception. Mr. Gary is afflicted with the very old delusion of the out-of or shield of magnetism, which is to cost less than what comes from it. His cut-off is a sheet of iron, which we know acts simply as an armature.

New Use of the Magnet. 79

The millers of Minnesota have been annoyed a good deal of late by wires in the wheat, caused by the use of wire-binding harvesting machinery. At one time the matter had become so troublesome that they thought seriously of advising the disuse of such machinery. But a way has been found out of the difficulty by the invention of a simple and hitherto seemingly ingenious device consisting of two gangs of horseshoe magnets, four in one and five in the other, placed in a spout through which the wheat passes. The process of extracting wire from the wheat in this manner was exhibited before the Millers' Association, in session at St. Paul, Friday. The *Press* of the 8th inst. says: "By the severest tests it was demonstrated that every particle of wire was arrested. Numerous pieces, from the size of a pinhead to an inch in length, were mounted and mixed with a quantity of wheat, and being passed through the spout the exact number would be found opposite the magnets. The millers were highly pleased with the workings of the simple device, and it will be undoubtedly introduced into all the mills. The chief point of interest of this matter is the fact that this is not a patent, nor have its projectors any to sell. It is merely a hint to millers that with an outlay of a few dollars they can themselves put magnets into their mills which will obviate the objections hitherto urged against wire-binding harvest machinery. —*Chicago Tribune.*

Terrestrial Magnetism.—One of the most remarkable results discovered by Mr. Broun is the fact that the

variations from day to day of the earth's daily mean horizontal force were nearly the same all the world over. He finds certain coincidences in these daily means which were due to the moon's resolutions and others to a period of twenty-six days: the latter he considers are due to the sun's rotation. It results from these investigations that the observed variations of the earth's daily mean horizontal force have been represented with considerable accuracy in all other sealed features by the combination of the means calculated for these different solar and lunar periods. During the discussion of these periods Mr. Broun found that the great magnetic disturbances were apparently due to action proceeding from particular points or meridians of the sun, a fact of very great importance. In succession he has also traced the apparent simultaneity of the changes of daily mean barometric pressure over a great part of the globe, and the whole discovered a lunar-periodic period of twenty-six days nearly. He was also the first to commence and carry out a long series of most systematic notes of observations of the motions of clouds at different heights in the atmosphere; and, lastly, he has found certain laws connecting together the motions of the atmosphere and the directions of the line of equal barometric pressure.

Magnetism and Polarized Light.—An interesting experiment has recently been made by M. Henri Becquerel. Two rays of light polarized in the same direction were passed through a plate of quartz, and then subjected to opposite directions to the action of an electro-magnet, as in Faraday's experiment. On leaving from the lenses the two rays were brought into interference with each other; and it is observed that when the current passes in the electro-magnet the fringes are displaced in one direction, while when the current is stopped they are displaced in the opposite direction.

Mch 7 79

A NEW THEORY OF THE EARTH'S MAGNETISM.

At the last meeting of the Physical Society, on March 8, Professor Ayrton brought forward a new theory of Terrestrial Magnetism, originated by himself and Professor Perry, of the Imperial Engineering College, Japan. It is well-known that mental cages act on screens against induction in the case of static electricity, or electricity at rest, and hence Clerk-Maxwell, at the B. A. meeting for 1876, suggested that no earth connection was necessary for lightning conductors since a cage would be sufficient. But dynamic electricity is different from static in this respect, and Professors Ayrton and Perry found that even a thick block of copper will not screen a coil of wire from the induction of a *current* flowing in a neighbouring one. Some

experiments of Dr. Muirhead, not yet published, would seem to favour the view that a current is a series of intermittent changes of potential, and that the inductive effects are due to a difference in the epochs of the currents in the two coils. It was found by Helmholtz that a quantity of static electricity in mechanical motion performs work. Conversely, Mr. Crookes finds that the streams of molecules from a — pole in vacuo is electrified and may be deflected by a magnet. It is upon this fact that Professors Ayrton and Perry have based their theory, which is easily explained by supposing the earth to be an isolated sphere with a static charge residing on its surface. Then since each electrified particle at the surface will be moving relatively to a point in the interior, it follows that the interior must be magnetic. The theory is independent of the existence of the interior; but in order to simplify the working, the authors treated the case of a solid iron ball, and curiously enough arrived at the result expressed by Biot's law for the distribution of magnetism on the surface of the earth.

$$\delta = m\sqrt{1+3\cos^2}$$

and similarly they found that if the earth were electrified to the potential of 10^8 volts relatively to interplanetary space, its magnetization would be as it is. If the earth were alone in the universe then, by this theory it would have its own magnetic axes by virtue of its electric charge and axial rotation. If other bodies, in the universe, however, had their magnetic axes inclined, their magnetic influence the earth's, and hence we should have terrestrial tides and storms of magnetic force, such as are known to exist, as for instance when changes take place in the sun's atmosphere by approach of planets or other causes. Lastly, the virus in the interior of the earth may give it a certain amount of coercitive force, but the theory does not rest on this.

over

ON THE NEW THEORY OF TERRESTRIAL MAGNETISM. 79

To the Editors of Nature.

Sirs,—In your issue of the 24th of March appears a very amusing review of the "New Theory of Terrestrial Magnetism" communicated by Professors Ayrton and Perry to the Physical Society at the meeting on the 8th inst., the fun of the article arises from a total misconception, on the part of the writer, of the point in question, viz. what to take whether "they have adopted their magnetic speculation to secure, varied, and repeated examination," as shown how completely he has lost sight of the fact that their theory is not based upon any doubtful experiments, but is a logical mathematical deduction from the experiments performed by Mr. Broun on Professor Hicholtz's (Helmholtz) theorem, and by Professor Helmholtz in the *Philosophical Magazine* for September, 1870, on the electricity (of which the reviewer makes absolutely no mention in his article) proved that a quantity of statical electricity in mechanical motion acted like a current in deflecting a magnetic needle.

Starting with this result Professors Ayrton and Perry have deduced the following conclusions: Since the points of the earth's surface have different linear velocities from those in the interior (although all the points rotate in the same angular velocity of rotation round the earth's axis) it follows that if the earth had an initial electrical charge, resulting of course in an enormous potential relatively to interplanetary space, the electrified particles would have relative motion to the remainder; and hence, as a direct consequence of the results of the experiments performed by Professor Helmholtz, the interior of the earth would be a magnetic field; and the conclusion, contrary to the assumption poised by the reviewer at the outset, is independent of the internal constitution of the earth, or the existence or not of other earths in the universe. By exactly similar reasoning it could easily be proved that external to the earth there is also a magnetic field.

Next they have deduced mathematically (again be it remembered without any special assumption regarding the constitution) that if the earth had an angular velocity of rotation round its axis ω, and a uniform charge of electricity e, there must be an electro-magnetic potential at any point inside the earth equal to

$$\frac{4\pi}{5}\omega e\, r\cos\theta,$$

and at any point outside the earth equal to

$$\frac{1}{5}\omega e\, a^5 \frac{1}{r^3}\cos\theta,$$

where the unit of length is the earth's radius, r the distance from the centre of the earth, and θ the angle that r makes with the equator.

Now the value of the magnetic intensity at different points of the earth's surface—existing with this electrostatic potential—will depend on the interior constitution of the earth, and will depend on their conclusion they assume that the earth is not in order to simplify the working, the authors treated the case of a solid iron ball, and curiously enough arrived at the result expressed by Biot's law for the distribution of magnetism on the surface of the earth.

$$\delta = m\sqrt{1+3\cos^2}$$

and similarly they found that if the earth were electrified to the potential of 10^8 volts relatively to interplanetary space, its magnetization would be as it is. If the earth were alone in the universe then, by this theory it would have its own magnetic axes by virtue of its electric charge and axial rotation. If other bodies, in the universe, however, had their magnetic axes inclined, their magnetic influence the earth's, and hence we should have terrestrial tides and storms of magnetic force, such as are known to exist, as for instance when changes take place in the sun's atmosphere by approach of planets or other causes. Lastly, the virus in the interior of the earth may give it a certain amount of coercitive force, but the theory does not rest on this.

Compasses with Nickel Needles.—According to the *Comptes Rendus*, Mr. Jos. Whanon has sent to the Académie des Sciences a marine compass with a nickel needle. Four such compasses constructed on a plan recommended by Sir W. Thomson) have been placed on Russian cruisers, and a fifth is to be placed on a French ship for comparison with steel needles.

---

formula for the distribution of magnetic intensity on the earth's surface, hence so far from agreeing with the reviewer that their theory of terrestrial magnetism is visionary, I cannot but feel that it has much weight.

Lastly, to put a rough approximation of what must be the difference of electric potentials between inter-planetary space and the earth, so that his own electric plaything alone combined with its known rate of rotation round its axis shall produce the earth's magnetism, we have calculated by the above rule, on a supposition of a solid iron globe of the size of the earth, and rotating with the earth's velocity, and have proved that a difference of potentials of almost a hundred million volts would be sufficient. Now, as they remark, there would be no difficulty in imagining such a difference of potentials, or a much higher one, to exist between the earth and space, if surrounded by an atmosphere of cells of interplanetary ether, of which the resistance is probably far higher than that of the best Crookes' vacuum, and experience has shown that some thousands of cells cannot cause a discharge across even a thin film of such a vacuum.

In the review there is given a confused description of the new body moving round the earth, and that I presume is the reviewer's version of the "magnetic ring" (mentioned in the introductory to his paper) by Professor Ayrton, and hence out, as he describes, by some unpublished experiments of my own, of the same way mentally senses do not exist, a body free from ponderability as they are known to do from static inductive action. But such a supposition, which is not necessary, and not at all affect the proposed theory of terrestrial magnetism, does not affect it in any way beyond on the other, the reviewer has been so unfortunate as to call the foundation

---

of the new theory, and so having raised a phantom of his own imagination has marshalled his forces to destroy it.

W. E. Ayrton.

Yokohama, Japan, January 24.

[We have not had the advantage of perusing Mr. Ayrton's paper (we hope soon to have the pleasure of reading it in extenso before our scientific publications); and this is the reason we permit at the meeting of the Physical Society, we had in form our opinion of the "new theory" from the—as it appeared to us—imperfect exposition of the author. If we should find it necessary to do so, in justice to Mr. Ayrton, we will give the writer further attention when his paper is published—Eds. N.]

At the International Meteorological Congress which will meet in Rome on April 14, the project of establishing an Arctic observatory at Nova Zembla, will be discussed. Electric and magnetic observations have been undertaken as part of the scheme of work which has been devised by Messrs. Weyprecht and Payer.

Magnetism and Clouds.—The auroral or magnetic circus is the name given to a remarkable set of meteorological circus orbits seen during auroral displays, and the Hon. Rollad Buchan, in the last *Quarterly Journal of the Meteorological Society*, argues that they are caused by the magnetic action of the earth or by atmospheric electricity. Cloud forms would seem to exist in the air at different levels in localities until a certain degree of condensation from the effect of external force is attained. Auroras and the phenomena of meteors are probably forces with this power. Mr. Buchan was led to this conclusion by observing an ordinary lunar halo, seen through cirrus clouds on the night previously known as Biela's night, on the night of Oct. 23rd, 1872, to change its form under the influence of the luminous waves of a meteoric shower.

Modifications of Ampère's Laws.—Mrs Marsden has communicated to the Vienna Academy the results of her investigations on the Theory of Application of Electro-Magnetic Rotation," which he embodies in the two following laws:—1. If a portion of a magnet rotates in the neighbourhood of an unmagnetic conductor, about an intersectional axis, then an impulse, a current will be induced within the conductor, but if a rectified hydrostatic pressure about its own axis, in the neighborhood of a magnetic pole, no current will be produced in it. 2. The rotation of a magnetic pole be produced in it. 2. The rotation of a magnetic pole around a rectified conductor about the pole produces the rotation of the conductor about the pole produces the rotation of the conductor about the pole produces an induced current. The first portion of the first law is a simple necessity relation; it has also been demonstrated by E. Naumann, and adopted as a fundamental law of the phenomena of unipolar induction. H. W. Weber, who first specially investigated the phenomenon to which Faraday invited attention, disputes the sufficiency of Ampère's explanation of the rotation of a magnet on its own axis when it is traversed by a galvanic current.—*Ann. der Phys. und Chem.*

the small lantern or shield. When the retaining catch is removed by similar means to those employed in connection with the striking mechanism of clocks, the notched wheel makes one-half of a revolution before it is again arrested by the catch, and in so doing it either closes the stop-cock and raises the shield so as to surround the burner, or vice versâ. If the stop-cock is closed the gas still continues to flow through the side passage, forming a minute flame which is protected by the shield. When in due course the warning cath is again removed, the notched wheel completes its revolution and the gas is fully turned on and the shield lowered. In Fig. 1

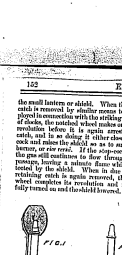

FIG. 1.

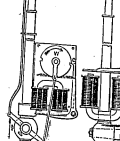
FIG. 2.

is shown the arrangement for turning the gas on or down by means of clockwork. In the case of the notched wheel W is merely fixed on a spindle S by a cord and weights, and on this the cord is passed through the coils of the clock mainspring, the free arm subsequently passing over and the wheel W makes a half-turn and moves the tap in the usually way. In the drawings the tap is represented by curved dots, the small flame being protected by the shield; on sending the cord through the circuit, which obviously may include a large number of lamps, the magnet attracts the armature, withdrawing the catch and allowing the shield to move in the direction of the arrow until the notch on the opposite side is reached. Each motion will of course lift the shield and cause a full supply of gas. See figure, the parts being set as represented each time the lamp is lit.

SEVERN'S TELL-TALE MARINER'S COMPASS.

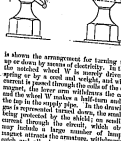
AN ingenious fisherman's compass for the use of masters of vessels has recently been patented by Mr. H. A. Severn, (Dublin New Zealand), a gentleman who frequently contributes to our columns, and who has already taken a position as a scientific instrument maker. The compass is represented in the accompanying illustration, and is intended to be placed in the captain's cabin, so that he can see at the wheel. It is obvious, however, that it may be hung in any other part of the vessel if he so chores to do. The compass itself is of the ordinary kind, but it gives a perspective illustration of the compass itself, and how much wilful deviation the captain the method of its action. An ordinary compass card carries a couple of magnetised needles on its lower surface, and attached to the centre of its upper surface is a metal bar C, which moves with the card. A wire two milled heads below leads, B B'. The milled headscrew actuates the globe lid of the compass box, the handle are fleshy, and at the free ends carry heavy platinum wires, D D', Having ordered the vessel to be kept on a certain course, the captain sets his tell-tale compass—allowing a certain amount of latitude according to its form it necessary to steer close'or free—by putting the index heads B B' at a greater or less distance on each side of the bar C. The point carrying the card is connected to one pole of a constant battery (four Leclanchés), and the milled heads with the index heads B, and the platinum wires D, are connected to the other pole. A bell is placed in the circuit which rings directly the position of the vessel alters the bar C in contact with one of the platinum wires The latter are made heavy enough to turn them the cards against the polarity of its needles, so that until the vessel is brought back to her proper course the bell continues to ring, and a pointer is fitted into the lid of a resonant box enclosing the whole apparatus, the sound is loud enough to be heard above the thrash of the engines in the forward part of the vessel. By the aid of this ingenious application of electricity, a captain can manage to remain with the exception of very fellows to carry out his orders, or any neglect on the part of the man at the wheel will be immediately detected, while those left in charge will naturally be more careful when they know that a detector is in the captain's ear. The compass can be used in the usual manner without the bell, by lifting the milled heads until the platinum wires swing clear of the compass box.



The invention will readily commend itself to all masters of sea-going vessels, as it takes from fellows there is a constant anxiety, inseparable from close attention on the part of the officers, and necessarily hard work. The compass is so arranged that it may be readily indicated differently to that of the binnacle, and therefore if little use as a check on the steersmen, but with the arrangement above described any deviation between the two compasses is at once apparent, because a stationary card is at that to be replaced.

LEESON'S ADJUSTABLE SPANNER.

AN improved adjustable spanner or wrench has recently been patented by Mr. W. H. Leeson, of Hopkinsville, Somerset, who sends us (39250) on p. 68. The invention is applicable to spanners and also to hand-screws, and depends mainly on the use of a toggle bar, so applied between the movable jaw and the shank or handle of the spanner as to cause the shank to be firmly gripped on pressure being applied to the jaw in a direction feuilloe to open the jaw. To release the jaw, the toggle bar is straightened and the movable jaw being pressed forward by a spring, the pressure on the shank is relieved. The toggle or lobster is applied between the shank and the movable jaw, and consists of a bar or bars of the spanner or handle of the shank of the bar or bars to distribute the pressure of the toggle bar. The upper surface of the shank of the jaw, the free end of this block and the edge of the shank along which the toggle bar moves are formed with a flange to prevent slipping. A spring is applied to bear on the toggle bar up to its shank and its teeth engage with those of the shank in order to hold the jaw immovable immediately pressure ceases apart from the act of loosening it. A spring is not absolutely necessary although it is preferable to use one, as the pressure caused in the labour and the strength of the movable jaw up to its work, a slight pressure is applied upon the releasing hook with the thumb. The releasing rod which terminates in a knob is attached to the movable jaw, and passes through a hole in the shank of the spanner, so that the knob is always within reach of the thumb. The end of the rod is bent at right angles to the shank of the spanner, and is provided with a projection which is adapted to engage with the teeth of the shank, and so hold the jaw in any position.



Proceedings of Societies.

PHYSICAL SOCIETY.—APRIL 26TH, 1879.

Prof. W. G. Adams, in the Chair.

Mr. C. V. Boys gave an account of some experiments made by Dr. Gothele and himself on the subject of Ampère's rotation. The experiments were begun with a view to determine if the drag on a copper disc when a magnet is made to revolve beneath it, or on the magnet if the disc is made to revolve above it, could be made use of for determining the velocity of running machinery.

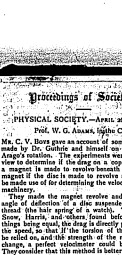
They made the magnet revolve and obtained the angle of deflection of a disc suspended by a torsion thread the hair spring of a watch. The disc was of Snow, Harris, and was found to have, that other metals, the speed of the drag depends properties not to be used as that if the torsion of the thread could be relied on, and the strength of the magnet did not change, a perfect voltameter could be constructed. They consider that this method is better than observing the deflection of a magnet over a resisting disc, as in this case they are limited to less than a right angle, and changes in the absolute magnetism of the earth would affect the results.

172: THE TELEGRAPH

They also determined the effect of change of distance, thickness, diameter and nature of the disc, &c., their results agreeing with those of former experimenters. They observed that the effect of concentric circular cuts was far greater than that of even many radial cuts; and that when radial sectors were entirely separated from each other the effect was much less than when these were united at the centre.

They then experimented on liquids by suspending a sphere or cylinder of the liquid between the poles of a revolving electro-magnet, and succeeded in getting a decided and measurable effect. The improvement of this is very great, for they have thus a means of determining the conductivity of liquid electrolytes by currents induced in the liquid without the useful electrodes and without polarisation.

Dr. Gottlieb states that as the push on the liquid is directly proportional to the current quantity, they hope to measure the conductiveness of liquids and connect these to the conductivity of solids through the intervention of mercury. Dr. Gothele stated that a conducting jelly made by dissolving gelatine in sulphuric glycerine at 100° was being prepared for trial.



Prof. Sylvanus Thomson then communicated five laboratory notes from University College, Bristol. The first relates to the source of sound in the Bell telephone receiver. Two theories are now being discussed as to this effect; the molar theory regards the motion of the diaphragm in mass as the source of sound, the molecular theory finds it in the molecular movements of the magnetic core of the instrument. Prof. Thomson applied his method of using rough cut curves with iron filings dusted on gummed glass to this problem. He found that there are curved lines formed in the telephone, the magnetic lines springing from the pole of the magnet, they gather together on the diaphragm opposite the pole, and spread out in the form which is represented lamellarly, or like a magnetic shell. The size of the plate beyond this region is, however, magnetised radially, the external poles n n being of the same name as that of the magnet, and between these two zones there is a neutral circle s s. It was remarkable, too, that the lines of force f f, touching the plate, were bent back around this circle forming a kind of valley v. When the current passed in the coil, in a direction so as to reinforce the magnetism, the lines are gathered more closely on the central region of the plate. If the current diminishes the magnetism, the lines are, on the other hand, repelled from the plate. The neutral ring is also silenced. In the first case it shrinks in size, in the second it expands. A small, thick disc is wholly magnetised lamellarly; a disc entirely magnetised radially becomes slightly conical in shape. In the actual telephone the disc is flat at the middle and conical at the edges. As the neutral ring shifts, the diaphragm will assume new radial lines. Dr. Thomson concludes that the molecular theory is not, therefore, necessary to account for the speech of the telephone, although it may exist. As confirming this view, he found that with iron, ring-wound a cardboard diaphragm and an iron core gave the enunciation was good though the timbre was altered; whereas, with radial pieces of iron on the cardboard, the timbre was good but the enunciation bad. In reply to Prof. Adams, Dr. Thomson said that the stronger the magnet the smaller the lamellarly magnetised space became, and that with a thicker disc the neutral ring was not so well marked.

Dr. Lodge suggested that the best place for the coil would be in the valley over the neutral ring which was in no unstable condition. It is also worthy of remark that the lines curve round the edge of the disc and project beyond the centre region n.

Dr. Thomson next wrote on a new blank with a magnet and dusted iron filings on it which arranged themselves so as to trace the writing. This is usually done on a steel plate, but a new retains the virtue for six or eight months. A modification of this experiment, due to Mr. Stroud, is writing on the blank with one pole of a powerful battery, the other pole being connected to the end of the blank.

The third "note" recommended the use of fine steel filings, got by breaking iron gauze of 24 meshes to the inch, instead of iron filings for exhibiting magnetic lines. The fourth note showed that the lines of force got by filings fixed on cards are magnetic, that of a bar magnet acting as a magnet. The fifth note explained that solid magnetic "figures" could be got by casting iron filings in shellac to make them rigid, and floating them in water; or by mixing filings in a wet paste of plaster of Paris, which could be cut into sections on hardening.

A. Bienfait a observé de nombreuses étoiles filantes et n'a jamais vu de mixte.

Modification des appareils d'Ampère. — M. Soubeiran répète facilement l'expérience de la rotation d'un aimant sous l'influence d'un courant au moyen de la disposition suivante (fig. 10). L'aimant est cylindrique et traversé par deux pointes. La pointe inférieure repose dans une capsule *a* remplie de mercure; la pointe supérieure est maintenue par un petit anneau *b*. Une courbe *c* est prise au centre d'une ouverture laissant passer librement l'aimant. On y verse du mercure qui, fermant un mini-que convexe, vient s'appliquer sur l'aimant. —*a* et *c* sont reunis aux pôles d'une pile; avec un élément Bunsen, l'aimant fait plusieurs tours à la seconde. L'expérience montre que la cuvette *c* doit être placée vers le milieu de l'aimant.

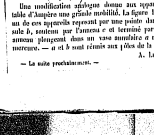


Fig. 9. Fig. 10. Fig. 11.

La modification adoptée donne aux appareils de la table d'Ampère une grande sensibilité. La figure 11 montre un de ces appareils reposant par une pointe dans la capsule *b*, soutenu par l'anneau *c* et terminé par un petit aimant plongeant dans un vase annulaire *a* rempli de mercure. — *a* et *b* sont réunis aux pôles de la pile.

— La suite prochainement. —

La corrélation du magnétisme terrestre et du rayonnement solaire

M. Ellis, directeur du département-magnétique et météorologique de Greenwich, vient de présenter à la Société Royale un mémoire *sur la relation entre la valeur diurne des variations de la déclinaison et de l'intensité horizontale et les périodes de l'apparition des taches solaires.*

Nous sommes heureux de trouver dans un travail si rigoureux toute l'exactitude du cercle dans un établissement célèbre, une confirmation indirecte des idées que nous exposons aujourd'hui même en tête de ce recueil.

Le rectenseur de cet éclatant scrupuleux établissement cherche à établir que les périodes magnétiques suivent les périodes de taches. Elles arrivent 27,066 d'années après, en enlevant tous les orages magnétiques. Si l'on se borne à faire la correction de l'inégalité annuelle, le retard tombe à 19,866 d'années. Possible serait-il admissible encore si l'on ne faisait pas de correction du tout et si l'on se bornait, méthode peu scientifique, à comparer les nombres que nous donne la nature. Car, les époques de maximum et de minimum concordent presque exactement pour le magnétisme comme pour les taches solaires, les variations de durée sont à peu près identiques, et les orages de magnétisme terrestre éclatent avec ceux de l'envelappe du soleil. Ils progressent ainsi dire, parallèlement elle à elle; ils finissent en même temps, comme si les uns et les autres dépendaient probablement d'une cause identique.

Expliquer cette intime liaison et se refuse de reconnaître l'universalité du magnétisme est une difficulté insurmontable.

Mais, ne pas trépaster les nombres sous prétexte de les corriger, est une idée trop simple pour être acceptée dans les observatoires.

ON MAGNETISATION OF STEEL DURING HARDENING.

IT is known that in proportion as permanent magnets, the steel is less hardened and then magnetised, because in hard steel, though the temporary magnetism is less, the fixation of the magnetism succeeds better. After Scoresby and De Senarmont proved, however, that the temporary magnetism of steel continuously increases — up to a dark red glow, it seemed possible, that remarkably powerful permanent magnets might be obtained if the magnetisation were effected during the very process of hardening. Experiments in this direction were made by Parelle in 1821, also by Hebbert, Abbe, and others. These researches, however, have not quite convincing in their results; partly because of the paucity of the experiments, and partly because of the lack of accurate description of how the methods used, and comparison of their results. Herr Holtz has therefore been led to take up the question anew, since, also, it is one of considerable theoretical and practical interest. His researches are described in the *Annalen der Physik*.

To get comparable results it was desirable to operate with two exactly similar steel bars, in the same way, with the same magnetising force, except that in one case the force should be made to act after hardening, in the other, during the process. As means of magnetisation Herr Holtz used in the first half of his experiments an electro-magnet, in the other a magnetising spiral. The current was supplied by one to three Grove elements. The steel bars were round and of various thickness. They were all 150mm. long, and from the same metals. The same bar could be used three times. A most important difference appearing in its magnetic behaviour. All the bars were quenched when red, and bright red, so that during the magnetisation all points had passed the dark red glow. Each pair of bars was heated to the required degree as regularly as possible in a wood charcoal fire; then one bar was quenched, and afterwards the other, after and while the magnetising force acted on it. The time of this action was fifteen seconds. Then the first bar was exposed to the same magnetising force for the same time. The time of magnetisation of both bars thus amounted to somewhat over thirty seconds, during which time the intensity of the current certainly remained constant. Other bars were being heated during the magnetising process. Then 20 to 30 pairs were ready in an hour, or 1½ hour. The magnetism was measured by the method of oscillation, each bar, suspended by a long cocoon fibre, being laid acting under the magnetic force of the earth, and observed with a telescope having cross threads.

We will not here pursue far the details of the two methods. Where an electro-magnet was used a portion of the end was left free of wire, and the coil was also protected from the water used in the hardening process by an envelope. The bars were fixed in holders, with which they were pressed against the last poles of the electro-magnet. In the case of a magnetising spiral being used, this was protected by being wound round a copper tube with caoutchouc, and surrounded by a metallic cylinder. The width of the copper tube was so chosen that the diameter of the thickest bar to be inserted, so that the water might get freely to the latter; and the renewal of the water by it insured by narrow the case in it. Experiments were made, in both cases, with constant and with variable magnetising force, the latter somewhat irregular.

The general result was, that the magnetisation during hardening is only conditionally worse than to ordinary magnetisation. The explanation of this follows from the behaviour of the iron at special points, which Herr Holtz expresses in the following propositions:—

The superiority of magnetisation during hardening decreases,

1. Where the magnetising force increases.
2. Where the thickness of the bar increases.
3. If it proceeds, where, with weak magnetising force, the bar is at the same time partly withdrawn from the action of the same magnetisation.

4. If is less, or passes into an inferiority, where with great magnetising force a great thickness of bar is used.

The third proposition is only a consequence of the first, the fourth a consequence of the first and second. Herr Holtz proceeds to indicate what circumstances the causes of these effects.

With regard to the practical bearing of the above, it appears that magnetisation during hardening could furnish magnets which, however are not limited in their power by the strength of the magnetising machine of installation. Their absolute strength was not remarkably small, because it was only with exceedingly weak magnetising force that so great a difference appeared. The more the latter increased, the more did the difference diminish, till at length the difference became in favour of the ordinary mode of magnetisation. With the maximum magnetising force used, three large Grove elements and a coil of 850 windings, a bar with even the thickness of 6mm. was better magnetised after hardening than during it. But for production of strong permanent magnets stronger forces would probably be used.

Nor did the permanent magnetism of the bars magnetised during hardening seem to offer a greater resistance to external influences.

The conclusion therefore from these and other considerations is reached that magnetisation during hardening presents no practical advantage whatever over the ordinary method of magnetisation.

Wm. V. De Pauls [illegible] 5 1849

A GIRL, 17 years of age, at Hamden, Ontario, is said to be a perfect electric battery. Very few can shake hands with her. By joining hands she can send a sharp shock through 18 or 20 people. Her magnetic attraction is so great that she cannot let go of any article of steel she has picked up. A paper of needles will hang suspended from her finger.

Ed. Journ. [illegible] 1849

Elias Journ. [illegible]

MAGNETIC INCREPENCE.—Herr Narr finds that the specific magnetism of magnetic ironstone is greater than that of any other magnetic substance known. Its magnetic susceptibility exceeds that of glass-hard steel, permanent magnetism exceeds that of steel, and is sooner neutralised by external forces than that of steel.

TESTING IRON AND STEEL BY ELECTRO-MAGNETISM.

June 7th

TWO interesting practical applications of electro-magnetism have recently appeared. In one it is applied to discovering the flaws of bars of steel; in the other to measuring the hardness of steel. The theory of the former principle was explained by Mr. Herring, an American mining engineer, in 1845. When an iron or steel bar is passed through a coil which is traversed by an electric current, the bar becomes a magnet. If the metal be homogeneous, the polarity of the bar may be inferred from known laws of electro-magnetism. If, however, there be a want of continuity of fibre at some point—a flaw, in fact—new poles are formed there, which a properly-mounted needle will readily detect, also giving a measure of the extent of the imperfection among those false poles. The apparatus is so contrived, then, that the wire or rod to be tested is passed horizontally first through a magnetising bobbin, then through a hole in a block of wood, which supports a nicely-balanced magnetic needle as magnetometer. The apparatus is, of course, adapted to the size, weight, and shape of the pieces to be examined. In testing plates the bobbin is flattened, and a number of magnetometers are mounted at short intervals on a bar, which can be moved to and fro in front of the bobbin and fixed at any desired distance from it. The new apparatus of Professor Tomlinson, of Dragon, for measuring the hardness of steel electro-magnetically, is a development into more practical form of a former idea of his. Its principle is that hardness of steel may be very correctly inferred from a numerical determination of its coercitive force. In its main features the arrangement is as follows:—From one end of a balance arm are suspended successively, in a horse holder, bars of the steels to be examined (these being as nearly as possible equal in weight). The other arm bears slidingly a movable coil, and bears a constant weight. Motion of the beam causes a pointer to move radially over a scale, the movement being magnified by toothed wheels. One of the steel bars having been suspended, the sliding coil, equal to it in length, is mounted on a stand so as to enclose the bar, and fixed with a binding screw when it dips. A galvanic current is sent through the coil; then the coil is released and moved gradually down, pulling the bar with it, till the latter is drawn away, and the deflection of the pointer is noted at which this occurs. This affords an estimate of the hardness of the steel. For example, a bar A gives a maximum attraction, 36°; a second bar, B, 100°; a third, C, 14°. It is inferred that A is harder than B, and B than C, and of the two latter C is harder than B.

Cautions are taken in the apparatus to prevent injury to the parts from the sudden recoil when the field of the coil on the bar ceases.

A MAGNETIZED WATCH.

A lady in Madrid, Me., who carried a valuable gold watch, was in a house last summer when it was struck by lightning. The watch stopped at the time, and, although jewelers have repeatedly examined it and pronounced it perfect in every particular, it cannot be made to move. It is so magnetized that watchmakers say no part of it could ever be made to do duty if taken out and put into another set of works.—*Springfield (Mass.) Union.*

L'ELECTRICITÉ

REVUE SCIENTIFIQUE ILLUSTRÉE

BEAUX-ARTS — INDUSTRIE — MARINE — ART MILITAIRE — MÉDECINE

2e SÉRIE — N° 11 — 5 JUIN 1879

L'ORIGINE DU MAGNÉTISME TERRESTRE

Sans l'étonnante propriété que possède l'aiguille aimantée de se diriger vers le pôle nord de notre hémisphère, l'Amérique ne serait peut-être pas encore découverte. C'est grâce à la connaissance de ce fait capital que le glorieux Génois brava la révolte de ses équipages et continua sa marche vers l'Ouest.

Mais l'application de cette puissance merveilleuse à la physique du globe reste encore à faire ; malgré les admirables travaux dont le magnétisme terrestre a été l'objet, les conclusions générales auxquelles nos plus savants prédécesseurs sont arrivés, sont ignorées du public et oubliées des académies mêmes dont ils étaient membres.

Nous allons essayer de combler cette grande lacune en rappelant les théories établies par Hansteen, directeur pendant un demi-siècle de l'observatoire de Christiania.

Quelque étonnant que soit le pouvoir directeur du globe terrestre, il n'est pas possible un seul instant de supposer rationnellement que cette merveilleuse propriété est particulière à notre sphère.

Autant vaudrait dire, comme on l'enseigne encore dans trop d'écoles publiques, que la Terre est la seule planète dont la surface est couverte d'êtres organisés, d'animaux et de plantes!

Pas plus que la vie, le magnétisme ne peut être le monopole de l'humble boule qui porte l'humanité et sa fortune!

Transportée dans tous les climats du firmament, l'aiguille aimantée éprouverait des orientations analogues à celles que constatent nos navigateurs en passant de l'équateur vers les pôles.

Si, par impossible, un aéronaut pouvait circuler dans le milieu céleste en dehors des limites de l'atmosphère, le pilote pourrait en regardant les vibrations de sa boussole se rendre compte de sa marche dans l'immensité.

L'intensité des soubresauts serait variable suivant la qualité et la grandeur du globe dans le voisinage duquel il passerait. Mais les approches d'un astéroïde seraient saluées aussi bien que celles d'un soleil.

Les astronomes qui nient l'universalité de la vie ne peuvent être convaincus d'erreur que par des raisonnements tirés de l'analyse spectrale ou de la constitution des météorites.

Tout en reconnaissant l'unité de matière répandue par le Créateur dans les espaces célestes, il leur reste cependant la ressource de prétendre que le groupement des molécules qui permet la constitution d'animaux organisés n'est possible que dans les conditions de lumière et de température spéciales à la distance du soleil où le hasard nous a placés; ils peuvent, à la rigueur, soutenir que les extrêmes limites sont, d'une part, les régions inférieures de l'air, et de l'autre, le fond des gouffres océaniques.

Ils peuvent soutenir que ce carbone qui tombe des plages lointaines du système solaire ne peut organiser autre part qu'à la surface de la terre des cellules vivantes.

Ces débris de mondes explosionnés ont beau ne révéler même aucune nuance nouvelle au microscope ou au spectroscope de nos chimistes, l'obstination de ces astronomes peut résister à cette éloquente analyse, en se réfugiant dans les conditions climatologiques.

Il n'en est pas de même pour le magnétisme terrestre. En effet, l'aiguille aimantée nous indique, par ses oscillations mêmes, que les deux astres principaux, le soleil et la lune, sont doués d'un pouvoir de nature identique.

En suivant avec soin les oscillations de la boussole, les physiciens ont reconnu, à l'aide d'un nombre infini de mesures précises, qu'elle ne se dirige pas constamment vers le nord, mais qu'elle s'en écarte de petites quantités. Les choses se passent comme si, malgré ses liens invisibles, elle cherchait à suivre encore les mouvements de ces deux grands

No. 184.

2020

be introduced, the difference can be at once detected by the sound. Thus, if a couple or of sovereigns/rods from the Mint be placed one in each hand, the balance is not upset; but if one of these coins be subjected to a very slight degree of attrition, the balance is destroyed and the ticking of the clock becomes audible. In this way not the existence of impurities in metals, or of inequalities in alloys, but minute to be discovered by analysis, are instantly detected, while perfect similarity is also as instantly proved. Many very interesting investigations with an instrument embodying the principle have been carried out recently at the Mint by Mr. Chandler Roberts.

From this brief description it will be seen that the value of the Hughes induction balance is not confined to telegraphic uses, but has wide and varied applications, many of which have been facilitated by the discovery Hughes himself, who has thereby placed in the hands of the scientific world the means of obtaining an electrical balance on scientific principles as it is simple in principle and construction.—*Engineering.*

ON SPIRALITY OF THE ENERGY IN BAR MAGNETS.

By R. C. SUTCLIFF, M.D.

1. THE very extensive field of research as to the cause of magnetic and diamagnetic phenomena has been brought within the compass of a brief paper by a new method of investigation and the discovery of the law regulating the force upon which the phenomena depend.

2. The method consists in an examination of the lines of force in bar magnets of a few powers, by means of test magnets made from the points of the finest needles; such test magnets being suspended with the greatest delicacy.

3. The great sensibility of these needles thus suspended possess as methods of research must be obvious—

First.—From the fact that the lines of magnetic force are always projected in lines of greater or lesser curvature, and

Second.—From their extreme lightness and delicacy of suspension they are capable of being moved by magnetic force of very low power.

FIG. 1.

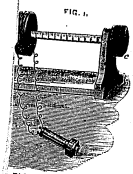

FIG. 2.

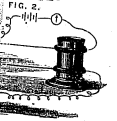

INDUCTION BALANCE.

It has been ascertained—

1. That the equator of a bar magnet is oblique and declinated.

2. That the impulses of energy or force pass from the equatorial direction to and the pole ends in oblique lines.

3. That similar impulses of energy or forces pass from the pole ends toward the equatorial direction.

4. That the moments or impulses of energy meet at a given point which is called for convenience of description the centre of balance, and that they then collide and are ejected in parallel lines from the side of the pole at each end.

5. That the energy which passes from the equator toward the ground line, for convenience of description is considered as that primarily induced, or the action which is disturbed by external force, the direction and energy of which action correspond with the direction and energy of such external force.

6. That the energy which passes from the pole end toward the ground line, for convenience of description—considered as secondary, or as the reaction, which according to Newton's third law of motion is always equal and opposite to action.

7. That this reaction takes place within the pole end in proportion to the capacity the body operated upon offers for the same.

8. That the power of exhibiting magnetic phenomena is also, and in proportion, to the energy with which these lines of force collide as they escape from the bar.

9. That the momenta impulses from either direction are oblique and characteristic by energy, which have forces—action and reaction—mutually exact as the colliding forces.

10. That this beverage increases from either direction toward the centre of balance, consequently the needle points resting on the magnet, and which are indices of the direction and degree of force, gradually becomes less oblique until at the centre line they take a direction at right angles to the axis of the bar.

11. That the reaction acquires a perfectly vertical direction

Exqueer July 1879

Mr. HENRY A. BESSEMAN, of Herne Hill, has associated in producing a marine's compass which enables the captain or officer in charge to hear, by the ringing of a bell, when the vessel is out of her proper course. The apparatus is contained in a small box which is screwed to the bulkhead, and is intended, as a rule, to be placed in the captain's cabin. The compass is mounted in gimbals which can be adjusted to any angle allowing a greater or less deviation in steering to either the port or starboard side. Assuming the captain, on quitting the deck, to have given instructions to steer the ship on a certain course, he sets the index hands to at that angle, allowing the requisite given limits for deviation, either to the right or left of that course. Should the ship be steered off her course beyond the limits allowed, the needle of the electric alarm will rise instantaneously and, moreover, continuous ringing until the right course is resumed.

Murray & Brooks July 14 1879

Magnetizing Molten Iron.

Mass., July 14, 1879.

In a letter to Dr. C. W. Siemens, and communicated by him to the British Society of Telegraphic Engineers, Mr. R. Cherneff records a very curious experiment. Believing that if it were possible to magnetize white cast iron a magnet of greater permanence than any made of steel would be obtained, Mr Cherneff cast some white refined iron in a mold, surrounded by an electro-magnetic reel, along which a current was allowed to flow during the process of casting, so that the fluid metal became magnetic, and cooled under the influence of the magnetic current.

The result so far justifies the expectation as to give a magnetized bar of white cast iron; but the form of the bar and the coiling what was expected. On allowing the metal into the mold to cool until the metal set, Mr. Cherneff observed a singular agitation of the metal, which could not have proceeded from damp, as the mold was thoroughly dry. On cooling the bar proved to be hollow, the cavity being symmetrical and extending about two-thirds the length of the bar. The metal was thinnest just opposite the center of the reel, where it did not exceed the thickness of writing paper. The agitation of the metal in cooling is accounted for by the repulsion of the molten metal toward the poles of the magnet.

By casting under pressure it may be possible to obtain by this method extremely permanent and powerful magnets of white iron. Possibly also this experiment may lead to some useful modification of industrial processes for casting hollow cylinders without cores.

Sc. Am. Fire Electrical Alarm Compass

A short time since Mr. Henry A. Besseman, of Herne Hill, England, brought out an ingenious compass alarm for use on shipboard. Its purpose is to make the compass signal automatically any considerable deviation of the ship from a desired course. Over the compass card are placed two index hands which can be adjusted to any angle; and these hands are so connected with an electric alarm that the moment the compass needle passes the limit of variation prescribed an alarm bell will ring in the captain's office, and continue ringing until the ship's proper course is restored. In this way any departure from the ship's course, as ordered by the officer in command, whether due to the steersman's inattention to duty or to a misunderstanding of the orders given, will be instantly made known. The officer on the other deck gives his orders to the steersman as now, the index hands to correspond, and after that he is relieved of the necessity of constant observation of the compass to be sure that his order is strictly carried out.

This invention is just now receiving much attention in the scientific and other journals in England; and it is extensively described as novel as well as unlikely to be useful. In novelty, however, is open to question. In principle, and apparently in mechanical construction, it is substantially identical with the electro-magnetic attachment to ship's compasses invented in this country by Alfred Fauvest, July 15, 1872.

The essential part of the claim for this patent was the construction and arrangement of a compass, so that, by reason of any material variation in the route of the vessel, the needle of the same would close an electrical or magnetic circuit and sound an alarm.

The apparatus was in demonstrating the practicability of this system was made in this city by Mr. William F. Heinke, model maker, now at No. 32 Park Row. Why the invention has remained so long undeveloped is not known.

Sc. Am. Aug 9 1879

Magnetization of Molten Iron.

To the Editor of the Scientific American:

In your issue of July 26 I notice a report of "Magnetizing Molten Iron," the experiment having been made by Mr. Cherneff and reported by Dr. C. W. Siemens. I do not know that it is a matter of much importance, but believe I was the first person to try the experiment, which I did in the foundry of the Fall River Iron Works in 1872. I had never thought it important enough to report in the scientific press, though I at the time reported it to some of my friends, among them Prof. John H. Appleton, of Brown University; Prof. Barker, of Pennsylvania University; and afterward Prof. Farmer, of the U. S. Torpedo Station.

I had two objects in view, one of which was the production of powerful permanent magnets, the other the application of malleable iron by a polarization of the atoms in the direction of the current, during the change from a molten to a solid condition. In the first I failed, as I believe every one else will; for, since heat destroys a magnet, heat will also prevent permanent magnetization. In the second I succeeded to a certain degree, and samples of the iron I made, heated to a cherry red, and drawn under the hammer to chisel points, are now, or were at one time, in the possession of Mr. A. A. Pope, President of the Cleveland Malleable Iron Co., and of Dr. W. W. Keen, Philadelphia.

If it would be of sufficient interest, I will send you a sketch of my apparatus and description of my experiments. I made use of the 60 cup Bunsen battery, of Brown University, kindly loaned me by Prof. Appleton, and was unable to carry the experiment to the end I would wish, because of the evolution of nitrous acid from my battery, which nearly suffocated the workmen at the foundry. I would like to try it again with a powerful Bunsh machine, for the results were very interesting.

My bars of iron came out of the mould solid, and if hollow ones were produced, by some one else, the reason must be sought in some defect of making the mould or pouring.

A New Theory of the Earth's Magnetic Poles.

From a study of the movement of the compass-needle produced by declination at London, Mr. R. G. Jenkins, of the Royal Astronomical Society, has become convinced that the various variations of the needle during the last 300 years can best be explained by the supposition of a strong magnetic pole above the earth's surface, and revolving around the geographic north pole in about 500 years. The only other magnetic pole, as ordinarily believed by Halley and Hansteen, is the one which is supposed to explain all the phenomena of terrestrial magnetism, but he places these poles at the earth's surface in the antipodes. These poles he regards as the free ends of as many loops of the earth's solid, ferruginous crust like the vicinity of the north pole to the equator, the other two coming down from the south pole to meet them, the highly magnetized of the northern belts uniting with that of the natural magnetism of the southern belts about the magnetic equator. These bands he believes to penetrate at about equal relative distances the poles of the earth, producing secular variations.

It will be observed that Mr. Jenkins describes the magnetism of the northern hemisphere as "normal." Contrary to the current theory, he holds that the north end of the compass-needle is a true north pole, and that the facts observed, when properly understood, in full accord with the great magnetic truth that like poles repel and unlike poles attract.

After adducing the evidence in favor of this view, Mr. Jenkins argues in this wise: If the north end of the needle is attracted to a south pole, pointing to the ground in Scotland (where Sir James Ross located the south magnetic pole) must be attributed to attraction. If it is attracted it is attracted by the magnetism in the crust of the earth at or in the center of the globe. If there is something in the earth's crust which attracts the needle in Scotland, it ought to attract the needle in London. But the needle in London is attracted westward, as the crust at Scotia ner to the earth's center. Again, Mr. Jenkins says, that the north pole of the needle pointed to the ground almost perpendicularly in Scotia became it was attracted by the true north magnetic pole in the atmosphere above that region when Sir James Ross was there 30 years ago.

Further evidence as to the existence of the alleged magnetic pole above the earth's surface is promised. Meanwhile, it is of the first importance, Mr. Jenkins thinks, that it should be clearly settled whether the magnetic variations are or above the earth. According to his calculation it should now be in latitude 72°, longitude 112°, in Prince Albert land.—*Scientific American.*

THE COMPASS.—The secret of the mysterious of a large compass [illegible] of the ship's head upon [illegible] of a large [illegible] is the simultaneous [illegible] three of a large [illegible] in the [illegible] period were by the methods of [illegible] in common use. In some [illegible] the *Admiralty* "card, pivoted for use in stormy weather] there is a swelling in the middle of each of the steel needles to make them heavier; in others heavy brass weights are attached to the compass cards as near the circumference as may be, being sometimes, for instance, in the form of a small brass [illegible] almost the inch and a half in diameter. Another method, scarcely less scientific, is to bind the bearing-point by grinding it or striking it with a hammer, as has not infrequently been done to render the compass less lively. Still another is the cup with brick-dust, as is reported by the Liverpool Compass Committee to have been done at sea by a captain, who was surprised to find after using it that his compass could not be trusted within a couple of points. All these methods are founded on the idea that friction on the bearing-point is the cure for unsteadiness. In reality, friction introduces a peculiar disturbance of a very serious kind, and a very ineffective in remedying the proper unsteadiness of which something is essential and inevitable in a compass on board a ship. Some time due east or due west.

Electro-Measurer of the Hardness of Steel.

A new apparatus has been produced by Professor Wattenhofen, of Prague, for measuring the hardness of steel electro-magnetically. Its principle is that hardness of steel may be very correctly inferred from a numerical determination of its coercive force. In its main features its arrangement is as follows:—From one arm of a balance arm are suspended successively, in a brass holder, bars of the steels to be examined—those being as nearly as possible equal in weight. The other arm holds obliquely downward, and bears a constant weight. Motion of the beam causes a pointer to move nobly over a scale, the movement being magnified by toothed wheels. One of the steel bars having been suspended, a magnetizing coil, equal to it in length, is raised on a stand so as to inclose the bar, and read with a leading screw when it does. Then a current is sent through the coil; then the coil is released and moved gradually down, pulling the bar with it, till the latter breaks away, and the deflection of the pointer is noted at which this occurs. This affords an estimate of the hardness of the steel. For example, a bar, a, gives a maximum attraction, 9·6; a second bar, b, 10·6; a third, c, 11·6. It is inferred that *b* is considerably harder than *a* and *c*, and of the two latter *c* is harder than *a*. Precautions are taken in the apparatus to prevent injury to the parts from the sudden recoil when the hold of the coil on the bar ceases.

1003. Magnetic Apparatus for Operating Pendants, *R. Sandeman*, Great Bed Street, Clerkenwell, Middlesex.—Dated 2nd April, 1879.

This invention consists in the employment of electro-magnetic apparatus for the purpose of causing the striking of a mechanical bell or gong at any desired moment, and for any desired number of times in succession, by the action of a clock or watch, or by the action of any other mechanism capable of giving motion to a suitable contact-maker at the moment when the striking is required to be effected, which contact-maker is thereby caused to complete an electric circuit, and so to form a temporary connection between the source of electricity, the coils of which, when acted upon by the current, form a magnet, and the bell, gong, or [illegible]

54

An Electric Alarm Compass, which, from its description, promises to become a valuable adjunct to the mariner's compass, has been devised by Mr. Henry Al. Stevens. The purpose of the device is to make known to course, should the man at the wheel fall asleep or misunderstand his instructions. Without attempting a description of the attachments, which would be difficult of comprehension without an engraving, it will suffice to say that it is applied in connection with the compass so to sound an alarm should the vessel deviate from her course beyond a certain limit, which is permit to be arranged at pleasure. The alarm is given automatically by the striking of a ring until the ship's course is righted, when, consciousness returning to the helmsman, it ceases. The value of the device is too obvious to be dwelt upon. A full description will be found in London *Nature*, July 3d.

The electro-magnetic rotation of the plane of polarization of light in gases has recently been proved and studied variously by Kundt and Röntgen, Bichat and H. Becquerel. The last-named observer, by a superior method, measured the phenomenon especially in ordinary coal gas, while the others demonstrated the rotation in sulphide of carbon vapour, gaseous sulphurous acid, and sulphuretted hydrogen. In a paper to the Vienna Academy, Prof. Lippich, of Prague, describes additional experiments on the subject. He aimed especially at perfecting the optical part of the apparatus, and attained remarkable accuracy. He succeeded in demonstrating the rotation *in air*, using a large coil of 5 metres long, with 365 m. length of copper wire (nearly 3 mm. thick) in twelve layers. The current was from sixty average Bunsen elements, combined in a battery of thirty double elements. The light-ray was simply sent through the hollow part of the coil. Under these circumstances an unmistakable electro-magnetic rotation was observed, and it was in the direction of the current coursing round the air. The angle of rotation could not have been far from 6 to 10 seconds of arc. (An exact determination was not possible, owing to the provisional arrangement of the optical apparatus.) *Nature*, July 24 1879.

Eine Abbilde ist darum durch ein Mittel, womit sich ein Schiff mit den anderen über seinen Cours verständigen kann, von höchster Bedeutung. Und dieses Mittel besteht lediglich in einem verbesserten Ziffernblatte für den Compass, der in seiner ursprünglichen Einrichtung nicht die geringste Veränderung erfahren, sondern nur an den gewöhnlichen Stellen mit den Zahlen und Inschriften versehen werden soll, wie sie die hier mitgetheilte Abbildung zeigt.

Die Ziffern, welche einer jeden Richtung oder den Inschriften auf dem Compasse beigefügt sind, zeigen die Signale an, welche ein Schiff mittelst der Dampfpfeife zu geben hat, um seinen Cours anzudeuten, und zwar ähnlich, wie bei Feueralarmsignalen der District bezeichnet wird, in welchem es brennt. Steuert z. B. ein Schiff im Nebel genaulenus nach Nord, und der Schiffskapitän will ein in der Nähe befindliches Schiff seinen Cours wissen lassen, so giebt er das Signal 212 vermittelst zweier rasch aufeinander folgender, dann nach einem kurzen Zeitraum mit einem, und dann nach einem gleichen Zeitraum wieder mit zwei aufeinander folgenden Pfiffen (11—1—11), und der Kapitän des anderen Schiffes sieht sofort auf seinem gleich eingerichteten Compass die Lage jenes Schiffes, kann auszeichnen und dem Nachbar antworten. So verhilft es sich mit allen den durch Zahlen angegebenen und verschiedene Richtungen bezeichnenden Mittheilungen, wie es sich aus der hier beigefügten Abbildung leicht ausfinden lässt.

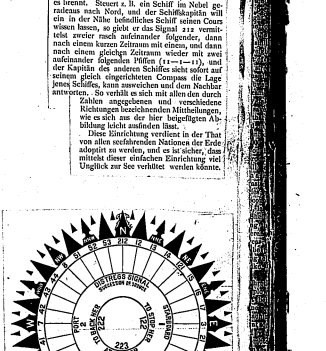
Dieser Einrichtung verdient in der That von allen seefahrenden Nationen der Erde adoptirt zu werden, und es ist sicher, dass mittelst dieser einfachen Einrichtung viel Unglück zur See verhütet werden könnte.

Der Techniker 1879

Hughes' Nebel-Signal-Compass.

Es sind schon zahlreiche Versuche angestellt worden, ein System von Signalen zu ersinnen, mittelst dessen Schiffe in dunkler Nacht oder bei dickem Nebel die Stellung oder den Cours anderer Schiffe bestimmen und dadurch Collisionen vermeiden könnten. Aber dieselben sind entweder zu complicirt oder praktisch unausführbar gewesen. Nun aber hat Capt. W. Hughes, der seit vielen Jahren schon als Steuermann auf den zwischen San Francisco und Oakland fahrenden Ferryboooten thätig war, ein solches entworfen, das einfach, leicht anwendbar und zuverlässig ist.

Das Schallmittel für Schiffe, welche sich in nebligem Wetter nahe bei einander befinden, besteht in den Umständo, dass keines derselben weiss, welchen Cours das andere einhält. Dadurch können die schlimmsten Collisionen vorkommen, selbst wenn man auf dem einen Schiffe in Folge der Dampfpfeife von der Nähe des anderen unterrichtet ist. Denn in nebligem Wetter ist die *Richtung* des Tones schwerer zu bestimmen, und es ist dadurch kein Schutz gegen ein verhängnisvolles Unglück gegeben.



Hughes' Nebel-Signal-Compass.

Fog Signal Compass

THE TELL-TALE MARINER'S COMPASS.

A very ingenious apparatus for reducing the risks of navigation has lately been patented by Mr. Henry A. Severn, of Ilfracombe, which will be understood by the accompanying engraving. It consists of an ordinary seaman's compass placed in connection with a small battery, and so arranged as to enable the captain or officer in charge of the deck to ascertain at any time the helmsman's due course. It is placed in the usual binnacle, and having, on spotting the deck, the first orders as to the course to be steered, he is enabled by the ear alone to detect any departure from his instructions. In designing this compass, Mr. Severn utilised the constant pointing of the card, and the ever-varying position of the ship for the purpose of making and breaking metallic contact. A pair of brass bands placed above the compass card can be adjusted to any angle, the one hand to port and the other to starboard of the direct course, thus allowing for a given amount of deviation to one side or the other. If the ship is steered off her course beyond the limit thus allowed on either side, an alarm bell instantly rings, and will continue to ring until the right course is resumed. In our engraving Fig. 1 is a section and Fig. 2 a plan of the compass with its accessories, the battery and bell. In practice these several parts are placed together in a small box, and can be easily carried about, and can be placed in any part of the ship.

Referring to our engraving, L' and K' are two flat brass milled bands of which the latter is adapted for being conveniently turned about their centres by the fingers. These milled heads are on the upper surface of the metallic lid of compass, and are themselves metallically attached to the rod L, which passes through and rotates within the hollow tube K which is attached to the milled head K'. Both the movable bands pass through the socket I which is cemented in the glass lid. The milled heads can be made to revolve within the socket I, and the band L' rotates in either direction within EC. The socket I is placed in metallic communication with the zinc of brass around the lid by means of the covered wire H. Under the glass lid and attached respectively to the terminations of the wires H and G are fixed the two metal bands K', L'. At the ends of these bands are suspended platinum wires K², L², which are free to move in metallic contact with the brass zinc O and connecting cover C. The metal point for suspension of the card is connected by a brass bevel at B', and is connected with one pole of a few cell constant battery cell. Mr. Severn prefers to use the card two magnetised needles, and not in actual contact with the metal cone for suspension. B B' is the metal point, A' the brass centre, and A A the card. Attached to the top of the brass centre A' is a light metal arm A³, the end of which is made of platinum for a length of one inch. This metal arm is therefore in metallic communication with the zinc O attached to the pole of the battery. To complete the circuit all that is necessary is to bring one of the hinged wires K² or L² (either will do) into contact with metal arm A³, and if an electric bell is placed in the circuit it will ring whenever the contact is made. Availing himself of the ever stationary position of the compass card, and the ever varying position of the brass pointed end, Mr. Severn simply moves the two index bands and their hinged wires K², L², as to bring them respectively to any required distance on either side of the metal arm A³, and so long as the vessel does not vary her course (so as to bring one or other of the wires K² or L² into contact with A³), no alarm bell will ring. If, however, that distance is reached or crossed, the bell will immediately ring, but will stop as doing so the helmsman or movement is rectified. It will continue to ring till a variation continues, because the hanging wires K², L² are very easily influenced by the slightest velocity of the card and its needles. The experienced officer using this apparatus has merely to adjust the index bands by means of their two milled heads, to any angle he pleases, after the vessel is on her course, and in heavy or fine weather, by night or day, the alarm bell rings when the steering is bad. The metal bands can be raised 1/4 in. through the socket I, and the bands can be raised from free of the metal arm A³, and the hanging wires are then at their lowest position.

It will thus be seen that by the aid of this compass the captain, when below can ascertain, without any trouble to himself, when the steering is bad, or the vessel is out of her course, and can have her right at once, by night or day. It will tend to make it known instantly as both officers and seamen are below. Another important point is that it will give intimation at night to the officer on deck when the vessel alters her position by swinging around her anchors. In short, the bell-tale compass appears to be well calculated to aid in preventing the risks and dangers of both coast and ocean navigation generally.

SEVERN'S TELL-TALE COMPASS.

Fig. 1.

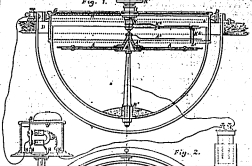


Fig. 2.

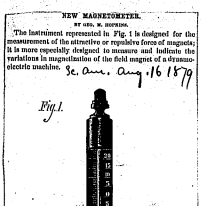
NEW MAGNETOMETER.

BY GEO. M. HOPKINS.

The instrument represented in Fig. 1 is designed for the measurement of the attractive or repulsive force of magnets; it is more especially designed to measure and indicate the variations in magnetization of the field magnet of a dynamo-electric machine. Sc. Am., Aug. 16 1879

Fig. 1.



NEW MAGNETOMETER.

The changes in the resistances of the current from the modern dynamo-electric machines effect a corresponding change in the magnetism of the field magnets. An indicator that faithfully shows these fluctuations will give a correct idea of the strength of the current. The instrument illustrated does this, and it may also be used in detecting the location of the greatest magnetic force in an electro or other magnet.

The instrument shown in Fig. 2 is virtually an electrometer, as it indicates the electro-motive force of the dynamo or magneto machine when its helix is included in the electrical circuit. These instruments are quite simple, and are nearly alike so far as the upper portion is concerned.

The horizontal metallic plate, which in one case is supported by the columns and in the other by three milled screws, is centered in the middle and supports a steel diaphragm that is held in place by the vulcanite cap secured to the plate by several screws, so as to clamp the diaphragm tightly.

The vulcanite cap is chambered out to receive mercury, and it has a stuffing box for holding a glass tube of small caliber. A vulcanite screw at the side of the stuffing box serves to adjust the height of the mercury in the tube. The graduations on the scale at the side of the tube represent the number of pounds of attractive force exerted on the instrument. The graduations from 0 upward indicate the degree of upward pressure when the force of repulsion is measured.

A short rod is attached to the middle of the diaphragm, and projects down through a hole in the base plate to receive in one case (as shown in Fig. 1) a convex soft iron armature, and in the other case (as shown in Fig. 2) a cylindrical armature or core which extends into the helix.

The instrument shown in Fig. 1 may be placed upon any part of the field magnet. The one end full of the mercury in the tube, resulting from a deflection of the diaphragm by the action of the magnet, constantly indicates the internal condition of things in the dynamo-machine. By bending the glass tube at right angles near the vulcanite cap the instrument may be applied to the side of the magnet. It may seem that the approach of the armature toward the magnet—thereby diminishing the distance between armature and magnet—would involve an error; but the motion of the diaphragm is very slight, and in a large magnet the variation of .02 of an inch in the distance between the armature and magnet is of no account.

The diameter of the diaphragm is 2 inches; the caliber of the glass tube, .02 inch; therefore a very slight motion of the diaphragm is indicated by a considerable movement of the mercury in the tube.

When the repelling force of a magnet is to be exhibited the soft iron armature is replaced by a permanent magnet.

The instrument shown in Fig. 2 may be placed anywhere in the circuit, and will indicate the strength of the current. An increase in electro-motive force results in the drawing in of the iron core and a consequent deflection of the diaphragm and movement of the mercury column.

The Electrical Alarm-Compass.

A short time since Mr. Henry A. Sawtell of Horse Hill, England, brought out an ingenious compass alarm for use on shipboard. Its purpose is to make the compass signal automatically any considerable deviation of the ship from a desired course. Over the compass card are placed two index hands which can be adjusted to any angle; and these hands are so connected with an electric alarm that the moment the compass needle passes the limit of variation prescribed an alarm bell will ring in the captain's office, and continue ringing until the ship's proper course is restored. In this way any departure from the ship's course, as ordered by the officer in command, whether due to the steersman's inattention to duty or to a misunderstanding of the orders given, will be instantly made known. Of course when the officer gives his orders to the steersman he sets the index hands to correspond, and after that the only interval of the necessity of constant observation of the compass to be sure that his order is strictly complied with.

This invention is just now receiving much attention in the steamship and other journals in England; and it is certainly described as novel as well as likely to be useful. Its novelty, however, is open to question. In principle, and apparently in mechanical construction, it is substantially identical with the electro-magnetic attachment to ship's compasses patented in this country by Alfred Fousnet, July 18th, 1820.

The essential part of the claim for this patent was the construction and arrangement of a compass, so that, by reason of any material variation in the route of the vessel, the needle of the same would close an electrical or magnetic circuit and sound an alarm.—*Scientific American.*

Tell-tale Marine Compass.

A very ingenious application of electricity to the purposes of navigation has recently been effected by Mr. Henry A. Severn, of Horse Hill, London, who has succeeded in producing a mariner's compass which enables the navigating officer in charge to befit, by the flagging of a bell, when the vessel is out of the ordered course. In the construction of this compass Mr. Severn has availed himself of the constant properties of the card and the ever-varying position of the ship for the purpose of making and breaking the metallic contact, which causes an electric bell to be sounded, and thus to announce the fact that the vessel is off her course. The whole of the apparatus is carried out in a small box which is easily carried about, and, generally, as a rule, to be placed in the captain's cabin. After the card are two index hands, which can be set to any point, so as allowing of greater or less deflection in steering to either the port or starboard side, according to the captain, so quitting the deck, takes with him instruction to steer the ship on a certain course; he sets the index hands to a point or two right, allowing the steersman a given latitude for deviation either to port or starboard of that course. Instead of having to be constantly watching the compass, as at present, to see that his orders are carried out, the captain leaves the instrument to tell him, by its silence, if they are, and by its sounding if they are not obeyed. Should the ship be steered off her course, beyond the limits allowed on either side, an electric alarm bell rings instantaneously, and, moreover, continues ringing until the right course is resumed. The index hands can be raised away from the card, when the ship requires characteristics, and the compass can be used in the ordinary way. It appears evidently this apparatus is calculated to be of much utility.

The metal point on which the card is hung is insulated from the compass bowl, and to it is attached a wire from one pole of a small battery. About an inch above the card, placed sensitively, is its surface and attached to its metal centre (which is insulated from the needle) is an arm of metal reaching nearly to the edge of the card. This arm is, therefore, in metallic communication with the wire from the battery already referred to. The glass lid of the compass has a short brass rod working within a tube passing through it. These are severally attached to two brass rings placed above the glass lid and to the two movable index hands beneath the glass. These are in metallic contact with the brass rods of the compass, and this with the other pole of the battery. Beneath the outer extremities of the index hands are suspended two pieces of platinum, the short brass rod passing of an inch long. These hands can, by means of the milled heads, be moved round to any position over any point of the card. Hence they admit of being placed on either side and equally distant and otherwise from the end of the metal arm on the card. It will thus be seen that whenever the platinum wires come in contact with the metal arm on the card the circuit is completed. The electric bell being placed in the circuit sounds whenever such contact takes place. The bell is disconnected by simply raising the milled head up half an inch through a sliding tube, and the compass then becomes in all respects an ordinary one. Two bells of different tones are used, and thus the instrument will indicate to the captain whether the deviation to steering is to port or starboard. The arrangement is simple and compact, and the invention promises to subserve a very useful purpose in navigation. By its use the captain will be saved much anxiety, and the knowledge that there is a check upon the careless or unobservant will no doubt give additional security, while in the case of vessels riding at anchor in a port or road this compass will at once give intimation of swinging—a matter of, importance, especially at night, when many vessels are together. In short, the dangers of navigation generally will be considerably lessened by its use.—*London Times.*

The Earth's Magnetism.

THE NEW THEORIES OF THE EARTH'S MAGNETISM.

At a recent meeting of the Philosophical Society, on June 29th, Mr. H. A. Rowland, Prof. of Physics in the John Hopkin's University, Baltimore, pointed out supposed error in the calculations by which Profs. Ayrton and Perry sought to establish their new theory of terrestrial magnetism. At that time, Prof. Rowland had not seen their calculations in full, so that he could not say exactly where the error occurred; but in the *Philosophical Magazine* for August, he, having at length seen their full working out, is able to point out the mistake, which seems owing to him in the sign of an exponent, where + 4 should be — 4. According to the correct results the earth in order to account for its magnetism by the new theory, would require to be electrified to a potential of about 4×10^{11} volts, a charge which would be sufficient to produce a spark in atmospheric air of ordinary density of about 6,000,000 miles. "It was," says Prof. Rowland, "this large quantity which caused me to reject the theory; for I now what an immense effect it would have in planetary perturbations; and I have even imagined to myself the atmosphere flying away, and the lighter bodies on the earth rushing away into space by repulsion. And, doubtless, had not Profs. Ayrton and Perry made some mistake in their calculation, by which the force was diminished 16×10^{22} times, they would have feared like results. For according to Thomson's formula, the force would be equal to a pressure outwards of

$$\frac{1}{8\pi} \frac{\mathrm{F}^2}{\mathrm{K}^2}$$

which amounts to no less than 1,850,000 grammes per square centimetre! or 10,000 kilos. per square inch! Such an electrostatic force as this would undoubtedly tear the earth to pieces, and dissolve its fragments to the uttermost parts of the universe. If the moon were electrified to a like potential, the force of repulsion would be greater than the gravitation attraction to the earth, and it would fly off through space. For these reasons I rejected the theory, and now believe that the magnetism of the earth still remains, as before, one of the great mysteries of the universe, beyond the solution of which we have not yet made the most distant approach."

But what if the earth's magnetism be the resultant of several causes, and the electrostatic charge of the surface, according to Profs. Perry and Ayrton, one of them?

Terrestrial Magnetism and Electricity.

Professors Ayrton and Perry, of the College of Engineering, Tokio, Japan, communicate to the *Philosophical Magazine* a short note, proposing the hypothesis that the phenomena of earth currents, terrestrial magnetism, and atmospheric electricity are due to the fact that the earth is an electrified condenser, whose capacity or potential is continually changing on account of its rotation and annual orbital motion, the successive cooling and warming of the air, the formation of clouds and rain, &c., etc. Thus changes produce electric currents tending always to restore the equilibrium, whence follow the phenomena in question. They suggest that observations of atmospheric electricity may be used to predict atmospheric changes.

Wymp Broun describes, in *Nature*, a new lecture experiment, to show the action of terrestrial magnetism. A rectangular frame of light wood, carrying twenty coils of insulated wire, was suspended in a horizontal position from the pans of a balance, so that the two sides of the rectangle were at right angles to the beam; and mercury connections were arranged at the middle of the short sides, so that a current could be sent through the wire. This apparatus being placed with the long sides of the rectangle perpendicular to the magnetic meridian, when the battery current passed from east to west on the northern side, and from west to east on the southern side, the north side would be attracted, and the south side repelled by the earth currents, both influences combining to deflect the beam of the balance. On reversing the current the deflection was in the opposite direction.

Terrestrial Magnetism and Electricity.

Profs. Ayrton and Perry, of the College of Engineering, Tokio, Japan, communicate to the *Philosophical Magazine* a short note, proposing the hypothesis that the phenomena of earth currents, terrestrial magnetism, and atmospheric electricity are due to the fact that the earth is an electrified condenser, whose capacity or potential is continually changing on account of its rotation and annual orbital motion, the successive cooling and warming of the air, the formation of clouds and rain, &c., etc. Thus changes produce electric currents tending always to restore the equilibrium, whence follow the phenomena in question. They suggest that observations of atmospheric electricity may be used to predict atmospheric changes.

William Leroy Broun describes, in *Nature*, a new lecture experiment, to show the action of terrestrial magnetism. A rectangular frame of light wood, carrying 20 coils of insulated wire, was suspended in a horizontal position from the pans of a balance, so that the long sides of the rectangle were at right angle to the beam; and mercury connections were arranged at the middle of the short sides, so that a current could be sent through the wire. This apparatus being placed with the long sides of the rectangle perpendicular to the magnetic meridian, when the battery current passed from east to west on the northern side, and from west to east on the southern side, the north side would be attracted, and the south side repelled by the earth currents, both influences combining to deflect the beam of the balance. On reversing the current the deflection was in the opposite direction.

New Theory of Terrestrial Magnetism.

Professors Perry and Ayrton have proposed the theory that the resultant of the earth's bounds the electrical charge originally and at all times present in the atmosphere may and is sufficient to account for the magnetism of the earth. They have also calculated the matter to a number, and find that the difference of potential between the earth and space necessary to produce a distribution sufficient to produce the observed magnetic effect can be represented by 54,000,000 volts. Professor Perry, according to this theory, that "if the earth be electrified, it must, from its very rotation, quite independently of all other bodies in the universe, be magnetic; and if it consist of a shell of iron, thick or thin, then that the law of distribution of magnetism produced by this electrical charge is mechanical rotation, will be identically that given by Biot; and, lastly, if the earth were wholly of iron, a difference of potentials of about 54,000,000 volts between it and space would be sufficient to produce the necessary amount of charge.—*Pub. Mag.*

New Theory of Terrestrial Magnetism.—The theory lately advanced by Professors Ewing and Ayrton, of Japan, to account for the magnetism of the earth, and which has provoked much discussion, is thus briefly summarized in the *Philosophical Magazine*. They find this cause in the rotation of the earth beneath the electrical charge originally met at the surface of the atmosphere. By calculation, they find that the differences of potentials between the earth and space necessary to produce would be represented by 51,000,000 Daniell cells. And, adds our authority, they prove that "if the earth be electrified, it must, from its very rotation, exhibit independently of all other bodies in the universe, be magnetized; and if it consists of a shell of iron, thick or thin, then that the law of distribution of magnetism produced by the rotation of the charge is mechanical rotation will be identical with that which exists; and lastly, if the earth were wholly of iron, a different law would obtain; the necessary amount of charge."

2e SÉRIE — N° 14 — 20 JUILLET 1879

ASTRONOMIE ÉLECTRIQUE

De l'origine du magnétisme terrestre

Nous avons rappelé déjà à plusieurs reprises les théories émises par le grand Haustcen, et protesté contre l'oubli dans lequel sont tombées les œuvres de l'archimède de Christiania. Mais il ne suffit pas de faire quelques allusions passagères à des travaux si considérables. Il est temps de leur donner successivement tout le développement que justifie la nature de cette publication.

En effet, malgré l'indifférence systématique d'un grand nombre d'astronomes et de physiciens, des idées analogues, mais bien moins grandioses, se font jour dans les *Comptes-rendus* de notre Académie de Paris et dans les *Mémoires de la Société royale de Londres*.

Pour peu que l'on réfléchisse quelques instants, on se n'étonnera pas que ces questions viennent enfin à l'ordre du jour. Ce qui surprendra, c'est qu'elles n'y soient pas depuis bien des années déjà.

En effet, il est impossible d'échapper à cette idée que la terre dans son ensemble est électrisée. Cette idée s'impose aussi bien que celle qui consiste à la considérer comme conductrice prise également dans son ensemble.

On voit même trois grands phénomènes naturels qui peuvent expliquer la présence de cette électricité primitive.

Le premier est le contact des mers et terres; le second le contact de l'air avec la surface terrestre, d'une part, et la surface océanique, de l'autre; enfin, le troisième l'échauffement produit par le mouvement diurne.

Mais si la terre est électrisée par suite de actions chimiques ou thermiques, est-il raisonnable, d'admettre qu'elle soit seule dans ce cas?

Le bon sens dira non; et les résultats de l'inspection des astres voisins de la terre répondront comme le bon sens.

Nous savons que toutes les planètes ont une atmosphère gazeuse comme la nôtre, que leur surface se compose de terre et de mers plus ou moins analogues à celles que nous connaissons; nous savons que toutes ont un mouvement diurne plus ou moins rapide; nous savons qu'elles sont formées de matière pondérable constituée à l'aide des mêmes éléments chimiques.

Il est donc incontestable que, prises dans leur ensemble, elles sont conductrices de l'électricité et que les mêmes actions chimiques ou thermiques qui se passent à la surface de notre monde ont des analogues dans le monde de Mars, de Jupiter et de Saturne. Il ne saurait en être autrement à la surface des planètes de Mercure, Vénus, etc., etc., plus rapprochées du soleil.

D'après leur plan primitif, Gauss et son élève M. Weber demandaient chaque année à leurs correspondants huit séries de quarante-quatre observations horaires. Mais, l'expérience ne tarda point à montrer que ces observations étaient trop peu fréquentes pour que les perturbations que l'on cherchait à étudier pussent être constatées. Car, des troubles considérables, se produisant dans l'intervalle, échappaient forcément aux observateurs chargés de les constater.

On se décida à les faire toutes les vingt minutes, pendant la durée des huit termes exigée.

Puis, on les rapprocha encore et on les fit de dix en dix minutes. Ces nouveaux intervalles de temps étant encore trop longs, on finit par prendre les lectures de cinq en cinq minutes, sauf à diminuer la longueur des huit termes.

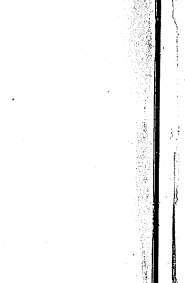
Enfin, l'invention de la photographie permit d'organiser des instruments magnétiques à indications continues, que l'on emploie maintenant dans un grand nombre d'observatoires.

L'histoire du développement de l'observation universelle est parfaitement identique à celui de l'Union magnétique.

PRACTICAL EXPERIMENTS IN MAGNETISM, WITH SPECIAL REFERENCE TO THE DEMAGNETIZATION OF WATCHES.—No. 5.

BY ALFRED M. MAYER.

Experiments which show Something about the Nature of a Magnet.—Take the piece of steel wire, six inches long and one sixteenth of an inch in diameter, mentioned among the articles required in our experiments; score this piece of wire at short distances apart, by filing it around with a sharp file. Now heat the wire to a cherry red, and then plunge it vertically into water. It will now be quite hard, and may be readily made into a magnet by drawing it over the pole of your rat-tail file magnet. Paste a small piece of paper around one of the ends of the steel wire before you magnetize it, and then, if you draw the wire over the N. pole of the magnet, from the papered end to the unpapered end, the papered end of the wire will have north polarity, as may be shown by applying the wire to the magnetometer. The magnetic condition of the wire having been found out, we begin by snapping the wire into small pieces, which is readily done, for the scores on the wire determine where it will break. Place each piece on the table as it is separated from the wire, and with its ends pointing in the same direction which they had when it formed part of the wire.



Examine each of these pieces in succession. They will be found to be perfect magnets, with N. poles turned all one way, their south poles turned in the other direction. This examination may be made by means of the magnetometer. The fact that each piece is a magnet may also be readily shown by rolling it in iron filings, when it will be found that the filings adhere to the ends of the pieces of wire just as they did to the large magnet. See Fig. 11.

Fig. 26 gives a view of the pieces of wire placed end to end just in the position they had when they formed parts of the steel wire. We see that each piece is a perfect magnet, and that the south poles of these pieces all point to the right and their south poles all to the left. But each of these little fragments may be broken into two, and so on; and as far as the unaided eye may be carried, it has been found that each minute fragment is a perfect magnet, with one of its ends a south, and the other a north magnetic pole. In imagination we may conceive of this subdivision carried so far that one of the particles thus reached may be invisible to the unaided eye. Indeed, nothing prevents us from logically assuming that even if a molecule of the steel should be reached it would be found to be a perfect magnet.

An Experiment with a Magnet formed of Steel Filings Packed in a Paper Cylinder, is interesting when studied in connection with the experiments just made, and will serve to give us further information as to the nature of a magnet.

Take a piece of letter paper, and having wrapped it several times around a lead pencil, paste the free edge of the paper on to that wrapped around the pencil. After the paste has dried you may draw out the lead pencil, and you will then have a tube made of paper. Cork one end of this tube, or you may close it by doubling over the paper at its end and gluing. Fill this tube with steel filings, and then close the other end of the tube. This tube, filled with steel particles, may be formed into a magnet by drawing it over the pole of your rat-tail file magnet. After you have performed this operation several times, present the tube to the magnetometer, and you will find one of its ends is a north, while the other is a south pole. Having thus satisfied yourself that it is really a magnet, shake the tube so that the positions of the particles of steel filings are changed. On testing the tube at the magnetometer it will be found that much, probably all, of the magnetism has gone from it. If it has not all disappeared it can be made to do so by repeated shaking of the tube. This experiment shows that not only must each particle or even molecule of a steel bar be a perfect magnet, but it also shows that these magnetized particles must be arranged in a definite order, that is, with all their N. poles pointing in one direction and their south poles in the opposite direction, so that the body, as a whole, may obtain and retain its magnetic polarity. Before the year 1600, when William Gilbert, the physician to Queen Elizabeth, made the celebrated experiment of breaking a magnet into many parts and testing the polarity of each piece, it had been thought that all of the north polar magnetism was contained in one end of the magnet, while the other end of the magnet held the south polar magnetism.

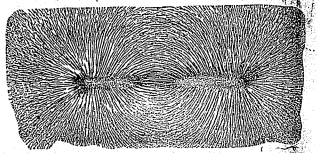


FIG. 24.—MAGNETIC CURVES AS SHOWN BY IRON FILINGS.

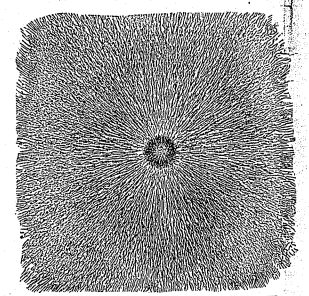

FIG. 25.—ARRANGEMENT OF FILINGS OVER THE END OF A ROUND MAGNET.

Interesting Experiments may be made with magnets acting inductively on a great number of iron grains spread on a surface placed over the magnet. We may thus form an idea of how this magnetic influence extends itself into space.

Take a piece of cardboard about one foot long and six inches broad. Support this at its corners on blocks of wood a little thicker than the diameter of your rat-tail file magnet. Place the latter under the cardboard. Now lift the cardboard off its supports and place it to one side on the table. Through a fine sieve sift soft iron filings evenly, and not too thickly, over the cardboard. Lift it up carefully and place it over the magnet. A slight bebeting of the filings is all that you will observe of the action of the magnet, but on vibrating the cardboard, by tapping it gently with a pencil, you will observe curious motions among the grains of filings. They will finally arrange themselves over the magnet in the curves shown in Fig. 24.

Fig. 25 shows the arrangement taken by the iron filings when they are placed on a card and vibrated over the end of a round magnet, the magnet being held in a vertical position under the cardboard.

Fig. 26 are the lines formed over the end of a magnet. Figs. 27 and 28 respectively show the actions of magnets with their unlike and like poles opposite each other.

Fig. 29 is interesting, showing the arrangement of the lines of filings produced on a surface when under it a magnet, 316 millimeters long and 13 millimeters in diameter, is acting inductively on a cylinder of soft iron, 32 millimeters long and 30 millimeters in diameter. In April, 1871, I published in the *American Journal of Science*, a method I had invented for permanently fixing these lines of iron filings (or *magnetic spectra*, as they are often called) on plates of glass. When thus permanently fixed these plates were used in a course in which a series of photographs were printed, exactly as a photographer prints from an ordinary photographic negative. The admirable engravings of magnetic spectra given in this article were made by a photo-engraving process directly from the glass plates made by me in 1871. These glass plates carrying the magnetic spectra I have also used for several years on slides in the lantern, in order to exhibit them before large audiences and college classes.

The following is the method of permanently attaching these magnetic figures to glass. A clean plate of thin glass is coated with a film of hard varnish by flowing over it the spirit varnish used by photographers in coating their negatives. If this is not handy, then a solution of shellac in alcohol will do nearly as well, only the latter requires more heating to cause the iron filings to adhere to it. The varnish is poured on one end of the plate, and then caused to cover the entire plate with an even film, by tilting and draining the plate just as a photographer does when he coats his plate with collodion. After the varnish has dried to a hard film the plate is placed, varnished side up, over the magnet or magnets, with its ends resting on slips of wood, so that the under surface of the plate just touches the magnet. Fine iron filings obtained from Norway iron, which has been repeatedly annealed, are now sifted uniformly over the plate, and then the magnetic curves are developed by tapping fall on the plate vertically at different points a piece of copper wire.

The vibrations of the plate momentarily detach the filings from its surface, and at these moments the magnet assumes that in obedience to its inductive action on them. The plate is now lifted from the magnet, being careful to keep it always in a horizontal position, and either placed with its ends resting on bricks over a hot stove, or it is heated over a gas stove. The film of varnish is thus rendered fluid, and the filings sticking into it are permanently fixed there after the varnish has cooled. If any filings should remain unattached, they are removed from the plate by letting its edge fall squarely on the table.

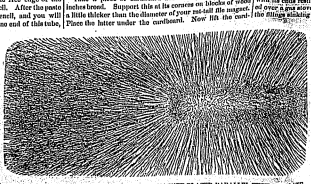

FIG. 26.—LINES FORMED OVER THE END OF BAR MAGNET PLACED PARALLEL WITH ITS PLATE.

The lines forming these magnetic spectra were called "lines of magnetic force" by Faraday. He also devised the term "magnetic field." *A magnetic field may be defined as any space at every point of which exists a finite magnetic force; while a line of magnetic force is a line* drawn through a magnetic field in the direction of the force at each point through which it passes. Before the time of Faraday natural philosophers were satisfied with the mere statement that magnets acted at a distance, and followed generally the same law as ruled in the action

PRACTICAL EXPERIENCES IN MAGNETISM.

SPECIAL REFERENCE TO THE DEMAGNETIZATION OF WATCHES.—No. 1.

BY ALFRED M. MAYER.

The extensive uses now made of electro-magnets in telegraphy, in dynamo-electric machines, and in the many practical applications of electro-magnetism, have greatly increased the risks of damage to watches by their magnetization. I have no doubt that in any one of our larger cities there are scores of watches safely packed away in drawers regarded as past recovery from overdoses of magnetism. They are looked upon by their owners as bullion kept in reserve for "a rainy day."

To be aware of the danger is not a sufficient guard against *accidents*. My own experience is a case in point: I had already allowed one watch, assuming it with magnetism by approaching an electro-magnet in my laboratory which had been allowed to remain in action by the person who had that day used it in his experiments. After purchasing another watch, I always took the precaution to place it on my office table before I approached the large electro-magnet of the Stevens Institute of Technology. I always did this, no matter whether the magnet was or was not in action. But one day I was suddenly called out of the room and detained by a visitor for a half hour or more. I took my watch from the table as I passed out of the room. I returned to my laboratory with my mind entirely engrossed with the experiments I had in hand, walked up to the magnet, rearranged the apparatus, and charged the magnet. My watch at the time was not 3 inches from the pole of this huge magnet! I was *only* aware of my "accident"—and it is, if you will, thoughtlessness about the watch or thoughtfulness about the experiments—when that afternoon I leisurely walked to the station to take a train, and was informed that "it had gone over half an hour." My watch had lost half an hour in about three hours! Persons more cautious than I have had the same experiences, for it is impossible, —most idlecy supervening, to be constantly thinking of a watch. I have also remarked that out of the two or three dozen owners who have had watches apparently ruined by this same large magnet, each one considered "the other fellow" a careless and thoughtless person until his turn came to do the same thing, when he was in a *really thoughtful* mood—about something, *which was not his watch.*

My last magnetic accident turned my thoughts to ways of taking the magnetism out of watches. I have succeeded perfectly, and the process which I have finally adopted as the best is so simple that any one can practice it, and that, if you wish, without even detaching your watch from its chain.

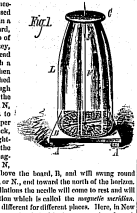
Though the process is simple, yet, of course a knowledge of the elementary facts and laws of magnetism is required to understand how it is done; and I know that every intelligent American mechanic really wishes to understand the reasons for performing the operations that he may be called on in practicing any new process.

To render clear to all the operations used in *demagnetizing* (that is, in taking the magnetism out of) a watch, I will assume that I am addressing those who have little or no practical experience as experimenters in magnetism, and also those who wish to be at the least expense in practicing watch demagnetization. I will, therefore, explain the facts and principles of magnetism on which the operations depend, by describing actual experiments made with apparatus which is so cheap and homely that it can be made by any one with a very little trouble and at a trifling expense.

I will at once proceed to show how to make the simple instruments required in our preliminary experiments and in the demagnetization of a watch.

The Magnet may be made out of a piece of a large rat-tail file. The one I have used is 7 inches long and averages ⅝ of an inch in diameter. There is something either in the quality of the steel or the temper of these files which makes them capable of receiving powerful charges of magnetism. The most powerful magnet I have ever examined is the rat-tail file just spoken of. It lifts several times its own weight. If a large rat-tail file cannot be had, then a piece of Sheffield steel, 10 inches long and ⅝ inch in diameter, must be obtained. This steel rod must be first heated to cherry-red, and then lowered gradually, while in an upright position, into a bucket of water. This will render it hard and capable of receiving and retaining a magnetic charge. The file or steel rod is magnetized either by drawing it over the pole of a powerful electro-magnet, or by wrapping around it insulated copper wire, and passing through the wire a current of electricity from a galvanic battery.

The Magnetometer.—We roll this the small magnetic needle, suspended in a glass shade by a fiber of silk, Fig. 1. It is made thus: Take a No. 4 or 5 needle, and draw it several times, from point to eye, over the N. end of your magnet. This operation will magnetize the needle, and when suspended from its middle, be pointed end will point toward the north. Now, on to a piece of wood, B, which is 3 inches square, glue and screw the slips, A and A, across its grain, so that it cannot warp. Then on its upper side paste a piece of damp white drawing paper. When this has dried it will be tightly stretched across the piece of wood. Draw on the paper a circle slightly less in diameter than the length of the No. 4 needle. Divide one half of the circle off into 180 parts of one degree each; or, if the eye can subdivide, divide the semi-circumference into ninety equal parts of two degrees each. To suspend the needle, you got a skein of floss silk, such as is used in embroidery. This silk is easily twisted, and from it you can readily draw a thread formed of



three or four fibers. Now, with a needle, pass a thread of this silk through the middle of the needle, and then twist it by rolling it between the fingers, until it is very hard and without kink. To suspend the needle, stick a pin through the middle of the wood, B, Fig. 1, and then pass the thread of silk through the eye of the needle, and bend it into the form of a loop, as shown in the figure. Then stick the end of the thread into the wax and work the wax over it with the fingers. The other end of the thread is passed through the eye of a large No. 1 or 2 needle. This needle is then passed through a hole in a piece of cardboard, C, placed on top of the lamp chimney, L. The silk thread must be of such a length that when the needle is pushed downward through the hole in C, the magnetic needle, N, may be brought to rest on the paper covering the block, B. Now, on slightly drawing up the needle, S, the magnetic needle, N, will hang just above the board, B, and will swing round with its pointed, or N., end toward the north of the horizon. After many oscillations the needle will come to rest and will point in a direction which is called the *magnetic meridian.* This direction is different for different places. Here, in New York, it makes an angle of 7° with the true north and south line, and the N. end of the needle points 7° to the west of the true north. This pointing of a suspended needle away from the true N. is called its *magnetic declination*, or magnetic variation. In New York and in vicinity the magnetic declination is 7° west.

In addition to the magnet and magnetometer the experimenter will need the following materials:

Three pieces of soft iron. One piece 12 inches long and ½ inch in diameter; another piece, 9 inches long and ¼ inch in diameter; a third piece, 1½ inch long and ⅜ inch in diameter. These pieces of iron should be made very soft by heating them to bright redness and then allowing them slowly to cool in hot ashes.

A piece of test wire, 6 inches long and ⅛ inch in diameter.

Iron filings, made from soft iron and passed through a fine sieve.

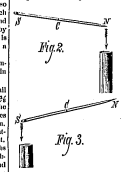
Pieces of window glass. Two 12 inches by 6, and two pieces 6 inches square.

A small bottle of spirit varnish, such as photographers put over their negatives.

Needles, nails, and tacks of various sizes.

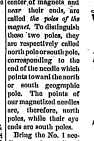
With the above simple and cheap things a great many interesting and beautiful experiments can be made; and we will now show how to obtain from these homely instruments much information that is really sound and useful.

Experiments showing in what a Magnetic Substance differs from a Magnet.—Place the magnetometer on the table and allow the magnetic needle to come to rest. Now take the piece of soft iron 3 inches long and bring it slowly up to the magnetic needle, always keeping the piece of iron pointing toward the point of the needle, as shown in Fig. 2. You will observe that the point of the needle moves toward the iron, bursting around its center, C, in the direction shown by the arrow.



Slowly and steadily draw away the piece of iron. As you do so the needle slowly turns on its center, C, and comes again into the magnetic meridian. Now bring the piece of iron up to the eye end of the needle, and you will see that this end turns toward the iron in the same manner as did the point of the needle in the previous experiment. Thus we find that a piece of soft iron attracts either end of the magnetic needle. Each end moves toward the iron. If this be so, it necessarily follows that if you point the piece of iron directly toward the center of the needle and bring it up to the needle in this position, keeping eyes always to have the length of the piece of iron at right angles to the length of the needle, the needle will not move, but remains steadily pointing in the magnetic meridian. Each end of the needle is equally attracted toward the iron, and as each end tends to turn in the direction shown by the arrows in Fig. 4, it remains at rest under the action of two equal forces tending to rotate the needle in opposite directions.

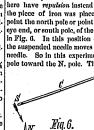
Now we will make some experiments similar to those just described, but differing in this: we use a magnetized No. 1 sewing needle instead of the piece of soft iron. Take a No. 1 sewing needle and draw it from point to eye over the N. end or pole of your rat-tail file magnet. You will, by this operation, have converted the needle into a magnet, and if you now, as before, bring the needle of the magnetometer, you will find that *it points in the magnetic meridian with its point toward the north.* The ends of magnets, or, more accurately speaking, certain points in the



center of magnets and near their ends, are called *the poles of the magnet.* To distinguish these two poles, they are respectively called north pole and south pole, corresponding to the end of the needle which points toward the north or south geographic pole. The points of our magnetized needles are, therefore, north poles, while their eye ends are south poles.

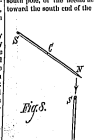
Bring the No. 1 needle up to the needle of the magnetometer, with its point toward the point of the magnetometer needle and with its length always at right angles to the magnetic meridian, as shown in Fig. 5. The N. pole of the needle moves away from the north pole of the No. 1 needle, and we here have repulsion instead of attraction, as we had when the piece of iron was placed in the same position. Now point the north pole or point of the No. 1 needle toward the eye end, or south pole, of the magnetometer needle, as shown in Fig. 6. In this position of No. 1 needle, the S. pole of the suspended needle moves toward the N. pole of the No. 1 needle. So in this experiment we have attraction of the S. pole toward the N. pole. Thus we have found out that the

north poles of magnets repel each other, while the north pole of one magnet attracts the south pole of another magnet. This being the case, it follows that the No. 1 needle, attracting the S. pole of the suspended magnet and repelling its N. pole, must, when pointed at right angles to the suspended needle and directed toward its center, C, cause the suspended needle to rotate, its S. pole moving toward the point of the No. 1 needle, as shown in Fig. 7.



The experimenter must now compare this experiment with the similar one with the piece of iron. The iron when pointed toward the center of the magnetic needle did not rotate it, but when the magnetized needle is placed in the same position the suspended needle rotates and its N. pole moves away from the N. pole of the No. 1 needle.

Let us vary these experiments by pointing the eye end, or south pole, of the needle first toward the N. end and then toward the south end of the magnetometer needle, and then



toward the center of this needle. Figs. 8, 9, and 10 show the results of these experiments. They differ from those of Figs. 6, 7, and 8 in this: the south pole of the magnetized No. 1 needle acts on the suspended needle in place of the north pole. The results are as follows: The S. pole of the No. 1 needle repels the S. pole of the suspended needle and

Testing Iron and Steel by Electro-Magnetism.—Professor Wetten-hofer, of Prague, has devised a mode for measuring the hardness of steel electro-magnetically. The principle is, that the hardness of steel may be determined by its coercitive force. Having inclosed a steel bar to be tested in a magnetizing coil, and magnetized it nearly to one end of a balance-arm, the other end bending obliquely downward and bearing a counted weight, a current is sent through the coil. The coil, being drawn along, is gradually drawn, drawing the bar with it, till the latter breaks away. The inclination of the pointer indicating usually over a number, and index indicates the degree of resistance. The bars to be tested are suspended in a brass holder; position is made against two sudden a recoil.

Comptes Rendus, June 27, 1870.

L'Electricité

Magnétization de l'acier pendant la trempe

M. W. Holtz a eu l'idée d'essayer si en opérant de la sorte on pouvait augmenter la puissance magnétique des aimants. Les résultats, exposés très-longuement par l'auteur dans les *Annales Poggendorf*, numéro de mai, prouvent qu'il n'en est rien. On nous dispensera de suivre l'auteur dans le récit de ses tentatives infructueuses, qui n'offrent aucun intérêt. Nous nous contenterons de mentionner cette exp.rience, afin de donner un exemple des combinaisons bizarres auxquelles peut conduire l'esprit de système.

Pouvoir magnétique de la poudre de fer

Le numéro de juillet des *Annales de Physique et de Chimie* de Wiedemann se confient qu'un article intéressant y utilis sur l'électricité. M. von Waltenhofen a communiqué à l'Académie des Sciences de Vienne un mémoire qui représente à doit le journal extrait deque premier, et dans lequel l'auteur consulte l'effet magnétique de fer pulvérisé.

On fer pulvérisé n'est produit par voie de réduction, à l'aide d'un courant d'hydrogène, ou d'autre toute autre méthode mécanique provenant de la lime.

A parait trouvé par les expériences de M. Waltenhofen que le pouvoir magnétique du fer ainsi préparé est en élevé *quelque croissant*, varies entre douze d'oxalate, de solid du fer massif.

Cette différence considérable tient-elle à ce que le rapport de la surface au poids est immense lorsque le fer est réduit en poudre? Toutefois à ce que la surface sur laquelle on admet que la magnétisme se transporte a subi un commencement d'oxydation? Cest ce qu'il est tout à fait impossible de décider, dans l'état actuel de la science.

Practical Experiments in Magnetism, with Special Reference to the Demagnetization of Watches.

By Alfred M. Mayer.

On the Magnetization and Demagnetization of Steel.—To understand thoroughly our processes of taking the magnetism out of a watch one must be in possession of clear ideas of what is meant by the magnetization and demagnetization of steel. These facts I will now give.

Fig.31.

Let A B, Fig. 31, represent a piece of steel laid on the table. N is the north pole of a bar magnet, which is held vertically over the end, A, of the piece of steel. Bring the pole, N, of the magnet to touch the end, A, of the steel and slide the magnet over the steel, in the direction of the arrow, to the end, B. Slide it off the end, B, and lifting it in the air, again bring N down on A, and repeat the operation. Every time one stroke of the magnet on the steel, the latter will be found to have received a charge of magnetism, which generally increases in strength up to a certain number of strokes of the magnet; after which further strokes of the magnet produce no effect in increasing the magnetic charge in the steel. Or now taking the steel, A B, to the magnetometer and testing for its magnetic conditions, as has already been explained in Figs. 7 and 10, you will find that the end, *bar* magnet, N, strokes the steel from B to A, thereby developing the south magnetic polarity in that end of the steel, A, while it has developed the north end of the steel of S. magnetic polarity at B. If the bar had been used with the end, S, of the piece of steel *forward* which the end of the magnet would have developed polarity in that of the end of the steel, A, which developed the north end of the steel that the magnet should rest on it while it glides over it, hard, the latter may be magnetized by passing the magnet along the length of the needle and at some distance above it, as shown in Fig. 31.

Let N, in Fig. 32, stand for the N. end of a magnet, while A B is a piece of steel which has been brought near to the end, N, of the magnet. If the magnet be strong, and the steel of the quality of soft iron needle steel, that is, not too hard, you will find on testing the steel, A B, at the magnetometer, that the end, A, which is placed the north end of the magnet is of south polarity, while the end, B, is of north polarity. If the piece of steel, A B, had been brought near the south end of the magnet, instead of the north end, then you would have found that the end of the steel which had been nearest the south end of the magnet had north polarity. In other words, when a steel rod is brought near a magnet it is magnetized, and the end of the steel rod nearest the magnet is of a polarity opposite to that of the end of the magnet toward which the rod points.

Fig.32.

If, instead of holding the steel rod at a distance from the magnet, we bring it to touch its end, then the magnetic charge given to steel will be greater than in the former experiment. The polarity given to the end of the steel which touches the magnet is opposite to that of the end of the magnet touched.

So much for the magnetization of the steel rod. Its demagnetization consists in taking the magnetism out of it, as has effected by operations similar to those just described in magnetization. These processes we had better describe by the aid of Figs. 31 and 32.

In Fig. 31, let A B be a magnetized rod of steel, with its north pole at A, its south pole at B. We have found that this rod was magnetized, with its poles as just described, by stroking it from A toward B with the north pole of the magnet, N. Now a reverse direction of stroking will demagnetize it, that is, if the north end of the magnet be drawn over A B, from B toward A, then the magnetism will disappear from the rod, A B; and if the operation is repeated after the rod has thus demagnetized we will even remagnetize it and its south pole at A.

It is but necessary, however, that the magnet should touch the steel not exceeding the operation of demagnetization.—It is sufficient, if the magnet be powerful, to pass it over the steel rod at a distance above it and in a direction always opposite to that in which the magnet moved when it magnetized the rod.

In Fig. 32, let A B be a magnetized rod of steel, having north polarity at A and its north pole at B. This condition of magnetism has been given to it by the presence of the north pole of the magnet, N. Now, if we take away the magnet, N, or bring it from lying up to the bar, A B, the south pole of the magnet was removed, that the rod, A B, will be demagnetized. If the rod, A B, be of very hard steel and the magnet not very powerful, it may be necessary for the magnet actually to touch the rod, A B, in order to demagnetize it.

Here it is in order to describe more explicitly the operation of demagnetization. To demagnetize a bar of steel you require as strong a magnetic action as that which was required to give the rod its present magnetic charge. In performing the operations of demagnetization, we should be careful not to give too many reverse strokes to the rod, nor to approach it too near to the demagnetizing magnet. It is better to pass the magnet over the magnetized rod at a short distance above it, and after each operation to test its gradually falling magnetic charge at the magnetometer. The critical point is when the residual charge becomes small; for then the danger is that you will not only demagnetize the rod by the next operation, but will actually remagnetize it, with, of course, its poles reversed.

In the course of my experiments on the demagnetization of watches I made a series of novel experiments on the demagnetization of steel rods placed at right angles to the demagnetizing magnet. The steel subjected to experiment was of the hardness of that of sewing needles. These experiments explain some curious facts in our mode of demagnetizing watches, and therefore form a natural introduction to the practice of our process.

The steel rods used in these experiments in demagnetization were made were formed of pieces of No. 1 rowing needles. The points and eyes of the needles were broken off, thus leaving rods of about two and one-eighth inches long. The rod to be magnetized was placed over the demagnetizing magnet.

The manner of experimenting was as follows: The needle was magnetized by stroking it repeatedly with the end of the magnet. It was then placed pointing toward the center of the magnetometer needle and at right angles to the magnetic meridian. In this position the needle produced a certain angular deflection in the needle of the magnetometer. The needle was now placed in an upright position, as shown at *a a* in Fig. 33. The demagnetizing magnet, *N S*, was

Fig.33.

mounted on a block which slid between guides, so that the magnet, *N S*, could be gradually brought up to the needle, *a a*, and during all the time of its approach the axis of the magnet, *N S*, pointed toward the center of and at right angles to the needle, *a a*. The approach of the magnet to the needle in these circumstances was found to have lowered the magnetic charge of the needle, and this took place even when the greatest care had been taken to have the magnetic axis of the demagnetizing magnet at right angles to the *magnetic center* of the needle, *a a*. The following table will show the manner in which the magnet, *N S*, demagnetizes *a a* when the former approaches the latter.

After the needle was magnetized it deflected the magnetometer..... 25°

After the magnet had been placed 12 in. from needle, 18°

" " " 10 " " 18°

" " " 8 " " 18½°

" " " 6 " " 18½°

" " " 4 " " 18½°

" " " 2 " " 12°

" " " 1 " " 12°

Remarking the above record of the experiments it will be seen that the approach of the magnet to within a distance of an inch of the center of the needle brought down the magnetic charge from 25° to 18°, and that a repetition of this experiment had no further effect in demagnetizing the needle. The same is observed on the repetition of the experiment when the magnet was placed at one eighth and one sixteenth from the needle. In each case the first approach of the south pole of the magnet to the needle had the effect of lowering the magnetic charge of the needle, but had no effect on the magnetometer from 12° to 12° of deflection. Of course it will be understood that in any one series of experiments the end of the needle was always placed at the same distance from the center of the magnetometer needle.

The reader will be careful to observe that I have stated that in these experiments I took every care to have the magnetic axis of the demagnetizing magnet at right angles to the magnetic center (or equator) of the needle. It is clear that in really done it might be a question whether the magnet would have any effect on the needle. Yet, all of our experiments show that it *always* has an effect of demagnetization. For a long time it has been known that for the demagnetization of a magnet it requires a far weaker magnetic action than that of the magnet which gave it its magnetism; now when the magnet is at right angles to the needle, as in Fig. 33, the north pole, *N*, of the magnet acts only on the two poles of the needle, *a a*. It tends to create south magnetism in *a* and north in *a*. But as the north pole of the center of *N* is so far from the needle, its action may be neglected. It is now safe to assert that, in a long series of experiments made according to the method above, with the magnet being magnet two feet long and the needles one quarter inch thick and of six inches long, and inserted to the greatest degree possible before magnetizing them, this large magnet had no effect whatever on the needles after a few strokes, though every care was taken to get the magnetic axis of the demagnetizing magnet truly at right angles to the axis of the needles and pointing toward their centers.

We will now describe another series of experiments in demagnetization in which the needle is rotated before the pole of a magnet, with the center of the needle in a line in the prolongation of the axis of the magnet. In Fig. 34, *N S* is the demagnetizing magnet, and *a a* is the needle operated on. The following description of one of the series of experiments will give an accurate idea of all of the series:

The center of the needle, *a*, was one inch and three quarters from the end of the magnet, *N*. *a*, *a* was placed in the magnetometer and its axis placed opposite the magnetometer, and caused a deflection of 41° in its needle. The needle was then placed in a vertical position at right angles to the magnet, *N S*, and with its center one inch and three quarters distant from the end, *N*, of the magnet. The needle was now turned around its center so that its south pole went through 90°, and approached the north pole, *N*, of the magnet. The magnet was now removed and the needle tested at the magnetometer. As might have been expected it produced the same deflection of 41° as it did before the experiment. The needle was again placed in its odd position, the magnet brought to the same distance from its center and the needle again rotated before the magnet; but this time the north pole of the needle turned nearly 90° toward the north pole of the demagnetizing magnet. After this operation the needle had had its magnetic charge lowered so that it now only produced a deflection of 32.5° in the magnetometer. A repetition of the experiment lowered the magnetic charge to 25°. A third experiment lowered the magnet to 21°, and a fourth to 18°, where a deflection on the magnetometer needle of 18° was produced by only 10° of rotation of the needle before the magnet. By further demagnetizing the needle, then in the magnetometer needle, it was found that the north pole was brought before the magnet (this tended to the magnetize the needle), then the needle's south pole was again brought before the magnet, and the experiment terminated. Thus we see that the magnet first tended to magnetize the needle, then to demagnetize it, and lastly to magnetize it. Notwithstanding that the needle was subjected to a magnetizing influence from the magnet after the demagnetization, it had its magnetism lowered, so much less magnetic force being required to demagnetize than to magnetize a magnet.

In the following series of experiments the needle was placed as in the preceding experiments, and it was rotated through a whole revolution before the pole of the magnet instead of through only a half revolution as in the preceding experiments. Before an experiment was made on the needle it deflected the magnetometer needle 40°. The needle was now rotated before the magnet through a whole revolution, its south pole approaching first the magnet, then passing it and turning over the circumference of the circle till it had made an entire revolution and had come back again to its

Fig. 34.

needle was demagnetized so that its effect in deflecting the magnetometer needle was only 4°, instead of 70°, the deflection which it caused before it was rotated before the magnet. The whole of this demagnetization was caused by the passage of the north pole of the needle across the S. end of the magnet, N. The passage of the S. pole of the needle athwart the N. pole of the magnet could have had no other effect than to magnetize it.

A second rotation similar to the above reduced the deflecting power of the needle on the magnetometer to 5°. A third experiment brought it down to 4°; after which no further rotation had any effect in reducing the magnetic charge of the needle.

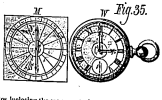
ON THE DEMAGNETIZATION OF WATCHES.

The reader who has made for himself the magnetic experiments, which we have so minutely described, or who has even read the accounts we have here given of them, will have no difficulty in seeing the reasons for the various operations which I will now describe in giving an account of the way to take the magnetism out of a watch.

A watch is formed of a case of gold or silver, and glass inclosing brass or nickel plates, between which are a number of steel arbors forming the axles and pinions of the brass wheels. There is also the spring of steel which uncoils itself in the plane of the watch. The other wanderers in addition a steel chain which uncoils from the fusee on to a brass drum inclosing the mainspring. The hairspring, parts of the balance wheel escapement, stem winding apparatus, etc., are also of steel. So we see that there is abundance of material for magnetization in a watch. Fortunately these parts are formed of steel which is only moderately hard, and, therefore, as we have already seen, easy to demagnetize.

Of these various parts some have their lengths at right angles to the plane of the watch, like the arbors; others, like the teeth and balance wheel springs and the nickel (nickel takes a magnetic charge like steel or iron, only feebler)

Fig. 35.



plates inclosing the movements, have their greatest dimension in the plane of the watch. The position of these bodies determines to a great extent the directions of their magnetic axes. By magnetic axes we mean an imaginary line joining the two poles of a magnet. The arbors will be their magnetic axes in the direction of their lengths, while the plates are most likely to have theirs in the direction of one of their dimensions. But we have already seen that no matter in what direction their magnetic axes are in the watch, all of these bodies (thanks to the facts already shown in our experiments) may be demagnetized *by properly oscillating the watch before the pole of a magnet.* How this is to be done I will now show, and in order to explain what might otherwise be a long story, I will give an account of the process by describing the experiments actually made in the course of demagnetizing an old Yorkshire Fuser watch, which I saturated with magnetism by deliberately placing it on one of the poles of the large magnet of my laboratory in the Stevens Institute of Technology.

We may now regard this watch as a magnet, having the form of a disk, and with its north magnetic pole at the hour XI, and with its south pole at III. o'clock.

This being the information given by our magnetometer, we are in possession of facts which enable us to take the north magnetism out of o'clock and of the south magnetism out of three o'clock.

You have already found, by your experimenting, that when you bring the north pole of one magnet near the north pole of a more powerful magnet, the powerful magnet will take the magnetism out of the weaker one because it tends to make the north pole of the latter a south pole. Similarly the south pole of a powerful magnet will demagnetize the weaker magnet when the south pole of the latter is brought near the south pole of the former.

You have also found out by your experiments that when a small magnet, made of steel not too hard, is vibrated athwart the center in front of the pole of a powerful magnet, the small magnet is demagnetized. Those facts show how we are to proceed in the demagnetization of the watch.

The hour XI is of the strongest north magnetism of any on the dial; therefore we place this hour opposite the north pole of our north-seil file magnet, as shown in Fig. 36. The center of the watch, C, is placed so that the prolongation of the axes of the magnet (shown by the dotted line, X X) passes through it. The watch is now vibrated around an axis passing through it and at right angles to X X. By this operation the watch is successively brought into the positions, A and B, of Fig. 36. After several vibrations of the watch before the north pole of the magnet, I turned the watch around its axis, and each hour on its dial is in succession brought opposite to the center, *c*, of the magnetic needle of the magnetometer.

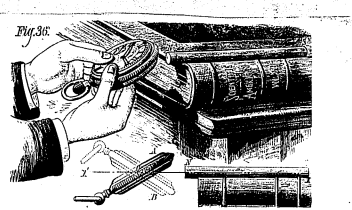
The following were the results of such experiments to ascertain the magnetized watch. We give them in the form of table N° I, and S. indicate the kind of magnetic polarity of each hour, and the angles show the effect in angular deflection on bringing that hour of the dial opposite the center of the magnetometer needle:

TABLE I.

Hour.	Ang. of Deflection of Magnetometer.	Kind of Magnetism.
XII.	20°	N.
I.	6°	N.
II.	18°	S.
III.	72°	S.
IV.	68°	S.
V.	22°	S.
VI.	9°	N.
VII.	7°	N.
VIII.	10°	N.
IX.	16°	N.
X.	20°	N.
XI.	24°	N.

When the hour III. was brought opposite the magnetometer needle the fusee axle and the center of the semicircular steel catch of the inner cover of the works were presented to the magnetometer. The strong south magnetism of hour III. was due to the magnetization of these bodies, which deflected the needle of the magnetometer 72°. The strong north magnetic action of hour XI. was due to the magnetized mainspring.

Fig. 36.



DEMAGNETIZING A WATCH.

nology, and thus purposely obtained a very badly magnetized watch to practice a cure on.

The watch is placed quite close to the magnetometer, and with the center of the thickness of the watch about on a level with the center of the needle of the magnetometer, and with the line, connecting the center of the watch, C, Fig. 35, and the center, *c*, of the needle, at right angles to the magnetic meridian; in other words, at right angles to the direction which the needle has when no magnetic body is near it. The watch is then turned slowly around on its center as an axis, and each hour on its dial is in succession brought opposite to the center, *c*, of the magnetic needle of the magnetometer.

There is certainly a great difference between the magnetometer deflections of Table I. and those of Table II. It is observed at once that the hours III. and XI., which were respectively of strong south and north magnetism in Table I., are in Table II. marked 8°. This result was not attained, however, at one trial, as might be inferred from our description of the experiments, but after each series of vibrations before the pole of the demagnetizing magnet the magnetic condition of hours III. and XI. was tested. Sometimes their magnetism almost disappeared. Then we found it had changed, or rather inverted, so that hour III. had south instead of south polarity, and hour XI. had south instead of north magnetism. When this happened we had to bring hour III. before the north pole of the magnet, and hour XI. before the south pole, and reverse the angles I succeeded in demagnetizing hours III. and XI., so that they produced no action whatever, or 0°, on the needle of the magnetometer.

I now again brought the watch before the magnet, and vibrated its V. o'clock before the south pole till this south magnetism had disappeared; in other words, produced no deflection whatever on the needle of the magnetometer. I then made an examination of the magnetism of the watch before the magnetometer, with the following results:

TABLE II.

Hour.	Ang. of Deflection of Magnetometer.	Kind of Magnetism.
XII.	4°	N.
I.	3°	N.
II.	6°	N.
III.	8°	S.
IV.	5°	S.
V.	0°	S.
VI.	3°	N.
VII.	6°	N.
VIII.	6°	N.
IX.	7°	N.
X.	5°	N.
XI.	8°	S.

I now demagnetized hour VII. of its 6° of north magnetism by vibrating this hour opposite the north pole of the demagnetizing magnet, and after I had succeeded in this I

THE DEMAGNETISATION OF WATCHES

By Professor A. M. Mayer.

IN an account of some practical experiments in magnetism, Professor A. M. Mayer describes a method of demagnetising a watch, which, as it may lead some interest to our readers, we quote from the *Scientific American* :—

A watch is formed of a mass of gold or silver, and plate, including brass or nickel plate, between the jewels of which the pivots of the balance-staff, escape-wheel and pinions of the train, revolve. There is also the spring of steel which vanish itself in the plane of the watch. The older watches have in addition a steel chain which unrolls from the fusee on to a brass barrel when the spring is wound. The balancing-parts of the balance wheel compensated, for heat and cold, are generally of steel, and the hair spring has flat thin coils of extremely fine magnetisable in a watch. Fortunately, these parts are formed of such feeble magnetic sub-stances that, and, therefore, easy to demagnetise.

Of these various parts some have their lengths at right angles to the plane of the watch, like the balance-staff, and the axes of the escape-wheel and pinions, and the watch jewels; others, as magnetic charge this steel or iron, only further, in demagnetising the moments, have their central directions in the plane of the watch. The position of these latter determines the axes of the steel discs positions of their magnetic axes. By magnetic axis of a magnet, I mean the line joining the two poles of a magnet. The ordinary bar magnets have axes in the direction of their lengths, and the poles are most likely to lay in the flat ends or sides of one of their diameters. But we have already seen that no matter in what direction the magnetic axes are in the watch, all of these feeble magnetic forces may be destroyed *by a proper alternating current* may be demagnetised *by proper oscillatory the watch before the pole of a magnet*, and it will be done I will show, and it is easy to describe what might otherwise be a long story, I will give an account of the process by describing the experiments actually made in the course of demagnetising a watch. Fortunately, which I assisted with magnetism by deliberately placing it on one of the poles of the large magnet in the Physical Room of the Stevens Institute of Technology, and I had purposely obtained a very badly magnetised watch to perform a cure on.

The watch is placed quite close to the magnetic pole—only a few millimetres of the thickness of the watch's case on a level with the centre of the needle of the magnetometer, and in a line connecting the centre of the watch, G, and the centre, C, of the needle, at right angles to the magnetic meridian; in other words, at right angles to the direction which the needle has when no magnetising force is present. The watch is then slowly moved on its axis as an axis, and each hour on its dial is in succession brought opposite to the centre of the magnetic needle of the magnetometer.

The following were the results of such experiments on my magnetised watch. We gave them a uniform rate of 24 hours. I determined the line of magnetic polarity at each hour, and the angles which the object in magnetic meridian on bringing that hour of the dial opposite the centre of the magnetometer needle:—

TABLE I.

Hour.	Amp. of Deflection	Kind of Mag-
	of Magnetometer.	netism.
XII.	70°	N.
I.	45°	N.
II.	15°	N.
III.	12°	S.
IV.	15°	S.
V.	12°	S.
VI.	5°	S.
VII.	15°	N.
VIII.	45°	N.
IX.	70°	N.
X.	90°	N.
XI.	90°	N.

When the hour III. was brought opposite the magnetometer needle the force exhibited by the centre of the southernmost steel catch of the main spring of the watch was presented to the magnetometer. The strong south magnetism of hour III. was found to be in a direction diametrically opposite to that of the north magnetism of hour 9, which defended the north magnetic centre of hour XII. was due to its magnetised mainspring.

It may now regard this watch as a magnet, having its form of a disc, and with its north magnetic pole at the hour XI., and with its south at III., of the dial.

This being the interpretation given by our magnetometer, we see it possesses the two conditions necessary to make the north magnetism, and of stores of electricity, and the south magnetism out of these materials.

We have already found, by your experimenting, that when you bring the north pole of one magnet near the south pole of a more powerful magnet, the powerful magnet will take the magnetism out of the weaker one because it tends to make the north pole of the weaker magnet a south pole. Similarly the south pole of a powerful magnet will take the magnetism of a weaker magnet when the south pole of the latter is brought near the south pole of the former.

We have now found out by your experiments that when a small magnet, made of steel and too hard, is vibrated around its centre in front of the poles of a powerful magnet, the small magnet is demagnetised. This is the principle which I have employed in the demagnetisation of the watch.

The hour XI. is of the strongest north magnetism of any on the dial; therefore we place this hour opposite the north pole of our not-tall-like magnet. The centre of the watch is placed so that in the prolongation of the axis of the magnet passes through the centre of the watch. The watch is then slowly moved around its axis at right angles to the axis of the magnet. By this arrangement I successively brought into position, making angles of 15° with the axis of the magnet. After several vibrations of the watch before the north pole of the magnet, I turned the hour III. of strongest south magnetism opposite the north pole of the magnet, and vibrated the watch as in the previous experiment. By these means I found that the lines across the fluxe of magnetic force, and, as we have seen, any magnetism in it thus taken out. After three successive performed on the hours X. and III., the watch was again examined before the magnetometer, and the following table shows the effect of the vibrations before the magnet.

TABLE II.

Hour.	Amp. of Deflection of Magnetometer.	Kind of Magnetism.
XII.	2°	N.

VI.	3°	S.
VII.	2°	S.
VIII.	3°	N.
IX.	2°	N.
X.	3°	N.
XI.	0°	

There is certainly a great difference between the magnetometer deflections of Table I., and those of Table II. It is observed at once that the hours

III., and XI., which were respectively of strong south and north magnetism in Table I., are in Table II. marked 0°. This result would, I see in however, in one hour, as might be inferred, from our description of the experiments, but after each series of vibrations before the pole of the demagnetising magnet the magnetic condition of the watch was tested, and the magnetic centre of magnetism almost disappeared. Then we found it had changed, or rather had developed hour III., had south instead of north polarity, and hour XI. happened we had to present hour XI. before the south pole of the magnet, the hour XI. before the north pole of the magnet, before I succeeded in demagnetising hours III. and XI., so that they produced no action on the magnetometer, as 0°, as the needle of the magnetometer.

I now again brought the watch before the magnet, and vibrated its V., which before the south pole of this south magnetism had disappeared; in other words, we need no deflecting whatever on the needle of the magnetometer. I then made an examination of the condition of the watch before the magnetometer, with the following results:—

TABLE III.

Hour.	Amp. of Deflection of Magnetometer.	Kind of Magnetism.
XII.	1°	N.
I.	0°	
II.	0°	
III.	0°	
IV.	0°	
V.	2°	S.
VI.	1°	S.
VII.	0°	
VIII.	0°	
IX.	0°	
X.	1°	N.
XI.	0°	

I now demagnetised hour VII. of its 0°, of equal

magnetism to the opposite pole of the magnet, by presenting the north pole of the magnet to the south pole of the watch when presented to the magnet, and after I had found that no hour on the dial affected the magnetometer needle, I demagnetised; in which condition I left the watch, having as good a watch as it did before it was magnetised.

The "sentiment" referred to, I have previously referred, happened to a valued friend, who, with special care by Jones, of Strand, had so strongly magnetised that IV. o'clock on the dial; therefore we place this hour opposite the north pole of our not-tall-like magnet. The centre of the watch is placed so that in the prolongation of the axis of the magnet passes through the centre of the watch. The watch is then slowly moved around its axis at right angles to the axis of the magnet. By this arrangement I successively brought into position, making angles of 15° with the axis of the magnet. After several vibrations of the watch before the north pole of the magnet, I turned the hour III. of strongest south polarity opposite the north pole of the magnet, and vibrated the watch as in the previous experiment. By these means I found that the lines across the fluxe of magnetic force, and, as we have seen, any magnetism in it thus taken out. After three successive performed on the hours X. and III., the watch was again examined before the magnetometer, and the following table shows the effect of the vibrations before the magnet.

TABLE II.

SOCIETY OF TELEGRAPH ENGINEERS.

At the meeting of this society, held in the theatre of the Institution of Civil Engineers, on Wednesday, Feb. 11, after the formal business, a paper, written by T. A. Mckinnaly, was read by the Secretary, on

TELEGRAPHY IN NEW ZEALAND.

It stated that the first attempt to introduce a system of telegraphy into New Zealand was made by the Government of Canterbury in the year 1862, the line first erected being from Christchurch to Lyttelton, a seaport distant eight miles. The next year the Government of Otago placed Invercargill and Bluff in telegraphic communication with each other. The next line was from Dunedin to Port Chalmers, a distance of seven miles, which was completed in the latter part of 1862. The work to connect Dunedin, province of Otago, and Christchurch, province of Canterbury, a distance of 225 miles, was commenced on the 4th October, 1865, and completed on 12th April, 1866. The line was carried on to Nelson, through the gold fields, and completed to that town in 1866.

The laying of the Cook Strait Cable, joining North and Middle Islands, was accomplished in August, 1866. After the laying of this cable communication was quickly established with Auckland, taking in the intermediate stations of Hull, Featherston, Greytown, Carterton, Masterton, Napier, Taupo, Tauranga, Grahamstown, &c., thus with Taranaki on the west. The line from Napier northwards was erected under great difficulties, owing to the hostile character of the natives of the district. The author then proceeded to give a graphic though condensed account of the natural features of the district, and suggested that it would be a good thing to embrace the first opportunity of visiting New Zealand, if only to view these wonderful works of nature.

On June 30th, 1866, there were 699 miles of line erected and 19 stations opened. Now there are in circuit 2,513 miles of line, carrying 8,414 miles of wire, exclusive of works in progress. These latter, when complete, will increase the line mileage to 3,021 miles, with 8,886 miles of wire. During the year ending 30th June last, 1,142,943 messages were transmitted, being an increase of 14 per cent. over the previous year, the cost being £26,301. There are 105 stations equal to the public, and the number of officials in the employ of the department is 201. The "collect" system is in use, but if the receiver refuses to pay, the sender is liable. The tariff is 1s. for ten words and 1d. per word after—address and signature not exceeding ten words free. The press rate is ten words 6d. and 1d. per word after. between 8 a.m. and 5 p.m. Evening papers 3d. per word after. between 8 a.m. and 5 p.m. Evening papers are allowed 1,000 words during the day at the above rates. Delayed telegrams are received—but not taken in at one time but transmitted any time during that day at the convenience of the department and posted at the destination the same night. Half-rates (1s. for postage) are charged for "delayed" messages. Last year 56,721 of these messages were sent. Money orders can be sent by telegraph. The charge is 4d. in the pound sterling, and a commission in addition to the telegraph fee of 1d. per pound. The amount transmitted last year was 261,952 9s., effected by 14,697 orders. Chambers of commerce are entitled to receive oil shipping messages at the rate of 1d. per message, and the engineers of vessels can telegraph to harbour masters at any port to which they may be bound to ascertain the state of bar, wind or tide for the which charge covers reply. The *employés* are mostly young men from the colony, though Englishmen have been sent out. The most substantial character, No. 8 galvanised BBBB wire, carried on poles varying from 20 to 30 feet, were from the heart of the Totara (*Podocarpus*). Poles from 20 to 25 feet are 9 inches by 9 inches at the butt, and 6 inches by 6 inches at the top. The battery in general use is the Daniell. To maintain this battery in circuit requires 1 lb. per cell per annum.

Fuller's bichromate battery has been introduced on some of the longer circuits, and has proved very efficient. The open circuit system is used, and every station is fitted with a battery capacity of 1,000 cells of 6 feet by 3 feet, with shelves containing the line and board. Auckland, the largest town, has 1,000 cells, the latter local batteries, the former consisting of 1,000 cells, the latter of 10 cells. The duplex upon Dr. Lemon's system is worked on No. 1 cable (42 miles), No. 4 cable (42 miles), Wellington to Napier (221 miles), Blenheim to Christ Church (206 miles), Blenheim to Dunedin (461 miles), Christ Church to Dunedin (255 miles), Dunedin to Invercargill (231 miles), Napier to Auckland (346 miles). Quadruplex working is to be introduced as soon as the instruments arrive. The Morse sounder is in general use. There are two cables connecting North and South Islands—No. 1 with three conductors, No. 2 with one conductor.

First-class operators send and receive on an average from 1,000 to 1,500 words per hour, second-class about 750 to 1,000.

The annual conversazione of this Society was held on the evening of Saturday, Feb. 7, in King's College. The Museum of King George III., the Wheatstone Laboratory and other parts of the College were occupied by a fine display of physical apparatus and electrical literature, including numerous relics of Sir Charles Wheatstone. There was a large number of ladies and gentlemen present, and during the evening selections of music were played by the Musical Association of the Royal School of Mines. The apparatus exhibited included the whole range of physical science, and was furnished in part by the College and in part by the various instrument makers and electric engineers of the Telephone Company and the British Telephone Company exhibited telephones and electric Electric Light Company exhibited an ingenious speaking machine. Lamps, and Mr. Fisher exhibited his ingenious speaking machine. Among the various objects on view, we may mention the original Wheatstone telegraphic instruments, the Daniell battery and coolers conferred on Sir Charles Wheatstone, the Bunsen battery and coolers conferred on Sir Charles Wheatstone, the Bunsen battery and coolers conferred on Sir Charles Wheatstone, the Bunsen

MAGNETIC "CURATIVE" APPLIANCES.

Can advertising beautify what is hideous?

It is, we give us any verifiable evidence that it can do work, or produce any physiological effect? We are particularly anxious to obtain information on these points, because both of the letters which, in our issue of the 24th ult., constitute the brief correspondence on *Magnetic Appliances* contain this expression; Mr. J. Wilkinson informing us that "the magnetic current is continuous and most penetrating," and Mr. Harry Lobb—whose name is well known in connection with the medical applications of electricity—positively that "magnetic appliances when worn upon the body produce magnetic currents, which we all know (?) closely resemble, and are intimately allied to, electric currents." *Moreover*, since the date of this correspondence, we have made the acquaintance, through one of its numbers, of what we presume is a contemporary, bearing the title of *The Magnetic Review*; and we have received some half-dozen trade pamphlets, all of which enlarge, in glowing terms, upon the multifarious curative virtues of the "magnetic currents" generated by appliances which, no doubt, may be shown to be more or less magnetic, but in which we should say that the really active agent is decidedly flannel. Our contemporary in question devotes about half his space to advertisements and testimonials relating to one of these appliances, whilst of the other half we can only say that it is devoted to the literary and scientific requirements of probable customers. In the latter portion, an "editorial" informs us that "what is called the luminiferous ether is but another name (*sic*) for Magnetism," that "the currents from the two poles of a horse-shoe magnet rush together" and "constitute a permanent magnetic atmosphere, corresponding in strength to the dimensions of the surfaces from which they emanate" and that "the enormous magnetic force at the poles . . . has contracted the solid earth until our polar diameter is twenty-six miles less than at the equator." But the interest of the paper is not confined to the "leaders." In a communicated article we are told that "in cases of fever the electric equilibrium is always destroyed; there is an excess of positive electricity; the skin is hot, the throat is parched, and the expanded brain refuses to sleep; the instinctive cry is for water; and how grateful is cool water applied to the skin. The electricity of cool water is negative, so that thirst in fever should be fully gratified, and perspiration promoted on the skin, so that the excess of positive electricity may be carried off, and electric equilibrium restored. Cold water in fever conveys a soothing magnetism throughout the whole frame." Nor is the writer in this case satisfied with the mere statement of such important scientific facts; he proceeds to show how the "negative electricity" and "soothing magnetism" of *cold water* may be utilised on a large scale. "An excited *mob suffers* from an excess of positive electricity and morbid heat. Under great excitement they become maniacs in their frenzy. The most instantaneous and effective remedy is a complete saturation with cold water; its negative properties draw away their positive electricity, cool the fever in their blood, and bowling infuriated madmen are converted into rational beings. A few hose pipes attached to vigorous fire-engines would be infinitely more effectual in restoring a mob to reason than snider rifles." And to those whose offspring may suffer from "excess of positive electricity," and may require a "soothing magnetism," the valuable hint is given that "the same rule applies to irritable children; a bath tub is more rational treatment than the birch."

In another part of the same article, we specially note that "all nature is magnetic; every drop of water that comes to us in rain-falls is a perfect magnet." We were under the impression that some bodies in nature, including that of the writer of the article, and particularly the fluid *water*, are diamagnetic, and cannot be made to assume magnetic polarity. But then Faraday was not infallible; and, if there be a little hitch here, it is soon forgotten when we read how beautifully magnetism acts as "the soother and harmoniser of Nature's disturbances." We will conclude our extracts from this article with one more bit of information, explanatory of the effect of *cold water*. "Heat is indispensable to life; but an excess of heat indicates an excess of positive electricity. An excess of cold indicates the opposite or negative condition."

Turning now to the advertisement department, we find, amongst the "special advantages" of the particular appliances therein recommended "their constant generating of electricity without the aid of batteries, metallic plates, chain-bands, or acids." This, too, in addition to a *magnetic current* which "passes readily through an intervening garment!" Can those of our readers who are striving to reduce the inevitable loss which occurs in the conversion of mechanical into electrical energy realise, by an effort, the full value of this wonderful but simple invention? Why, it is nothing less than perpetual motion—the overthrow of the principle of the conservation of energy! Do you refuse to admit this? Do you assert that the electrical effect on the body, if produced, must be attended with an equivalent diminution in the motion of the *blood*? You are wrong. In the first place the lines of fluid particles do not ordinarily move in a direction perpendicular to their length, so as to cut the lines of magnetic force; and in the second place we find, in another of the advertisements in our contemporary, that "by the wearing of magnetic appliances, additional magnetic currents are soothingly [how enticing are this adverb and the corresponding adjective!] infused into the system, thus giving a *better circulation*, [the italics are ours] together with greater purity of the blood and increased nervous action. Are you not now convinced that we have here a case of perpetual motion?

Taking up one of the pamphlets above referred to, we are assured that "When it is fully known that magnetic currents are as healthful as pure air, and as indispensable to the life of man; that they are not confined or local forces, but form a general principle, pervading all material things; when it is understood that man himself is truly magnetic, [*how could* Faraday make him diamagnetic?] *then* the employment of this powerful agent in the cure of disease will become general." Surely, in presence of evidence such as that laid before us, the period anticipated cannot be very long in arriving. In this *brochure*, and in one or two of the others, we find the statement, put forward on the authority of a Dr. James Chapman, that "During the last visitation of cholera it was noticed that telegraph clerks and those who were continually brought within the sphere of *magnetic* influence were exempt from cholerine attacks—the close proximity of the magnetic element doubtless neutralising the subtle effects of the earth's disturbed magnetism." Some of our telegraphic readers will rejoice, no doubt, at being favoured by circumstances with such immunity; whilst few, we think, will have the perversity to omit to magnetise their pocket-knives and brace-buckles, since magnetism in homœopathic doses is evidently protective of the most beneficial effects. In another pamphlet, the writer asserts, as a fact within his own knowledge, that "the 'magnetic currents' can be controlled, varied, reversed, or removed at the pleasure of the wearer," and that "invalids can localise a 'magnetic current,' or make a complete circuit at will." Unfortunately, our own appreciation of these important statements is marred by the fact that we do not know what a magnetic current is. With the magneto-static circuit, and with some of its laws, we are tolerably familiar; but as to the magneto-dynamic circuit, we have to confess our total ignorance. Will some of our readers enlighten us?

It is remarkable that, from the evidence before us, magnetism would appear to be much more efficacious in homœopathic than in allopathic doses. From powerful steel magnets carried about on the person, and from still more powerful electro-magnets kept in proximity to the body for several hours, we have never been able to observe the slightest effect. Our experience is that even those persons who are termed "magnetic sensitives" are totally unable to perceive, through any physiological effect, when the circuit of a strong electro-magnet is completed and when it is broken. That this is the case was fully shown in some experiments with two renowned "sensitives"—Miss Tilley and Miss Mansell—which were carried out in our presence some years ago. The following statement by Dr. Pereira, referring to some experiments by Faraday, is of interest in this connection:—"As all substances are under the influence of the magnetic force, it might be expected that the vital functions would suffer some modification from the action of magnetism on organised bodies; but hitherto no conclusive and unequivocal evidence on this point has been obtained. Various phenomena have been ascribed to it, but the inconstancy of their occurrence throws great doubt over the opinion that they are really the effects of the magnetic force. The failure of their production in persons on whose statements confidence can be placed, and their occurrence chiefly in females, and in those called nervous, are reasons for suspecting some error or fallacy in the statements of practitioners who advocate the influence of magnetism on the vital functions. Dr. Faraday does not appear to be sensible of the magnetic force; for some years ago he allowed Dr. Keil to try, in a variety of ways, the influence of powerful magnets on him, but no perceptible effects were produced (*Lancet* for 1835-36, vol. 1, p. 716), and he informs me that he was never sensible of any effect produced on him by the powerful magnets which he used in his recent experimental investigations on magnetism (see *Phil. Trans.* for 1846), although he purposely submitted various parts of his body to their influence, and tried in all imaginable ways to obtain some evidence of their effect."

Dr. Pereira nevertheless describes some modes of using magnets for curative purposes. "The toothache," he says, "*a simple straight bar magnet*, sometimes called a *magnetic staff*, is used. It is first made warm, and its *north pole* applied to the tooth; if the pain be not relieved, the *south pole* should then be substituted." Unfortunately, Dr. Pereira does not tell us what is to be done if the south pole is equally ineffective, an omission which has been fatal to success whenever the process has been tried in our presence.

We wish clearly to define our position in relation to magnetic curative appliances in general, and such things as *Shewanna, Augsterion, Magnetico, Magnetico, Magnetico*, and magnetic *lung or nerve Invigorators* in particular. We have no intention or occasion to occupy illogical and dangerous ground by stating an absolute negative. We do not assert that under no circumstances can magnetism have any effect upon the complicated and delicate functions of the animal organism; but we do say that it has not been shown either that it performs any physical work or exerts any physiological effect whatever, even under conditions in which the magnetic force is intensified almost to the highest degree practicable. In regard to any alleged psychological effect, we can only say that it is altogether outside our province, and that, to be admitted, it must be susceptible of experimental verification. In regard to that portion of the question which is more particularly within our province, we are bound to go even beyond the position we have above taken up. A magnet is a mass, most frequently of steel, up to which is stored up a certain quantity of magnetic energy, viz., just sufficient to do the work of completing its own circuit, since when a perfect magnetic circuit is formed all energy disappears. It is therefore impossible that a magnet can do any physical work unless (*a*) the mass undergoes a chemical or mechanical change, (*b*) the magnetic energy varies, or (*c*) energy is supplied from without. Lastly, in regard to any physiological effect, it is now established that the most powerful magnet can affect the irritability of nerve, the contractility of muscle, or the circulation of the blood as shown in the frog's foot under the microscope. Under these circumstances, an expression of the opinion that the various "magnetic" appliances are absolutely without any curative efficacy cannot be correctly termed "dogmatic." We are aware that the popular belief and the public, consequent trade in such appliances are assuming very extended dimensions, and that testimonials *ad libitum* are

PRACTICAL EXPERIMENTS IN MAGNETISM, WITH SPECIAL REFERENCE TO THE DEMAGNETIZATION OF WATCHES.

By ALFRED M. MAYER.

THE extensive use now made of electro-magnets in telegraphy, in dynamo-electric machines, and in the many practical applications of electro-magnetism, have greatly increased the risk of damage to watches by their magnetization. I have no doubt that in any one of our larger cities there are scores of watches which have been ruined, or more expensive as past recovery from overdoses of magnetism. They are locked upon by their owners as bullion kept in reserve for "a rainy day."

To be assured of the danger is not a sufficient guard against accidents. My own experience is a case in point. I had already attended one watch, saturating it with magnetism by approaching an electro-magnet in my laboratory, when I had been allowed a certain latitude by the person who had that day used it in his experiments. After purchasing another watch, I determined to take the precaution to place it on my office table before I approached the large electro magnet of the Stevens Institute of Technology. I always did this, so much for whether the magnet was or was not in action. But one day I was suddenly called out of the room and detained by a visitor for a half hour or more. I took my watch from the table as I passed out of the room. I returned to my laboratory with my mind entirely engrossed with the experiments I had in hand, walked up to the magnet, rearranged the apparatus, and charged the magnet. My watch came in time was not three inches from the pole of the large magnet! I was only aware of my "accident"—call it, if you will, thoughtlessness about that watch or thoughtfulness about the experiments—when that afternoon I leisurely walked to the station to take a train, and was informed that it had gone over half an hour." My watch had lost half an hour in about three hours! Nothing more continuous than I have had the same experience, for it is impossible, without idiocy supervening, to be constantly thinking of a watch. I have also remarked that out of the two or three dozen owners who have had watches apparently ruined by this same large magnet, each one considered "the other fellow" a careless and thoughtless person really to turn to do the same thing, when he was in a hasty, thoughtful mood—about something, which was not his watch.

My last magnetic accident turned my thoughts to ways of taking the magnetism out of watches. I have succeeded perfectly, and the process which I have finally adopted as the best is so simple that any one can practice it, and that, if you wish, without even detaching your watch from its chain.

Though the process is simple, yet, of course, a knowledge of the elementary facts and laws of magnetism is required to understand how it is done; and I know that every intelligent American mechanic will be willing to undertake the easy task for performing the few operations that he may be called on in practicing my new process.

To render clear to all the operations used in *demagnetizing* (that is, in taking the magnetism out of a watch), I will assume that I am addressing those who have little or no practical experience as experimenters in magnetism, and also in demagnetization. I will therefore, explain the facts and principles of magnetism in which the operations depend, by describing actual experiments made with apparatus which (I very little trouble and at a trifling expense.

I will also proceed slowly when we come to make the simple instruments required in our preliminary experiments and in the demagnetization of a watch.

The Magnet may be made out of a piece of a large rat-tail file. The one I have used is 7 inches long and averages ¼ of an inch in diameter. There is something, either in the quality of the steel or the temper of these files which makes them capable of receiving powerful charges of magnetism. The most powerful magnet I have ever examined is from a rat-tail file just spoken of. If this several inches in length, steel, 16 inches long and ¼ inch in diameter, must be obtained. This steel must be well tempered, that is, obtained by heating it to a cherry red, and then lowered gradually into a bucket of water. This will render it hard and capable of receiving and retaining a magnetic charge. The file or steel rod is magnetized either by drawing it over the pole of a powerful electro-magnet, or by wrapping around it insulated copper wire, and passing through the wire a current of electricity from a galvanic battery.

You have already found, by your own experiments, that when you bring the north pole of one magnet

The Magnetometer.—We call thus the small magnetic needle suspended in a glass shade by a fiber of silk. Fig. 1. It is made thus:—Take a No. 1 or 2 needle, and draw it several times, from point to eye, over the N. end of your magnet. This operation will magnetize their needle, and when suspended from its middle, its pointed end will point toward the north. Now, on to a piece of wood, B, which is 2 inches

Fig. 1.

square, glue and screw the slips, L and L, across to guide so that it cannot warp. Then on its upper side paste a piece of damp white drawing paper. When this has dried it will be tightly stretched on the piece of wood. Draw on the paper a circle slightly larger in diameter than the length of the No. 1" each; or, if that be too tedious, divide the semi-

circumference into ninety equal parts of 2° each. To suspend the needle, you get a skein of floss silk, such as is used in embroidery. This silk is untwisted, and from it you can readily draw a thread formed of a few fibers, which is very delicate and without the slightest twist or tension in it. To suspend the needle, stick in its middle a small dot of wax. The wax over-coat it, with the fingers. The other end of the thread is passed through the eye of a large No. 1 sewing needle, board, C, placed on top of the lamp chimney, L. The sewing needle is then passed downward through the hole in C, the needle is swelled, N, may be brought to rest on the paper covering the magnetic needle, S, will hang just above the Board, B, and will swing to and with its pointed, or N., end toward the north of the horizon. After many oscillations the needle will come to rest and will point in a direction which is parallel to *the magnetic meridian*. This direction is different for different places. Here, in New York, it makes an angle of 7° with the true north and south line, and the N. end of the needle points 7° to the west of the true north. This pointing of a *magnetic declination*, or magnetic variation. In New York and its vicinity the magnetic declination is 7° west.

In addition to the magnet and magnetometer the experimenter will need the following materials:—

Three pieces of soft iron. One piece 12 inches long and ½ inch in diameter; another piece, 7 inches long and ¼ inch in diameter; a third piece, 1½ inch long and ¼ inch in diameter. These pieces of iron should be made very soft by heating them to bright redness and then allowing them slowly to cool in hot ashes.

A piece of steel wire, 6 inches long and ⅛ inch in diameter.

Iron filings, made from soft iron and passed through a fine sieve.

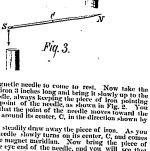
Pieces of window glass. Two 12 inches by 6, and two pieces 6 inches square.

A small bottle of spirit varnish, such as photographers put over their negatives.

Needles, nails, and tacks of various sizes.

With the above simple articles cheap things a great many interesting and beautiful experiments can be made; and we will now show how to obtain from these homely instruments much information that is really sound and useful.

Experiments showing in what a Magnetic Substance differs from a Magnet.—Place the magnetometer on the table and



allow the magnetic needle to come to rest. Now take the piece of soft iron 1 inches long and bring it slowly up to the magnetic needle, always keeping the piece of iron pointing toward the point of the needle, as shown in Fig. 2. You will observe that the point of the needle moves toward the iron, turning around its center, C, in the direction shown by the arrow.

Gently and steadily draw away the piece of iron. As you do so the needle slowly turns on its center, C, and comes again into the magnetic meridian. Now bring the piece of iron up to the eye end of the needle, and in such a way that this end turns toward the iron in the same manner that the point of the needle in the previous experiment. Thus we find that a piece of soft iron attracts either end of the magnetic needle. Each end moves toward the iron. If this be so, it necessarily follows that if you point the piece of iron toward the center of the needle and bring it up to the needle in the position shown, keeping care always to have the length of the piece of iron at right angles to the length of the needle, the needle will not move, remaining steadily resting in the magnetic meridian. Each end of the needle is equally attracted toward the iron, and as each end tends to turn in the direction shown by the arrows in Fig. 4, it remains at rest under the action of two equal forces tending to rotate the needle in opposite directions.

Now we will make some experiments similar to those just described, but differing in this: we use a magnetized No. 1 sewing needle instead of the piece of soft iron. Take a No. 1 sewing needle and draw it from point to eye over the N. end or pole of your rat-tail file magnet. You will, by this operation, have converted the needle into a magnet, and if you suspend it, as I with you now to do, like the needle of your magnetometer, you will find that *it points in the magnetic meridian with the point toward the north.* The ends of magnets, or, more accurately speaking, certain points in the center of magnets and near their ends, are called *the poles of the magnet.* To distinguish these two poles, they are respectively called north pole or south pole, corresponding to the end of the needle which points toward the north or south geographic pole. The points of our magnetized needles are, therefore, north poles, while their eye ends are south poles.

Bring the No. 1 needle up to the needle of the magnetometer, with its point toward the point of the magnetometer needle and with its length always at right angles to the magnetic meridian, as shown in Fig. 5. The N. pole of the needle moves away from the north pole of the No. 1 needle, and we here have *repulsion* instead of attraction, as we had when the piece of iron was placed in the same position. Now point the north pole or point of the No. 1 needle toward the eye end, or south pole, of the magnetometer needle, as shown in Fig. 6. In this position of No. 1 needle, the S. pole of the suspended needle moves toward the N. pole of the No. 1

A New Form of Electric Lamp.—Carbon pencils of steel and borings of brass, with a MIXTURE OF SALTS, are used in a lamp has been invented by MR. ERNST WOLFF, of Berlin, Germany. The mixed materials are put into a leaden cylinder or drum, to which the brass and steel adhere, while the copper and brass fall into a special reservoir below. There are two hollow cylinders rotating in the same direction, so that the iron which escapes from the first cylinder is retained by the second. The surface of the cylinder is formed by flat bands or strips of soft iron alternating with strips of copper, and each of the iron bands is in contact with a row of horseshoe magnets. The adherent metal is removed by revolving brushes.

EDISON'S MAGNETIC ORE-SEPARATOR.—WASHINGTON, June 1, 1880.—Thomas A. Edison, of Menlo Park, N. J., was to-day granted a patent for a magnetic ore-separator, which allows magnetic and non-magnetic substances to fall together, and then, by magnetic attraction, allows or causes the trajectory of the falling magnetic substance without stopping its fall.

ON SOME POINTS CONNECTED WITH TERRESTRIAL MAGNETISM.

I HAVE to make further remarks on the various points brought forward some of the various points which are here grouped together. These points are three in number.

(a) Regarding the sustaining power of the earth's magnetism.

(β) Regarding the diurnal and other changes of the same.

(γ) Regarding earth currents and auroras.

I may state at once that this only professes to be a working hypothesis.

(α) Regarding the Sustaining Power of the Earth's Magnetism.—I do not here intend to discuss the cause of the earth's magnetism, but I would ask in the first place if it is not possible that this cause may be something small and one which (assuming it to continue at the present moment) we may not readily perceive. If we assume this cause or magnetic nucleus to be small it is not possible to imagine that there is a machinery which acts upon this nucleus (just as we have in certain magneto-electric engines) so as to swell up the magnetism of the earth ultimately to saturation.[1]

May not this machinery be the great convection currents, the anti-trades, that go from the equator to the poles in the upper regions of the earth's atmosphere, and which may be looked on as conductors moving across lines of magnetic force?

It would appear to me that the tendency of such currents will be to swell up and sustain the magnetism of the earth.

(β) Regarding the Diurnal and other Changes of Terrestrial Magnetism.—It will of course be natural, entertaining the views now enunciated, to regard the diurnal changes of the convection currents of the earth's atmosphere, as these are manifested in the upper regions, to be the cause of the diurnal changes of terrestrial magnetism.

If this view be taken it might be argued that solar changes in these upper regions should also produce magnetic variations. The reply is that apparently they do. In conjunction with Mr. Mortabha Hirzaka I have compared together the simultaneous records of magnetic declination taken at Kew and at Trevandrum, and I find evidence of a progress of things from west to east, so that on the whole a particular magnetic change phenomenon occurs at Kew 27 days before it occurs at Trevandrum. Again, I have attempted to show, in conjunction with Mr. Dodgson, that a particular magnetic phenomenon occurs at Kew one day before it occurs at Prague.

It would thus appear that there is a progress of magnetic phenomena from west to east, just as we know there is a progress of meteorological phenomena. As, however, the meteorological phenomena which we can examine occur in the *lower* atmospheric regions, while the magnetic phenomena are, according to this hypothesis, associated with currents in the *higher* regions, it does not follow that magnetic and meteorological phenomena should travel from west to east at the same rate. I may also mention that we have reason to believe that magnetic changes lag behind corresponding solar changes just as meteorological changes would do.

It is manifest that it will be comparatively easy to settle the fact of a progress from west to east of magnetic vexation, and that if such exists it will most readily ally itself with the hypothesis above mentioned.

In the next place, if we regard these changes in the convection-currents of the earth which depend on the year we have reason to imagine that such are most pronounced at the equinoxes. It is also well known that magnetic disturbances are most frequent at these times.

Let us next proceed to regard the secular change of the earth's magnetism. To account for this magneticians have felt the need of something movable, and the hypothesis of a "little earth," a solid nucleus moving within the recesses of our planet, has found much support. But is it not more likely that the result may be caused by a secular variation in the distribution of the convection-currents of the earth? If the question be asked, What reason have we for imagining the existence of such a variation, the answer will be, A much better reason than we have for entertaining the conception of a "little earth." For there is some reason, at any rate, for imagining the power of the sun to be subject to a complicated series of periodicities. Now a secular variation in the power of the sun would produce a secular change not only in the intensity, but in the direction of the convection-currents of the earth, and, according to the above hypothesis, these in their turn would produce a secular magnetic change.

(γ) Regarding Earth Currents and Auroræ.—I have for some considerable time looked on the earth as a Rohmkorff's coil with a magnetic nucleus. Above this nucleus we may suppose that we have the primary rocks, which are non-conductors, while above these we have the moist or comparatively moist surface of the earth, which is a conductor. Above this, again, we have the lower strata of the atmosphere, which are non-conductors, while above this we have the upper strata, which are conductors.

Now suppose that a small but abrupt change of the earth's magnetism takes place, no matter how. We need not enter into the causes of such.

We have thus two secondary coils, if I may use the expression: (1) the moist surface of the earth, (2) the upper regions of the atmosphere; and both of these will be animated with secondary currents, on account of the abrupt change of the earth's magnetism. These secondary currents will be in one direction for a magnetic change of one kind, and in the opposite direction for a magnetic change of the opposite kind.

Now whenever there are magnetic storms, that is to say, when there are small but abrupt changes of the earth's magnetism, it is well known from the Greenwich records that we have violent earth currents, which are alternately positive and negative, and that we have also auroral displays in the upper regions of the earth's atmosphere. We cannot examine the auroral displays as we can the earth currents. But with regard to earth currents I would remark that the *form* of the phenomena they display is entirely against the supposition that such currents are the main cause of the changes in terrestrial magnetism, and in favour of that which maintains that they are secondary currents induced by magnetic changes.

In conclusion I would guard against its being supposed that all luminous appearances in the atmosphere are due to the same cause. I only hold that certain appearances which occur at times of magnetic perturbation and simultaneously throughout a large portion of the earth have the origin now mentioned.

B. STEWART

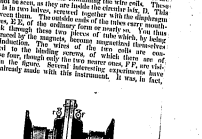
[1] If I am not mistaken, Sir W. Thomson is inclined to regard the earth as a magneto-electric engine.

bursing of which their brittleness is diminished, and the re-
quisite elasticity imparted. If they are to be very hard, but
a small portion of the casting is allowed to harden off; but, if
softer, it may be allowed to harden until it goes out. If the
objects are of greater or less uniform strength, as many
springs, the blasting off is repeated upon the whole object,
or on portions of it until the desired uniform degree of hard-
ness results. Gunlock springs are sometimes tempered by
boiling in oil, by which a very uniform temperature for all
portions is secured, and the thinner portions do not suffer
from the continued heat of blasting off.

DUPLEX TELEPHONE.

The principle is that of soldering a single diaphragm
to the action of a magnet and coil on each side of it, and
the two, to affect two separate circuits with their coils by the one
diaphragm. The instrument as constructed is shown in the
cut.

A A are the north and south poles of a horse-shoe magnet,
are laminated out so as to embrace short pieces of soft iron
into useful coil B. On the ends of these pieces of soft iron
slipped the usual bobbins containing the wire coils. These
fastened in two hollows, screwed together with the diaphragm
between them. The outside ends of the tubes carry mouth-
pieces, E E, of the ordinary form or nearly so. You thus
speak through the one piece and hear with the other, by being
connected by the two circuits, because suggested in the
inverted to the binding screws of which there are our
course four, through only the two shown, F F are, of
ble in the figure. Several interesting experiments have
been already made with this instrument. It was in fact,



NEW DUPLEX TELEPHONE.

with this that the phonograph was used as described in my
former letter, though not quite in the present form.

If one magnet and coil be properly coupled up to the
other so as to bring both into unison, the sound will be
much greater than when only one is used. Indeed, it is found that if two persons speak or sing simultaneously, one into
each mouthpiece, the diaphragm will vibrate responsively, so into
of vibrations, that both voices will be repeated by both coils of the
telephone, so that both persons will be heard at the distant
received from the single diaphragm. Even two near sounds
Again, by coupling an ordinary telephone, A, with one
end of the "duplex," and another, B, with the other coil
ends of A and B, a circuit is thus established between the
wires A and B. This would be naturally carried on
the diaphragm receives and "draws on" the vibrations, but
Melodeon. It hums at first sight rather odd.—*English*

MANIFOLD USES OF PRESSED PAPER LETTERS AND ORNAMENTS.

ornaments formed by gluing the letters on a suitable piece
state.

Dr. HOPE has recently instituted a comparison between
the indicator that "the velocity of the wind and its pressure
wheel is inversely proportional to the number of
penetrating rays," and the relation of the latter
view that the former is due to the least action of
of heat rays, which "is confirmed by the
water," says Dr. Hoff, "to penetrate the glass is due to an action
layers of light. A new plate has been made, having a mechani-
with full light. It is a long time before the opening a mechani-
quickly closed by the action of a spring. The velocity with

horse instantly.

APPLICATION OF ELECTRICITY TO CHRONOMETRICAL MEASURE.—M. HIPPOLYTE FONTAINE, of Paris, has recently invented an apparatus for obtaining by means of electricity, so-called electrical machine consists essentially of a wheel, the axle of the crank within reach, the poles of which are set, with by means of wires sewed to the bottle and pass, one with the stopper. Turning the crank is said to stop a vicious horse instantly.

the magnet has been removed from it. This difference in the after effects of induction on soft iron and steel is best observed in the following experiment:

Take a piece of the softest iron, and having ascertained that it is entirely free of magnetism, draw it repeatedly over the end of the magnet; if the iron is really soft, you will find that even repeated stroking on the magnet confers upon it no power of attracting the filings. However, passed over the iron will retain a slight, though often very slight, amount of magnetism, and will cause a few particles of filings to adhere to it. Now perform the same experiment with a large sewing needle, and observe how powerful a magnetic charge has been given to it. When rolled in the filings large tufts adhere to the needle, surprising those who have never before how strong a magnet may be thus made of a large sewing needle.

The retention of a magnetic charge by steel enables us to readily fashion magnets of any size or form. If steel are some other easily worked body had not this property we would be obliged to construct our magnets of compound pieces out of the hard and brittle cementite or lonsdalene. Indeed, it would be difficult to select from the whole range of the especial properties of matter one more valuable to man, or more necessary to its present high and widely spread civilization, than this one of the capability of steel to receive and retain the properties of the lonsdalene.

Further Experiments in Magnetic Induction.—Let us, by means of other simple experiments, examine more minutely into the nature of this magnetic induction.

Take two pieces of very soft iron wire and suspend them by silk fibers, as shown in Fig. 19. Hold the ends of the fibers separated, between the thumb and forefinger, and the wires may hang a quarter of an inch or so apart. Now bring them slowly down toward the N. end of the magnet, as shown in Fig. 19. They now no longer hang parallel to each other,

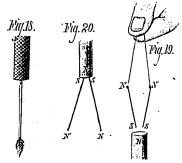

Fig. 19.

but are inclined, the upper ends of the wires repelling each other, so that the two suspending threads are forced outward and no longer hang vertically. This repulsion between the upper ends of the soft iron wires is caused by the magnetism that the ends have received. We have already seen that like poles mutually repel. (See experiments described, in Fig. 1, as to the N. poles of the magnets.) Again, by reversing the experiment described in Fig. 19, then the lower ends of the suspended iron wires are N. polarity and their upper ends assume north polarity.

The experiment just described may be modified by simply

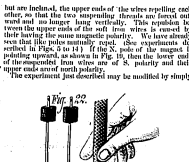

Fig. 20.

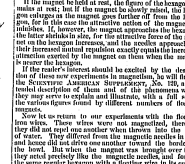

Fig. 19.

Fig. 21.

holding the two wires parallel to each other between the thumb and forefinger and bringing their ends to touch the end of the magnet. They will adhere to the magnet, and on reflection it will be observed that the lower ends of the wires will at once fly apart, from their mutual repulsion, as shown in Fig. 20.

Take seven pieces of iron wire, each about 1 inch long, and run them through a small cork, about ¼ of an inch long and ¼ inch in diameter. Throw these pieces of wire into a tumbler of water and they will float upon the surface, the cork resting on the water, and the wires projecting downward. Now bring the N. pole of a magnet near the tumbler. The wires will be attracted toward the magnet, and after many unsuccessful endeavors, they at last take up the definite position shown in Fig. 21.

This beautiful illustration of magnetic induction, and this experiment tells the whole story when viewed in the light which another glass, and which we have so described before awakening further of the one just made.

Take seven sewing needles (Milward's No. 4 tapersare good for this experiment. At the N. Y. Cork Cutting Co., 48 Fulton street, New York, you may buy a gross of corks, of ¾ inch in length and ¾ inch in diameter, for 40 cents. Magnetize each needle by drawing it from the eye end over the N. end of your small bar magnet. Push one each needle through the center of a cork, using for this one of the corks just described. In other words, push the corks which will float three needles on 1½ inch long and ¼ inch in diameter. Now throw these needles in the bowl of water. They repel one another, and if close enough together will at once fly to the edge of the bowl and will arrange themselves at equal distances apart around the border of the water. They are in a measure wire floating upon their like poles are opposed to each other, as shown in Fig. 22, and these like poles mutually repel.

We add the needles remain on the border of the water in the bowl, as long as they float upon the surface. Now take hold of the long sewing needle, with its N. pole pointing downward. The magnetic needles at once move from the middle of the bowl, and after moving about each other for a while, they end by forming themselves into a regular geometric figure of the seven, with 2 needles in the center, as happened in the experiment with the floating iron wires, shown in Fig. 21. In the experiment with the magnetic needles we know the exact magnetic conditions of the experiment. We know that the needles are magnetized, and that their south poles are pointing upward and their north poles are pointing downward. The like poles of these needles being strongly and mutually repel, and keep apart till the N. end of the magnet has been brought over them; then the strong north pole attracts the upper or south poles of the needles, and they draw toward the N. pole of the magnet. In other words, the attraction existing between the N. pole of the magnet and the south poles of the needles is stronger than the repulsive force existing between the needles. The needles therefore move toward the magnet and approach one another till their mutual repulsion activates keeping them apart just balances the attraction of the magnet which tends to bring them together.

If the magnet be held at rest, the figure of the hexagon remains at rest; but if the magnet be slowly raised, the hexagon enlarges as the magnet goes further off from the hexagon, for in this case the attractive action of the magnet diminishes. If, however, the magnet approaches the hexagon, the latter also shrinks, for the attractive force of the magnet on the hexagon increases, and the needles approach till their increased mutual repulsion exactly equalizes the increased attraction exerted by the magnet on them when the magnet is nearer the hexagon.

If the reader's interest should be excited by the description of these new experiments in magnetism, he will find in the SCIENTIFIC AMERICAN SUPPLEMENT, No. 122, an extended description of them and of the phenomena which they may serve to explain and illustrate, with a full set of the various figures found by different members of floating magnets.

Now let us return to our experiments with the floating iron wires. These wires were not magnetized, therefore they did not repel one another when thrown into the bowl of water. They differed from the magnetic needles in this, and hence did not drive one another toward the border of the bowl. But when the magnet was brought over them they acted precisely like the magnetic needles, and formed the same regular hexagon with a floating wire in its center. The force acting on the wires and the needles was the same. It was the N. pole of the magnet. We know that the needles were magnetized, and that the N. pole of the magnet threw their south poles upward and their north poles downward. In the water we could not find the latter, but we therefore have a right to assume that such was the case. The N. pole of the magnet kept upper ends were made south poles by the inductive action of the magnet, and their lower ends under the water, were made north poles by the same action.

We can now understand the condition of the polarity in the magnetic chain formed by the suspended nails, brads, etc., in the experiment shown in Fig. 17. To the N. pole of the magnet is attached a nail. The end of the nail touching the magnet is made its south pole by induction, while its other end is made its north pole. This nail now acts just like the magnet which magnetized it, and the nail in turn magnetizes by induction nail No. 2, and this nail No. 3, and so on to the end of the magnetic chain, which is terminated by the magnetized iron filings.

Experiments which show Something about the Nature of a Magnet.—Take the piece of steel wire, six inches long and one-sixteenth of an inch in diameter, mentioned among the articles required in our experiments, screw this piece of wire at a short distance apart, by filing it some with a sharp file. Now heat the wire to a cherry red, and then plunge it vertically into water. It will now be quite hard, and may be readily made into a magnet, by drawing it over the poles of your magnet. Lay the wire upon a piece of paper and scatter around one of the ends of the steel a few pins, needles, or nails, and you will find that the one over the N. pole of the magnet, from the paper, and the other will have north polarity, as may the general end of the wire will have north polarity, as may be shown by applying the wire to the magnetometer. The magnetic condition of the wire having been found out, we begin by snapping the wire into small pieces, which are readily done, for the spores on the wire determine where it will break. Place each piece on its side in the same direction from the wire and with its north pole in the same direction as the wire, and you will have a perfect row of the wire. Examine each of these pieces by means of the magnetometer. They will be found to be magnets, with N. poles turned all one way, their south poles turned in the other direction. This experimentation may be made by means of the magnetometer, but it can be more readily and easily made by means of iron filings, shown by rolling it in iron filings, when it will be found that the filings adhere to the ends of the piece of wire just as they did to the large magnet. See Fig. 11.

In Fig. 23 is given a view of the pieces of wire placed end to end just in the position they had when they formed parts of the steel wire. We see that each piece is a perfect magnet, and that the north poles of these pieces all point to the right and their south poles to the left. But each of these little fragments may be broken into two, and so on; and as far as the subdivision may be carried, it has been found that each minute fragment is a perfect magnet, with one of its ends a south, and the other a north pole. Experiments in imagination was my constant aid in the exhibition carried on in the following manner, and reached may be invisible to the unaided eye. Indeed, nothing prevents us from logically assuming that even if a molecule of the steel should be reached it would be found to be a perfect magnet.

An Experiment with a Magnet formed of Steel Filings Rolled in a Paper Cylinder. is interesting when studied in connection with the experiments just made, and will serve to give us further information as to the nature of a magnet.

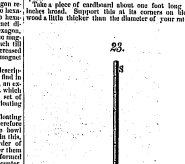

Fig. 22.

Take a piece of letter paper, and having wrapped it several times around a lead pencil, pass the free edge of the paper on to that wrapped around the pencil. After the paste has dried you may draw out the lead pencil, and you will then have a tube made of paper. Cork one end of this tube, or you may close it by doubling over the paper at its end and gluing. Fill this tube with steel filings, and close also the other end of the tube. This tube, filled with steel filings, will now form a good bar magnet. After you have magnetized the tube (operation several times, present the tube to the magnetometer, and you will find one of its ends is a north, while the other is a south pole. Having thus satisfied yourself that it is really a magnet, open the tube as before, and the positions of the particles of steel filings are changed. On testing the tube at the magnetometer it will be found that, strange to say, the magnetism has gone from it. If it has not all disappeared it has been reduced to so low a potential as to be of no practical use. This experiment shows that not only must each particle or even molecule of a steel bar be a perfect magnet, but it also shows that these magnetized particles must be arranged in a definite order, that is, with all their N. poles pointing in one direction and their south poles in the opposite direction, so that the body, as a whole, may obtain and retain its magnetic polarity. Before the year 1600, when William Gilbert, Elizabeth's physician in Colchester, made the celebrated experiment of forming a magnet into many parts and testing each of these parts, and then use of its ends is a north, while the other is a south pole. Having thus satisfied yourself that it is really a magnet, open the tube as before, and the positions of the particles of steel filings are changed. On testing the tube at the magnetometer it will be found that, strange to say, the magnetism has gone from it. If it has not all disappeared it has been reduced to so low a potential as to be of no practical use. This experiment shows that not only must each particle or even molecule of a steel bar be a perfect magnet, but it also shows that these magnetized particles must be arranged in a definite order, that is, with all their N. poles pointing in one direction and their south poles in the opposite direction, so that the body, as a whole, may obtain and retain its magnetic polarity. Before the year 1600, when William Gilbert, Elizabeth's physician in Colchester, made the celebrated experiment of forming a magnet into many parts and testing each of these parts, and then use of its ends is a

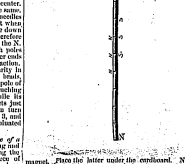

Fig. 23.

magnet. Place the latter under the cardboard. Now lift the cardboard off the magnetic parts and place it to one side on the table. Through a fine sieve sift soft iron filings evenly, and not too thickly, over the cardboard. Lift it up carefully and place it over the magnet. A slight bebedling of the filings at all times will discover the general direction of the magnetic lines as they are forming the cardboard, by letting fall very gently a few pieces of iron filings. Should it gently tap the cardboard, you will observe certain motions among the grains of filings. They will finally arrange themselves over the magnet in the form shown in Fig. 24.

Fig. 25 shows the arrangement taken by the iron filings when they are placed on a card and vibrated over the ends of a round magnet, the magnet being held in a vertical position under the cardboard.

Fig. 26 are the lines formed over the end of a magnet; Fig. 27 and 28 respectively show the position of magnets with their saddle and like poles opposite each other.

The effect of the magnetic arrangement of the lines of filings produced on a surface when under is a magnet, and filings have long and attracted by it gently tapping the surface, is represented in a cylinder of soft iron, 12 millimeters long and 10 millimeters in diameter. In April, 1871, I exhibited this piece in the *America*. A piece of Sweden I had invented for permanently fixing the lines of force of any magnetic centre, and they are shown on plates of glass. When these permanently attached lines are required, a sheet of paper from which a series of plates were printed, exactly as a photographer prints from a negative, is placed over the magnet. The sensitized varnish of magnetic spectra given in this article were made by a photo engraving process closely from the glass plates made by me in 1871. These glass plates carrying the magnetic spectra I have also used for several years as slides in the lantern, in order to exhibit them before large audiences and college classes.

The following is the method of permanently attaching these magnetic figures to glass. A clean plate of this glass is coated with a film of hard varnish by flowing over it the varnish used for photographers in coating their negatives. If this is not handy, then a solution of shellac in alcohol will do nearly as well, only the latter requires more coating to cause the iron filings to adhere to it. The varnish is poured on one end of the plate, and then caused to

Why the magnetic needle points to the north is thus explained by *Prof. C. T. Patterson, of the United States Coast Survey*:

"The needle does not point to the true north, but at present it points to the northwest. The magnetic north is not found to be affected by the action of the sun in a manner not yet understood. The magnetic poles of the earth are not in the same position as the geographical poles, but make an angle with them of nearly 20°. The magnetic pole at present time the northern magnetic pole is near the Arctic circle, on the meridian of Dundas, and, from the nature of the case, the pole may better be described as a region rather than a fixed point. The needle does not point to the magnetic pole, but to some astronomical north, but varies within certain limits. At San Francisco it points 17 degrees east of north, and the variation is annually to the west. At the northern magnetic pole a balanced needle points with its north end downward in a plumb line; at San Francisco it dips about 60 degrees, and at the southern magnetic pole the south end points downward. The action of the earth upon a magnetic needle at its center is much about the same force as that of a hard steel magnet forty miles from the needle suspended, at a distance of one foot. It is very probable that a study of dynamo-electric machines, now so much used in electric illumination, will soon reveal some far-reaching truths regarding magnetism in general."

EDISON'S ORE SEPARATOR.

THE annexed sketch, [illegible] as illustrative of the principle on which Mr. Edison, of Menlo Park, proposes to construct a magnetic ore separator. The device is intended for working tailings which are now thrown away as being too poor to pay for working by any of the processes now in use. The machine is simple in the extreme. The sand is fed in a cone of the form shown, over the magnet. The magnetic attraction changes the trajectory of the falling magnetic sand without stopping its fall, so that while the

silicious sand, gold, and other non-magnetic substances fall straight down into one compartment of the receiving hopper, the trajectory of the magnetic sand is changed, so that it falls into another compartment of the receiving hopper. By this means the separation of the black sand is rapidly and completely effected with the expenditure of very little power. It is not clear how it is that the magnetic attraction, which decreases so rapidly with increase of distance between things magnetic, attracts the particles when at a greater distance than that at which it lets them go.

EDISON'S ORE SEPARATOR.

Electrician

In our "Report" for last week we quoted an American statement to the effect that an apparatus identical with Edison's vaunted ore separator had been in use in that country for some years. It is satisfactory to find that the Americans have thoroughfares found out the ancient character of that latest bantling from Menlo Park. But the same device has been before the world in France for the last twenty years at least in Fremont's machine for separating magnetic oxide from copper ore. Fremont is the well-known mechanical electrician of Paris, and his apparatus consists of a hopper, through which the ore was poured, and a powerful electro-magnet, which was placed underneath so as to attenet the magnetic particles of sand aside from the rest of the nonmagnetic copper ore. The contrivance is, in fact, essentially the same as Edison's. No doubt there are several English patents describing the same arrangement; but Fremont's is, so far as we are aware, the first instrument of its kind.

A similar device has been used for some years in America for extracting the bits of wire left in gouia from the wire bands of the binding machines so commonly employed by American farmers. In fact, magnetism has been applied in the same way to a great variety of purposes.

The ore separator which was to cover Mr. Edison with the wealth of Eldorado, and transform him into a rival of Mr. Mackay, the owner of the "Big Bonanza" mine, is an old affair refurbished up, and though it may make the New York interviewers gape, and tickle the sensation palate of omnivorous Yankees, it will, weimagine, hardly pay for its own manipulation in gold extracting. The proportion of "black sand" or magnetic oxide in gold "tailings" is, we are assured by an experienced gold miner, so very small, that its separation from the rest of the ore will make hardly any appreciable difference in the expense of extracting the small percentage of gold from the residue by washing over mercury. Had the black sand formed a considerable proportion of the whole "tailings" there might have been some value in the magnetic separator. As it is the game is not worth the candle.

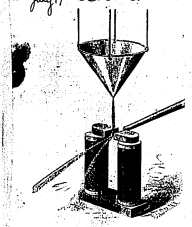
M. BECQUEREL finds that in the case of the diamagnetic gases, protoxide of nitrogen, carbonic acid, nitrogen, and olefiant gas, the amount of magnetic rotatory polarization which rays of light undergo in traversing them in the same direction as the magnetic force rolls in the case of the ores lengths is for nonmagnetic bodies. Oxygen, a magnetic gas, acts differently, for red rays it gives a rotation which is a little above the green rays; in the case of the diamagnetic gases the reverse is the case, the maxima for green as compared with red being as 10 is to 8.5.—*Comptes Rendus*, lxxvii., 1873.

EDISON'S ORE SEPARATOR.

The *Scientific American* of June [illegible] contains an illustration of the new invention of Mr. Edison for extracting gold from the refuse "tailings" of a placer. This remarkable contrivance which the "sensation heading" writer of the *New York Herald* dubbed "Edison's Big Bonanza," turns out to be nothing more than a wooden funnel through which the "tailings" are poured in a stream past the poles of a powerful electro-magnet, which has the effect of deflecting the "black sand" or magnetic particles in a branch stream towards it, and leaving the barren sands and non-magnetic gold to fall vertically downwards into a separate receptacle.

NEW ORE SEPARATOR.

In one of our recent issues we described a device invented by Mr. Edison for separating magnetic sands from the non-magnetic particles of ore by altering the trajectory of the



EDISON'S ORE SEPARATOR.

falling magnetic substance by means of an electro-magnet. We now give an engraving of another magnetic ore separator recently invented by Mr. Edison, which operates on an entirely different principle, and effects a still further concentration of the ore by the separation of the metallic from the non-metallic part by diamagnetism.

The auriferous sands are placed in the hopper and allowed to fall between the poles of a powerful electro-magnet, and a blast of air is directed at right angles against the falling stream of sand just as the latter passes between the poles of the magnet. The non-metallic substances are readily blown away, while the metallic portions are retarded by diamagnetism, so that the blast of air has less effect on them than it has on the non-metallic substances. The concentration of this operation is that the sands are divided into two heaps, one containing a large percentage of metal, the other containing a very small percentage, or none at all.

CURIOUS MAGNETIC EXPERIMENTS.

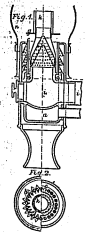
Mr. Obalski has made some curious experiments in relation to the French Academy's experiment, in which needles are suspended over water by the attraction of two magnets, similar poles attracting each other by an almost imperceptible and even distant force, each of mutual attraction; but rather than the sum of their radii of mutual attraction; water is gradually brought up over them by means of the tube of caoutchouc connected with the vessel and wound on a drum. When immersion commences, the needles approach each other by their inner and outer third or fourth and when the immersion has reached a little over half of the needles' length, they touch together. The explanation seems to be, that what hindered the approximation of the needles was their own weight; and the force of gravity being surmounted by the immersion, the magnetic forces become manifest. If the needles are suspended by their poles of the same name, a corresponding though opposite phenomenon is witnessed.

THE *Journal of Gas Lighting* says:—Considerable importance was formerly given by English and French papers to the fact that the Paris *Salon* was to be lighted by electricity, and the assumed superiority of this light over gas for the illumination of paintings was accepted unquestioned by those who were too indifferent or too prejudiced to inquire very closely into the matter. We find, however, that a class of persons who must be admitted to have some slight knowledge of what is a good and what a bad light for a picture—the artists themselves—have protested against the use of the electric light at the *Salon*, this being stated to be the most unfavorable kind of illumination for effectively showing off their productions. The protest, however, comes rather too late. The agreement entered into with the Jablochkoff Company for the supply of the electric light has been carried out, and this system will, we suppose, remain in use until the end of the season, artistic protests notwithstanding. Again, when asked, right-thinking people are inclined to express a doubt as to the perceptible superiority of the electric light by the exhibitors at Paris who had been so ready to make use of it as a novel and attractive, that is, as a money-getting kind of advertisement, their feelings were not spared by the worshippers of the rising Company with all the impertinent contempt usually manifested towards opponents by converts to a new faith. Yet what do we find? The *Figaro*, whose office in the Rue Drouot was one of the first buildings to be illuminated exclusively by means of the electric light, has positively abandoned that system, and substituted for it two gas lamps similar to those used by the Paris Gas Company in the Rue du Quatre Septembre, where, by the way, only half the original number of burners are now lighted, and yet the general illumination of the thoroughfare is, we learn, if anything, a trifle better than that of the neighbouring Avenue de l'Opéra, where the electric light still reigns supreme."

THE Influence of Magnetization on the Tenacity of Iron has been lately studied by Signor Pizzoli. Iron wires were hung between two hooks and ruptured by pouring water into a vessel suspended from them. They were about 350 mm. long, and were inclosed in a spiral with four windings one over another, which were either all traversed by a current in one direction, or two by a current in one direction, and two by an equal opposite current, so that in both cases the wires were equally strongly heated by the spiral; but in one case they were magnetized, in the other not. The weights applied to break wires annealed in charcoal—weight of one metre, G = 0·299—were, during magnetization, P = 1266·5906; without magnetization, P = 1213·1276. In the case of wires annealed in carbonic oxide—where G = 0·48 g—P = 1732·4·1742·7; P' = 1707·62, 1710·87. In the case of wires annealed in hydrogen P = 1289·5·1310·1; P'=1163·1197·7. In each separate series accordingly the difference, P − P' was frequently less than the difference between the highest and lowest weights required for rupture of apparently identical wires; still, the mean values in each of the fourteen series were from about 1 to 3 per cent greater for the magnetised than for the unmagnetised wires, showing that the tenacity of iron increases on magnetization.

THE Annealing Process of Steel.—It has been proved by Hermes Stroinal and Reese (*Wied. Ann.* No. 13, 1880), from experiments in which steel wire was treated so as to show all degrees of hardness between the glass-hard and annealed state, that the thermo-electric and galvanic properties of steel vary with the degree of hardness in a perfectly regular manner. Their researches throw some useful light on the nature of the annealing process, and on the magnetic behaviour of steel in relation to its hardness and other properties.

1861. Lampe! F. Siemens, Dresden. (Gb. 11 Sept.)—The subject of this patent is a lamp having currents of air passing from the flame through a second regenerative chamber within the annular burner of the lamp, while the air required for combustion is passed through the space in the regenerative chamber surrounding the burner of the lamp. The annular burner carries a number of small vertical tubes, which are open at the top, and communicate with the gas being admitted into the chamber a (fig. 1), and the products of combustion of a row of small tubes, lateral, the air for supporting combustion is passed through the regenerator c, and being partly caused to flow by the action of the ring of tubes will exist in combination with the gas, and form a mixture which will burn at the upper surface of the plate e. In a few seconds a tube placed immediately above the lamp-tool shown in the figures will become heated and will have the effect of increasing the draught. The products of combustion, such as exist so as to form a certain current of electricity, in consequence of the suction thus produced, a portion of the products of combustion will proceed from the flame through the regenerative chamber from which it derives its heat, through into the tube above the lamp. The products of combustion between the chimney a and the tube, by means of a throttle-valve, will above, in the figures, the bulk of the products of combustion will be conducted through the tube b into the regenerative chamber c. This heat will be imparted partly by radiation and partly by conduction to the regenerative chamber c and gas inlet. The products of combustion will then pass through the tube, thus producing a greatly increased draught, and being thereby reduced air deficient, shown at g and h which are formed by the passage of small currents impinging on each side of the flame, as described in Specification 2153, 1860. The cylinder f is made of fireclay, or other suitable material, and the upper part of the lamp is drawn downward over the edge, the height of the cylinder will determine the height of the flame. In some cases the regenerative hollow perforated annex to the regenerative chamber c may be dispensed with, and the tube f may, if convenient, be connected with the chimney instead of reaching straight instead of to the chimney for above the lamp. In a modification the combined



products of combustion from two or more such lamps pass to-gether at the lower central part of the stove in which the lamps are placed, and the regenerative hollow being provided with a gas inlet for producing the requisite draught. The invention is described as applied to a lamp with open flame.—Sealed 16, 1861.

Curious Experiment in Magnetism.—The following experiment is described by M. Oberbeck, in communication to the Academie des Sciences: "Two magnetic needles are hung vertically by fine threads, their upper poles being opposite one another. Below them is a vessel containing water, its surface not quite touching the lower needle. They are hung so far apart as not to move toward one another. The surface of the water, blown quickly aside by bellows, forms quantity of flow in from below. As soon as the water covers the lower ends of the needles they begin to approach one another, and when they are nearly immersed they rush together. This effect appears to be due to the fact that the gravitation force downwards is counteracted by the upward hydrostatic pressure, due to immersion, the magnetic force, being relatively greater, is able to assert itself.

magnétique ayant été mesuré au moyen d'un compas à miroir, on compensa l'action déterminée par l'hélice précédente au moyen d'une seconde hélice, et le barreau fut ensuite chauffé de 20° à 140° C., au moyen de courants d'huile chaude. Après une première aimantation, on rétablit successivement l'intensité du courant au moyen de résistances croissantes, introduites dans le circuit, afin de pouvoir mesurer le magnétisme rémanent, et on achèvera de démagnétiser au moyen de courants alternatifs plus faibles. On répéta l'expérience aux trois autres barreaux avec des actions magnétisantes moins énergiques, et on arriva aux conclusions suivantes :

1° Le maximum d'aimantation d'un barreau correspond à sa température la plus élevée, et cet effet est d'autant plus caractérisé que la force magnétisante est moindre. A 140° le maximum est de 3 o/o plus petit.

2° Si les courbes de magnétisation aux températures $t = 20°$ et $t' = 140° - 150°$, sont déterminées en prenant les moments magnétiques comme abscisses, et les forces magnétisantes comme ordonnées, l'abscisse du maximum correspondant au point très près les trois quarts de sorte qu'il existe un degré d'échauffement qui correspond au maximum d'aimantation.

3° En chauffant et refroidissant lentement à plusieurs reprises le barreau, les courbes de magnétisation pour les températures basses vont en s'élevant, et en s'abaissent pour des températures élevées, sation pour les températures basses vont en s'élecorrespond au maximum d'aimantation.

Ce travail est un peu maigre, et nous engagerons ceux de nos lecteurs que cette question intéresse, de se reporter aux travaux de M. Gaugain que nous avons analysés dans le tome II de ce journal, p. 365 et 489. On y verra que ces conclusions avaient été déjà formulées par lui, et on y trouvera même l'indication des deux effets inverses qui viennent d'être signalés. Voici, en effet, ce qu'il dit à cet égard : « Si on élève graduellement la température du barreau, jusqu'à ce qu'il prenne la teinte bleue, *on constate que l'aimantation grandit d'abord, atteint un maximum, puis subit une rétrogradation.* » Il discute ces effets d'une manière bien autrement intéressante que le physicien allemand, et nous sommes étonnés que des savants aussi sérieux, aient étudié les travaux recherches, n'aient pas mentionné travaux plus complets que tout ce qui a été fait jusqu'à présent.

Influence de la température sur la distribution du magnétisme dans un aimant permanent.

Ce que nous venons de dire précédemment, relativement au mémoire de M. Weinhold, qui conclut, qu'un aimant cylindrique de 80 centim. de longueur, sur 0,5 mm. de diamètre, chauffé plusieurs fois à la température de 250° C. et ensuite refroidi à la température ambiante, ne présente pas la même distribution magnétique avant et après le chauffage, et qu'à 14 ou 15 centimètres du pôle nord, la puissance magnétique est plus forte qu'à 28 centimètres, etc. M. Gaugain a mieux précisé les faits, car il montre que des aimants qui ont subi plusieurs alternatives de chauffage et de refroidissement, subissent deux sortes de modifications, l'une permanente, l'autre passagère. (Voir t. II, de ce journal, p. 489.)

Bibliotheca Phil. Journal Jan 1 1824

On the Permanent Magnetism of Hard Steel, and the Influence of Concussion.—II. Eight hard pieces of steel were permanently magnetized and the decrease of the permanent magnetism was observed on their being submitted to concussion. The same process was repeated three times. The magnetism was never inverted as is the case with soft iron. The decrease is less smaller the greater the original magnetism. Soft iron behaves in a manner exactly opposite.

ELECTRICITY AS A MOTOR.

NEW YORK, August 27, 1883.

TO THE EDITOR OF THE HERALD:—

Professor Puget Higgs, author of the communication on "Electricity as a Motor," printed in this morning's HERALD, is well known as a distinguished scientist who has compiled from the various newspaper and other publications several most interesting and valuable works on electric lighting and electro-dynamics in particular, and his opinion, therefore, has some weight thus attaches to that of the professional gentlemen who endeavor to upset the teachings of practice by unveiling the visions of theoretical electricity. I make these observations because Professor Higgs is not as well known here as in England, and might, consequently, owing to the latter fact, his specialty is not electricity, but another one of science, be classed among the many gentlemen of a scientific turn of mind in this country who take to electricity as the solution of the most difficult problems as ordinarily as the average humanity to pill-ills.

Probably the most advanced work on theoretical and practical electricity in existence is that of Professor Sprague, a careful, conscientious investigator, whose researches and inductions are of incalculable value to science; and yet there are few works less widely known and understood. That portion of his masterly production which relates to the conversion of power into electricity and electricity into power sets forth with great clearness the conditions and actual data of such conversion. Any person who will study this work so as to acquaint himself with the facts and figures therein contained, hand them in memorandum form, and the latter, the comprehension of the facts and figures, will be able to tell at a glance if he is to invest for the safety, stability and continuity of the exercise of enthusiasts and "amateur professors" in this science in the investigation and display of this science in the most unexpected modes and freaky directions. I merely refer to this work because I consider it necessary to elucidate this subject and because Professor Higgs refers to it as "the classic" in electricity of the leading importers of electric apparatus in New York.

I take pleasure in answering the stated regarding the employment of electricity as a motor and accept Professor Higgs' conclusion that I must either mistrust the statements of the inventors or the veracity of the gentlemen opposed to me, but not the veracity, Professor Higgs' premises as I appeared rendered it impossible for me to accept his conclusions. Professor Higgs, if, instead of resulting in such a long list of mistakes, which will cover nearly two columns of close type, would have taken the trouble to read my statements and a pencil and, noting the steam pressure and speed-relation, will observe that I stated that I expected to save—as I actually did save—one ton of coal per hour, and not 2½ tons—as Professor Higgs says they did. Professor Higgs says that I used a Greenwood-Baxter machine and compared the generator with another dynamo machine and attacks me for not stating the speed of the latter machine. I have not stated the speed, because, having the power high the same quantity of water will be required to drive the machine at any speed, and the only possible will encounter in the conversion is electrical loss. There will be more actual loss in the electric conversion at a high speed than at a low speed, but I am not aware that I stated any other to make it myself, with my own generators, which I have run at speeds as a minute, beyond which I could not travel twenty-five per cent. without a decrease more than one-third. I say to Professor Higgs, in all sincerity, that he is wrong in this, but will not, however, will accept his statement as the gentleman selected to compare machines, and will not be led astray by any of his electrical questions, but will do my own thinking, and please remember, my dynamo machine is not a motor, but a generator, and dynamo machines are used for the purpose of converting mechanical power into electricity by the first method, and electricity into mechanical power by the second method. Professor Higgs, in his list of electrical questions, asks the difference between the second dynamo and the different apparatus. I do not understand the question, but will say that the electric motor is designed to receive the mechanical electricity by the first method, and my reversed

telegraphist may at pleasure send the currents so as to transform him positive pole either the pole on the right or that to the left of the electro-magnet, the south pole of the oscillator A may at the will of the operator travel either to the right or to the left, and consequently touch either the spring q, or that r. The small bar A being in metallic contact with the fork a by the intermediary of the small block or the fork a by the intermediary of the small block or the link k by the intermediary of the small block or the link k by the intermediary of the small block or the link k

THE ACCUMULATION BY REACTIVE PRINCIPLE OF DYNAMO-ELECTRIC CURRENTS has been the subject of a recent controversy in the columns of one of our contemporaries. From this discussion it appears that the principle of accumulating electricity in magneto-electric machines by echoing the electricity excited in the revolving armature in turn to intensify the exciting electro-magnets has been almost simultaneously applied by Dr. Werner Siemens, Professor Wheatstone, and Mr. S. A. Varley. Mr. Robert Sabine has summed up the respective claims of these gentlemen in the following words:—"The date when an undeveloped idea of making any machine first occurs to an inventor is of very little comparative importance, unless the idea be productive of some evidence of its being, without which one would certainly be inclined to suspect that memory might alter the lapse of years by a little treacherous. Who had the first happy inspiration of a reaction machine no one scarcely expect to know now. Of its fruits we have better evidence, and I venture to think that the claims of the three inventors in question stand then—Professor Wheatstone was the first to complete and try the reaction machine; Mr. S. A. Varley was the first to put the machine officially on record in a provisional specification dated Dec. 24, 1866, which was therefore not published till July, 1867; Dr. Werner Siemens was the first to call public attention to the machine in a paper read before the Berlin Academy on the 17th of January, 1867." In connection with this subject our attention has been called to a forgotten English patent, No. 2198, of the year 1854, and in the name of Moses Ugarth, Copenhagen. This patent clearly sets forth the mutual accumulation principle of magneto-electric machines as will be seen from the following extract:—"The main feature of this battery consists in applying one, two, or several permanent magnets of cast iron, and shaped as above, in connection with an equal number or more electro-magnets, shaped as indicated in drawing, in such a manner that the currents induced in the coils of the revolving armatures are allowed to pass round the electro-magnets; consequently, the more the electro-magnets are excited in the said manner, the more will the armatures be excited, and more electricity of course induced in the respective coilings; and while a mutual and accelerating force is thus produced in this manner between the electro-magnets and the armatures, an additional or secondary current is at the same time induced in the coiling of the electro-magnets by the motion of the armatures, the said current flowing in the same direction as that of the primary current after having passed the commutator." This important patent evoked provisional protection only, because notice to proceed was not given in the time prescribed by the Act.

492. "An improved apparatus for generating electricity and motive power."—PAUL JABLOCHKOFF, Paris, dated Feb. 5, 1877. 6d. This consists in a novel form of voltaic battery, in which the current is produced by the reaction of fused nitrates upon carbon and zinc rods, the latter constituting the negative pole, and the former the positive pole. The gas generated is the result of combustion, and is utilized as a source of motive power by conducting them in a closed pipe from the cells to a reservoir. There, gases are similar in their nature to those produced by the explosion of gunpowder.

Regulating, and Directing Electric Light, part of which is Applicable to other Purposes. Dated February 19, 1873. My invention consists, firstly, in improvements in the electro-magnetic induction machine described in the specification of No. 841 (1867). In the present improvement the bobbins in which the currents are induced, instead of being wound round the armatures, are coiled round the extremities of the iron cores of the electro-magnets, which are prolonged for that purpose, or have iron cores fixed thereto, and an iron yoke, or keep, the periphery of which is divided into as many segments as there are electro-magnets in each series, serves to receive between the circles of stationary electro-magnets and coils for the purpose of generating electric currents. My invention consists, secondly, in improvements in the apparatus for regulating the apparent of the carbons used for producing the electric light as they are consumed by the current. In this improvement the carbons are made to approach and to separate from each other by means of a right and left handed screw, connected with the carbon holders. Each of the screws, with its carbon holder, can be actuated independently of the other. My invention consists, thirdly, in apparatus for directing and projecting the electric light upon distant objects. In this improvement the light is concentrated into a single beam by means of a bull's-eye, or double reflector mounted on a pedestal, on which is also placed the regulator above described. The whole apparatus retains whatever position is given to it both horizontally and vertically without the use of any locking movement.

Tel Jour Nov 15, 76

Professor W. A. Anthony, in the course of a recent series of experiments with an electro-magnetic machine of the Gramme pattern, made the following interesting observations:—The electric machine was driven by a five-horse Hayden petroleum oil-engine. The engine consumed a little over six-and-a-half lbs. of crude petroleum per hour. The lamp used in the engine, by which the explosive mixture is fired, had a one-inch flat wich, and consumed 278 grammes (450 grains) of oil per hour. The power resulting from the motion of the engine, when applied to the electric machine, produced a stream of electricity or electric light having an illuminating power equal to that of 234 of the lamps mentioned, showing that three times more light may be produced from a given quantity of oil, if its energy is converted first into mechanical power and then into electricity, than if the oil is directly burned in a lamp.

JULY 15, 1878.] THE TELEGRAPHIC JOURNAL.

THE ELECTRIC LIGHT AT NOTTINGHAM.

LAST night at 10 o'clock, in accordance with the arrangements made by the borough engineer, Mr. Tarbottom, Messrs. Siemens Bros., exhibited the electric light at the Health Committee's Wharf in the East Croft, London Road. The light was similar to that exhibited in the Market Place and at the Castle on Wednesday. The effect in and adjoining the wharf was satisfactory, every point being clearly illuminated. A number of gentlemen had been invited to attend on the occasion. Amongst those present we noticed Mr Councillor Lindley (ex-Sheriff), Mr. Ald. Lambert, Mr. Ald. Woodward, Mr. Ald Ford (Chairman of the Health Committee), Mr. Councillor Walker, Mr. Councillor Tutin, Dr. Benton (Medical Officer of Health), Mr. W. Richards (Chief Sanitary Inspector of Nottingham). After the electric light had been exhibited for some time, those present retired to an adjacent office, when Mr. Tarbottom stated that originally it was intended that Messrs. Hall & Co. should illuminate, by means of their light which had been used by the French and English Governments. Large manufactories in Paris had been illuminated by electric lights, and it had been considered advantageous to apply it to those premises in order to see the effect of the application, in consequence of the results which had been produced in Paris. Messrs. Hall and Co., however failed to come forward, but fortunately the promotery managed to fall back on the firm of Siemens Bros., who made the necessary arrangements there in 18 hours. One of the lights was exhibited in the Market Place, and another at the Castle on Wednesday night, but those present had been invited to inspect the light as it was exhibited at the Works of the Health Committee.—*Nottingham Daily Express.*

We may remark that the apparatus employed by the English Government is the same as that exhibited at Nottingham, namely, Siemens' apparatus; and that several manufactories in England now employ Siemens' electric light in preference to gas.

REPORT OF THE AMERICAN COMMITTEE ON DYNAMO-ELECTRIC MACHINES.

THE Board of Managers of the Franklin Institute having empowered its Committee on Instruction to purchase a Dynamo-Electric Machine, it was deemed advisable to examine into the merits of, and to test, the various machines offered for sale. This was undertaken partly as a guide in making a selection for purchase, and also to obtain reliable data regarding the adaptability of such machines to the production of light.

In view of the scientific importance of the work, the Committee on Instruction, which consists of five members of the Board of Managers, availed themselves of the services of four other members of the same, who, by request, assisted in the investigations, and now join in this report.

The work was divided among sub-committees as follows:

1. On Photometric Measurements, Messrs. Briggs, Profs. Rogers and Chase. On Electric Measurements, Profs. Houston, Thomson, and Mr. Rand. (Mr. Rand's business engagements prevented his taking active part in the work of this sub-committee.) On Dynamical Measurements, Messrs. Jones, Bartain and Haight.

The source of power for the experiments was an upright steam-engine belonging to the Institute. It has 6" bore of cylinder, and 8" stroke, heavy fly-wheel 30" diameter, and governor so adjusted as to give speeds from 100 to 230 revolutions per minute.

The machines submitted to examination were as follows:—Their dimensions are given in Table I: A Gramme machine (similar in form to that given on page 191, Vol. V. of the *Telegraphic Journal*). A large and small Brush machine, which each have for their magnetic fields two horse-shoe electro-magnets, with their like poles facing each other, at a suitable distance apart, the circular armature rotating between them.

In each machine the currents are generated in coils of copper wire, wound upon an iron ring, constituting the armature. This ring is not entirely covered by the coils, as in the Gramme armature, but the alternate uncovered spaces between the coils are almost completely filled by iron extensions from the ring, these exposing large surfaces of the armature ring for the dissipation of heat, due to its constantly changing magnetism, as in the Pacinotti machine.

The ring revolves between the poles of two large field magnets, the two positive poles of which are at the same extremity of the diameter of the armature, and the two negative poles at the opposite extremity, each pair constituting practically consequent poles of opposite character.

The coils on the armature ring are eight in number, opposite ones being connected end to end, and the terminals carried out to the commutator. In order to place the commutator in a convenient position, the terminal wires are carried through the centre of the shaft, to a point outside the bearings.

The commutators are so arranged, that, at any instant, three pairs of coils are interposed in the circuit of the machine, working, as it were, in multiple arc, the remaining pair being cut out at the neutral point; while in the Gramme machine, the numerous armature coils being connected end to end throughout, and connections being made to the metal strips constituting the commutator, two sets of coils in multiple arc are at one time interposed in the circuit, each set constituting one-half of the coils on the armature.

The commutator consists of segments of brass, secured to a ring of non-conducting material, carried on the shaft. These segments are divided into two thicknesses, the inner being permanently secured to the non-conducting material, the outer ones, which take all the wear, are fastened to the inner in such a manner that they can be easily removed when required.

The commutator brushes, which are composed of strips of hard brass, joined together at their outer ends, are inexpensive and easily renewed. The high speed at which these machines are run, together with the form of the armature, save the rotation of the latter to be considerably resisted by the air, and producing a humming sound, but otherwise they run smoothly; the heating of the armature being inconsiderable, not exceeding 120° Fahr.

by drawing a down, breaks the earth connection. The cups which contain the mercury are formed by small portions of test tubes, the rounded bottom being slightly softened by heat, and pressed inwards by a suitable point, so as to form a hole of the proper dimensions. This forms the top of the cup, which resembles somewhat the top of a *soft-boiled egg*. The bottom of the tube is open and is cemented into a brass cup, as shown in fig. 2. Not only does this form of cup circumscribe any possible splutterings of the mercury, but the level of the mercury is also seen through the glass, and, since the sides of the instrument case are of glass, adjustments may be made without removing the cover. When, however, this is necessary, in order to fill the cups and fix the balance, it is readily done by removing the screws *g g*, when the cover, together with the plate *e*, may be taken off.

Although such a modification will materially reduce the efficiency of the discharger, it is evident that by varying the connections, and putting *A* in line and *a* to earth, *or vice versâ*, the balance, when attracted, forms a bridge between the two. By employing the mercury cups, however, the contact with earth is not always perfect, but there is less danger of the wires being fused together, as is not unfrequently the case with the ordinary *pistol discharger*. Moreover, as the instrument is dust-tight and firmly screwed down, the mercury contacts, when once adjusted, need furnish no source of inconvenience.

GRAMME'S ALTERNATING CURRENT MACHINE.

By ALF. NIAUDET.

It will be remembered that M. Jablochkoff endeavoured during several months to kindle his electric candles by means of currents from a battery, or from the ordinary Gramme machine. He succeeded in placing six candles in one continuous circuit, but could not get them to burn alight for more than twenty minutes at a time, owing to the unequal wasting of the carbons, and he therefore had recourse to alternating currents, which transferred the carbons alternately in opposite directions and wasted them equally, a plan which was a practical success.

This new demand obliged M. Gramme to produce a alternating current machine; and here it may be remarked that the invention of a continuous current machine is very difficult, and there are only two or three of them which are truly original; but the production of an alternating current machine is relatively easy.

M. Gramme, before arriving at the crowning invention which made his reputation, had patented a host of machines giving reverse currents, some of which are very interesting. He was therefore provided to furnish M. Jablochkoff the machine which he required.

Before entering on the description of this machine, it should remind our readers that the power of an electro-magnet is easily rendered much greater than that of a permanent magnet. Given equal volumes of machine with electro-magnets is much more energetic than one with steel magnets. M. Gramme, therefore, adopted electro-magnets for the new machine, although their use involved the employment of a special Gramme machine to supply the continuous currents necessary to magnetise them, since the alternating machine itself did not generate continuous currents. The alternating apparatus at now made consists, then, of two machines, the Exciter, as it is called, which excites the electro-magnets of the other, and is relatively small, and the Distributor, which furnishes the alternating currents in one or more circuits.

Of the Exciter we need say nothing here; it is simply the well-known continuous current Gramme. The Distributor is represented in end elevation and plan by figs. 1 and 2. A large "Gramme ring" fig. 1, is placed at the periphery. It will be remembered that this organ is composed of a soft iron ring, on which are wound, parallel to its axis, coils of cotton-covered copper wire. Whilst the ring of the ordinary Gramme machine is acted upon by induction from the outside, the ring in question is subjected to induction from within by eight electro-magnets which are fixed round an axis. The cores of these electromagnets are placed parallel to the axis, and radiate from the axis; and the wire is wound upon these cores parallel to the axis. The outer or inner poles of these electro-magnets are expanded so as to act on a larger extent of the outer ring. They are all excited by a continuous current from the Exciter in such a manner that the alternate poles are of opposite name, thus N, S, N, S, and so on. Now, when the system of electro-magnets is rotated round the axis in the centre of the fixed outer ring, each of the wires crossing the inside of the said ring, finds itself placed alternately between a north pole and the iron of the ring, and then between a south pole and the iron of the ring, that is, under contrary inductive influences. All these wires wound round the ring being fixed, they can be connected in different ways; but in actual practice they are arranged so as to make 9 sections, marked *a, b, c, d, e, f, g, h, i*, &c., as shown in the figure. These sections are connected in four groups, each of 8 sections or elements; the first being composed of all the sections marked *a*; the second of all those marked *b*, and so on. It will be easily seen from the figure that the 8 elements *a a* placed in the same position relatively to the eight poles of the multiple electro-magnet, which turn in the middle; and from this it will be seen that these 8 elements are grouped together because at each instant they are traversed by currents of equal intensity. It will be seen, too, that it would be easy to divide the eight parts of the 4 sets (*a, b, c, d*) into more than four sections; for example into eight sections, thus giving eight instead of four distinct currents. The dimensions given are in millimetres.

The intensity of these alternating currents of course varies with the intensity of the electro-magnets and the speed of rotation of the central armature. For large machines, feeding 16 or 20 candles, the speed amounts to 600 turns per minute, and consequently there are 600 by 8, or 4,800 reversals of currents per minute.

In small machines, feeding four candles, the speed

NEW CONTINUOUS CURRENT MAGNETO-ELECTRIC MACHINE.

By ALFRED NIAUDET.

I HAVE explained Gramme's machine to the readers of *La Nature* in the numbers for the 1st November, 1877, and 30th January, 1875. If you refer back to these two articles, and to a pamphlet which I have published on the same subject, you will perceive that the invention of Gramme comprehends two distinct parts.

The first relates to a new method of producing magneto-electric currents, and I have clearly shown in what points this machine differs from that of Pixii or of Clarke. I have stated that there at present exist two classes of magneto-electric machines, those of the type of Pixii better known by the name of Clarke, and those of the type of Gramme.

The second part of the invention consists in a new method of collecting the currents, or, in other words, in a combination which takes the place of the commutator in the old machines. This chief distinction in two points of the invention of Gramme is so far established that M. Worms, of Romilly, could conceive the first without the second, as you can see from the communication made by him to the academy, following that of M. Gramme.

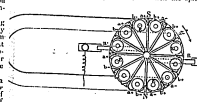
"This division once thoroughly established, it is natural to ask oneself if you cannot apply to a machine of the Clarke type the same method of collection which we find in the Gramme's machine? I have been thus brought to realise a new magneto-electric machine, giving continuous currents. This machine has been thought of by several persons; but I think I am able to say that I was the first to take up the idea, for we have, on the 12th January, 1872, a patent taken out, which every one can read, in the report published by the Minister of Commerce.

"These machines were constructed about this time, and we have had occasion to exhibit them before a great number of persons."

DESCRIPTION OF THE RUDIMENTARY APPARATUS.

On the circular plate, PP, perpendicularly to its plane, are placed at equal intervals around the axis AA, a series of straight electro magnets. This system is placed with respect to the poles, N O S, as shown in the figure, and is movable around the axis. The apparatus can be regarded as a Clarke's machine, sextupled, as this machine consists, as a rule, of a magnet and a system of two movable bobbins. The bobbins of the electro magnets are all connected one with the other, the inside end of one being joined to the outside end of the other, exactly the same as a series of galvanic elements would be joined together to form a battery, that is to say, the positive pole of one element to the negative pole of the next.

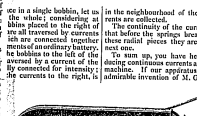
When the plate turns in the direction of the arrows, this is what takes place in each of the bobbins: In proportion as the distance of the bobbin from the North Pole, N, increases, a current is developed, the positive pole of which is at the east side end, a+, and the negative pole on the inside end, b—, and this current remains the same whilst the bobbin travels from the pole N to the pole S. As for the approaching the pole S has the same



ce in a single bobbin, let us in the neighborhood of the axis, where the cur- the whole; considering as rents are collected.

bbins placed to the right of The continuity of the current results from this; are all traversed by currents that from before the springs touch contact with one of ents of an ordinary battery, these radial pieces they are in contact with the ts bobbins to the left of the next one.

To sum up, you have here an apparatus producing continuous currents analogous to Gramme's machine. If our apparatus, proceeding from the admirable invention of M. Gramme, does not pos-



sum of the currents to the ative bobbins may be com- of six elements each, with ut, or if the two extremities connected with the points elements are opposed, it is urrents of the two batteries, d up for quantity.

The currents developed in ave described, it is necessary to fix springs which touch the points connecting the several bobbins together, at the instant they pass the line of the poles.

If the same reasons which guided Gramme in the construction of his machine, we have placed pieces of metal radiating from the centre, which communicate with the points of junction of the bobbins, on which the springs R are made to rub

sess much originality, it will, perhaps, have the advantage of explaining more clearly the working, which is difficult enough to understand from the machine used by him as a model.

Certain reasons, which it is difficult to explain here, will show that Gramme's machine is superior to ours. It is not impossible, however, that the latter would be employed in cases where a great tension and very little quantity is required. When you wish to establish telegraphic communication

VARLEY'S MAGNETO-ELECTRIC MACHINE.

The principle and chief features of novelty in this machine mainly consists in employing natural or permanent magnets, in combination with the electro-magnetic armatures. The magnets are the poles of the revolving magnets. The magnets are surrounded by bobbins, and upon rotating the armature the electro-magnetic current induced in the armature or electro-inducing coil is sent, by means of a commutator, through the coils of the magnets, and simultaneously, direct communication with armature or electro-inducing coil is established, so that the currents induced in the armature, when raised and rendered powerful by the combined magnetic action of the magnets, part of the current is sent through the coils of the magnets, and part through the line wire, or other circuit, in which the latter are placed. The armature or electro-inducing coil is wound in the machine in connection with the magnets, so that every part or coil of work does its full share of duty.

The machine on this principle, has been placed opposite one another, and with two armatures placed between them, so that the magnetic poles of each magnet face their poles. This two armatures, one of the cores, and the two south poles are together, while the two north poles are together. The armatures, which are fixed parts of the apparatus, have a commutator, which is fixed to the spindle, and which is automatic, which places it first in contact or nearly in contact with one armature, and then with the other, transfers it to a corresponding position in respect to the other armature, and then back again, and so on, in such a manner as to bring the armatures into proximity, and leave them at the proper moment, so that the attraction of the magnets on the armature may also be made double, so that the poles of the magnets may be placed at a greater distance apart. The attraction of the magnet for the two armatures is thus made to act in the same direction, and by a screw adjustment the surfaces of the armatures may be brought very near to the poles of the magnets, without giving rise to friction. In place of the commutator, a reciprocating armature may be employed, or a tuning fork may be employed to connect and disconnect the work

pole of one magnet with the south pole of the other, and as it rotates to couple the poles alternately.

In Figure 1, N and S² are horse-shoe magnets; permanent magnets are represented but electro-magnets are also available. Between the magnets and in with them are two cores of soft iron wound with coils of insulated wire C, C¹; they form part of the circuit or circuits in which the electricity generated by the apparatus is transmitted. S, S, and S¹, S¹, mark the poles of the magnets N and S². O, O, are guides made of gun metal in which the rod B is free to slide to and fro; it has upon it the armature of soft iron marked A. A reciprocating movement may be communicated to the armature between the guides O by connecting the rod B directly or indirectly with a steam engine or other motor. It will be observed that in this arrangement the reversal of the magnetism in the armature A takes place.

Figure 2 is an end view of the armature A shewing how it is grooved into the horns of the permanent magnets N, S². Figure 3 shows the rotating armature arrangement. The armature is mounted upon a rotating axis B, and as it revolves it alternately closes the pole N with S¹ and S² with S. In this arrangement the reversal of the magnetism in the armature A takes place.

4748. "Magneto-electric Machines."—E. Weston, New York, U.S. Dated December 14, 1877. 6d. This consists in improvements in Wheatstone machines, described in a prior patent, No. 4280, of 1876. These are the combination with a commutator of two levers attached to a pivoted disc, whose axis coincides with the axis of the commutator studs, the disc being provided with one or more set screws, whereby it may be clamped in variable positions, for the purpose of regulating the strength of the current. Also a device for automatically closing and breaking the circuit, by means of a disc attached to a studs, which has its bearing in the end of a pillar, and is rotated by means of a belt from the shaft of the machine. The disc contains two radial slots, each of which contains a sliding switch block, which is pressed inward toward the axis of the disc by an adjustable spiral spring. These blocks rest against a metal link, when they yield to the action of the springs. When the speed of the machine falls below a certain rate, the switch blocks form an electrical contact with the hub, and the current from the machine is short circuited. On the contrary, when the desired rate of speed is attained, the current is sent through the line into the electro-typing vats, &c.

162. "Producing and applying magneto-electricity."—W. R. Lake (communicated by James J. McTighe, Pittsburgh, Penn., U.S.) Dated January 12, 1878. 6d. This invention consists in producing currents of magneto-electricity in coils by the vibratory motion of one or more magnetic poles in the vicinity. These vibratory currents can be utilised to reproduce vibratory motion or for telephonic purposes. One mode of producing the currents is to set upon a thin magnetic pole by a toothed wheel so as to set it in vibration when it generates undulatory currents in the coil beside it. The vibrations of the voice or the force of a steam jet may also be used to vibrate the thin pole, which can be made in the form of a vibrating diaphragm. Economy of power is claimed for this method, as it will not be necessary, for the production of intense currents, to whirl large masses of iron. A speaking telephone, consisting of a tubular magnet bent into a horseshoe form and having the coil between its poles is also described. One end of the tube is an open mouthpiece, the other end is closed by a vibrating iron diaphragm, which vibrates before the coil, the latter being fixed to the other pole.

On Freak Improvements upon Magneto-Electric Machines.—J. T. Graham.—Compared with his model of 1872 his new model for this year possesses many advantages. This galvanoplastic machine has now only one central ring instead of two, and two bar electro-magnets instead of four. Its weight is 177 kilogrms., that of the copper ring and the electro-magnet bars 50 kilogrms. The dimensions are—0·53 m. wide, 0·60 m. high. In comparison with his 1872 model this last one possesses the following advantages:—(1.) Half the size. (2.) One-seventeen the weight. (3.) The copper used in its construction reduced to three-quarters. (4.) The motive force necessary to work it is much reduced. Three improvements are obtained by the suppression of the rheitor habitually by putting the electro-magnet in the circuit itself of the current; by a better arrangement of the copper portions of the electro-magnet bars; and by a slight increase of speed. "The electro-magnet setting, which I used to make with round wire, is now formed of a band of copper half the width of a bar magnet. The arrangement of putting the electro-magnet in the circuit has given rise to a change of pole, which I have been obliged to enact. When the machine are in motion, and the circuit closed by metallic baths, the poles remain the same; but as soon as a catch or a stoppage takes place, accidentally or by design, the poles change, so that if the machine be again put in motion without re-arranging the conductors as *inverse* work will be performed. For telephonic purposes, of alternating the objects for the baths, it will be observed. To obviate this inconvenience I cause the machine to be put in motion initially as soon as the machine stations, and thus establish galvanic currents, which alone constitute these pole reversals. Similar improvements in construction, and very considerable reductions in weight and size, have also been effected in electro-magnetic lighting machines, whether for lighting gas-lights or lighthouses."

THE TELEGRAPHIC JOURNAL.
VOL. VI.—NO. 136.

THE OUTLOOK OF ELECTRICITY.

It has often been remarked that of all the sciences there is none which has been of more vigorous and rapid development than electricity. Long hidden in the dark womb of nature, like a spellbound genii, or a faculty asleep in the soul, it has within these latter generations sprung into quick existence, growing like a plant, and doing a giant's work. With all its practical power there is a brilliancy about its marvellous effects, which renders it a most fascinating pursuit, the most fascinating science of all perhaps. And this very shining quality has had an untold effect in furthering its own increase. The minds of men, however philosophical they may be, are ever fascinated by the miraculous and lured by beauty. What wonder then that electricity, whose effects are so beautiful, and withal so miraculous that to the uninitiated they seem to be creations of the magician, should number among its admirers and votaries all kinds and conditions of men. It has been said that a science progresses by the compound interest law, but electricity, at least, is an exception to this rule. The recent burst of electric invention, indeed, points to a more complex order of development than can be expressed by any known formula. Human genius, an altogether incalculable thing, must be taken into account in science, even as it is taken into account in poetry. The telephone and the microphone are pregnant factors in the advance of electrical science, corresponding to cataclysms in the uniform process of evolution. They have of late carried the science forward by a jump, and it is natural now to pause and view the outlook ahead.

The Victorian era will be ever memorable in history as the nurse of the steam-engine, of gas lighting, and of the electric telegraph. But it does not require a prophet's eye to foresee that ere long electricity will supersede both gas and steam. Men uses first those resources of nature which are nearest to him, then seeks out and utilises those which lie deeper. He hunts the wild animal crossing his path, then herds it on the ground, then tills the surface soil, then digs up coal and metals from the bowels of the earth, and at last when these palpable resources begin to fail his mind and sense, he looks into the secret store-room of matter with the eye of intellect, and discovers new mines of power even richer than the old. At present we are consuming one hundred and fifty million tons of coal per annum, and this waste cannot go on for ever. Our coal fields will inevitably become exhausted. But shall it then be necessary to buy our coal from other countries, say from our more prosperous "sister beyond the sea," as Mr. Gladstone poetically calls our American cousins, who doubtless in the shabby future which that fermenting patriot gratuitously depicts for his countrymen, will despise their impoverished relative and, at the same time, grow fat upon his poverty. Perhaps not. Perhaps the electro-motor will worthily replace the supermannered steam-engine, and the restless waves which ring our rocky coasts, the cascades which flow from our highland fells will relieve us from the necessity of filling the Yankee purse, and carrying the wherewithal to keep us warm, and turn our mills, and lighten our darkness, over two thousand miles of stormy sea. The electric light is now fairly equipped as a formidable rival of coal gas. For large works and public squares, where a few light centres suffice, it is in every way superior to gas, at a smaller cost; and if it could be distributed with less loss of energy, and at smaller expense, it would speedily take the place of gas for street lighting also. It is certain to become a dangerous competitor against coal gas, and unless the latter is improved in quality and reduced in cost, its employment will by no means be so universal as it is at present.

The possible applications of electricity are indeed, legion. Every day sees a new one. Its great mission is manifestly that of a vehicle of energy, and it appears to be capable of reproducing all modes of motion. If it is true that all the known forms of energy are mutually convertible, then electricity will probably be the practical channel of this transformation. We have seen during the latter years how magnetism, heat, and sound, can be transported into space by the electric current. In the future, near or remote, it will in all likelihood bring the shafts of light, and as sure now hear by telegraph, so will they see. Nerve force is merely a form of physical energy too; and with the fair prospect which we have before us, it is "only reasonable" to anticipate the time when the sensation itself may be transformed into electricity and pain and pleasure sent by wire.

THE MAGNETO-ELECTRIC MACHINE OF M. DE MÉRITENS.

By TH. DU MONCEL.

The commercial and industrial field, opened up lately by the electric light given by magneto-electric induction machines, has led, on all sides, to researches and improvements which have considerably advanced the problem of electric lighting. Everyone now knows the beautiful machines which MM. Siemens, Gramme and Lontin con-

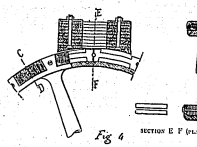

FIG. 4 SECTION E F (PLATES REMOVED).

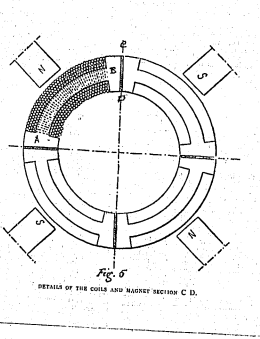

FIG. 5

DETAILS OF THE COILS AND MAGNET SECTION C D.

The system of charging the condenser through the joint-thread of course be made unless one end of the core is at hand to which to attach one pole of the battery.

When a joint is made in a cable core at sea neither end can be got at. The resistance, however, could be measured by arranging with the shore, before the joint is made, that at a certain time the end of the cable shall be put to earth. The rate at which the charged condenser would discharge itself through the joint could then be observed, and the resistance estimated from the rapidity thereof.

To enable the tests for fall of charge to be made readily with the condenser and resistance are not in use, as in a cable, the connections may be made as shown by fig. 20.

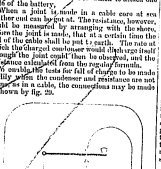

FIG. 20.

The plug switch S has one of its plugs placed in the left hand hole permanently. Another plug is placed in the bottom hole, and the key being pressed down so as to charge the condenser, the "discharge" trigger is pressed, and the condenser commences to discharge itself through the resistance R. After a noted time the key is again pressed, but only far enough to hitch it on to the "insulate" trigger.

The plug is then removed from the bottom to the top hole in the switch, and the "discharge" trigger being pressed the discharge deflection (V) is obtained on the galvanometer.

When testing a joint on board ship the terminal of the switch, which is joined to one end of the resistance in the Fig., would be attached to the metal plate in the testing trough, and the wire attached to the other end of the resistance would be put to earth.

GRAMME'S MAGNETO-ELECTRIC MACHINES.

By ALFRED NIAUDET-BREGUET.

(Concluded from page 190.)

LIGHTING MACHINES.

THE first machine of this description weighed 1,000 kilogrammes, and gave a light equal to 800 burners. It had a ring and electro-magnets. One of the rings excited the electro-magnet, whilst the other two supplied the lighting current. The copper twined round the electro-magnets weighed 250 kilogrammes; that round the 3 rings 15 kilogrammes. Its measurement was 60 centimetres in width; 1·25 metre high. This apparatus, for a long time used in experiments on Westminster Tower, grew warm when in action, and resulted sparks between the metallic brushes and the bundle of conductors upon which the current accumulates. However, for two years, it gave rise to no serious inconvenience.

Mower, Gramme endeavoured to eliminate the sparks and the heating of the machine; and, as the intensity of the light demanded by various governments did not exceed 200 burners, he was impressed to reduce the dimensions of the first machine, as shown by Figure 6. This instrument still had 6 electro-magnets, but, instead of being grouped in straight lines, they form triangles: the total current from both rings may be used into the magnets, or one only, or lastly, the whole of it may be made to produce two separate lights. Its statistics are:—

Weight	700 kilogrammes.
Height	1·20 centimetres.
Width	65 "
Copper on electro-magnets..	120 kilogrammes.
" two rings	28 "
Normal light ..	200 burners
Light from great speed	1000 "
Sparks and heating..	nil.

The latest type is shown by Figure 8, and embodies vast improvements on all previous machines of this class.

Its form is of the same character as that of the electroplating apparatus. Its weight is 180 kilogrammes; requires but 47 kilogrammes of copper for the ring, and the same quantity for the electro-magnets. Length, 35 centimetres; width, 80 centimetres, and height 60 centimetres. Normal power about 200 burners, but it will reach much more.

The following are the mean results of six series of experiments:—

Number of Turns.	Number of Burners.	Remarks.
630	77	No heat nor sparks.
840	153	" "
970	200	" "
1020	240	" "
1035	280	Slight heat, no sparks.
1053	300	Heat and sparks.

Among the improvements introduced into this machine may be mentioned the construction of the central ring, according to the "double" principle already referred to; an arrangement whereby the sparks disappear. By suitable means it can be joined up for "intensity" or "quantity," or it may be used to produce two distinct lights instead of one only. The capacity for one machine to produce two lights is of practical benefit for the reason

N° Electricité
nov 8.78.

183367 : 29 mars 1878. — *Machine dynamo-électrique*, par MM. Siemens et Halske.

La disque mandrine est construit en fil de fer, tôle de fer ou bien en fer massif, recouvert entièrement de fils de cuivre; il est maintenu en mouvement de rotation entre un certain nombre de pôles d'aimants, disposés par paires sur ses deux faces, de telle sorte que ceux placés en regard les uns des autres présentent toujours des pôles de même nom alors que ceux juxtaposés ont des pôles contraires, le tout dans le but de produire des courants intermittents ou autos sens, et cela dans un ou plusieurs circuits.

introduced by M. Gramme are so original and so important that they constitute in themselves a work able, so to speak, to revolutionize a host of industries. We therefore give this subject prominent notice, although we may recapitulate what has already appeared in our columns.

The discovery of magneto-electric induction currents by *Faraday*, in 1832, opened a new field of study to physicists and inventors. Hall, maker of scientific instruments at Paris, was the first to construct an instrument furnishing practical induction currents; his apparatus, successively improved by Saxton, Clarke, Wheatstone, Wilde, Siemens, and Ladd, has bestowed immense service upon science and industry. Singularly, this invention of Pixii is best known by the name of Clarke's machine, although Clarke, of all the persons just mentioned, introduced the least important improvement. The Nollet machine, generally known as the *Alliance*, is but a particular arrangement of a group of Clarke's instruments.

Gramme's machine is not, however, a mere or less fortunate modification of Hall's apparatus; it is the first of its kind, as the following explanation will clearly show.

PRINCIPLE OF THE MACHINE.

To understand its principle it will be advisable to describe the most simple magneto-electric induction experiment which it is possible to make.

Contemplate a magnetic bar A B (Fig. 1) one metre long, and a spiral of conducting wire, in reciprocal movement. If the helix, starting from the position N, is made to approach the bar, an induced current is set up in the helix. Such is the sum and substance of the phenomenon, and three explanations as a rule stop; but let us proceed further and examine more closely what is the result in properties as the bar enters into the helix by a series of successive and equally spaced movements—5 centimetres for example.

It will be observed that an inducet current corresponds to each of these movements, and that these currents are in the same direction until the helix surrounds the neutral line M of the bar A B: and that the currents are in the opposite direction if the movement continues beyond that line.

Thus in the entire course of the helix over the magnet two definite periods are observed: in the first half of the movement the currents are *direct*, in the second they are *inverse*.

If, in place of motion from left to right, the movement is effected from right to left, the results

FIG. 1.

the *Revue Industrielle* and the *Chroniques de l'Industrie* have already especially referred to the admirable invention of magneto-electric continuous-current machines; but the modifications recently

* Several articles and abstracts from *Comptes Rendus*, &c. on Gramme's machines, have been from time to time appeared in our pages.—Ed. T. J.

are the same, but the currents are in opposite directions.

Let us now investigate a more complex case still represented by figure 1. Two magnets, A B and B' A', are placed end to end, in contact by poles of similar names, B and B'. The whole becomes a single magnet with a consequent point in the middle.

If the spiral is moved in accordance with this

system, it is clearly seen from the preceding explanation that it is traversed by a positive current during the first quarter of its movement (between A and M); by a negative current in the second quarter (from M to B); again by a negative current in the third quarter (from B' to M'); and lastly by a positive current during the last quarter of the bar (from M' to A'). It will be soon hereafter how this very simple explanation gives the key to the production of currents in the machines about to be described.

DESCRIPTION OF THE APPARATUS.

The essential portion of the machine is the "ring" (Fig. 2), which turns around its centre between the poles of a magnet. It is an electro magnet of particular form. It may be conceived as a straight electro-magnet, bent into a circle and soldered together at its extremities, iron with iron, and wire with wire.

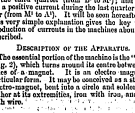

FIG. 2.

The wire is distributed upon the "ring" as in straight electro-magnets, notably those of powerful induction coils. It is rolled into distinct bobbins, which are then placed side by side, as shown in Fig. 2. These coils constitute the elements of the

machine, just as voltaic couples form the elements of a voltaic battery. To render its construction intelligible, the engraving represents the "ring" complete in one part only; in another part the coils are figured by ones or twos; and in another portion the iron ring is exposed bare and out.

This ring of soft iron is magnetized by the magnet N S (*Fig.* 3), and the magnetism becomes distributed in the following manner. At B and A are the poles, whilst at M and M' (at right angles to the poles) are the neutral points. During the movement of the ring, this distribution of magnetism does not change, or at least it is invariable in position on account of the want of coercive force in soft iron. Hence, the result of turning the soft iron ring is just as if the circular iron upon which the coils are mounted was stationary, and as if those bobbins alone moved upon it as a magnetic bar.

The ring may be considered as composed of two magnets B A and A B joined by their poles of similar names. If any particular coil is followed in its movement throughout the complete circle it will be observed by referring back to fig. 1, and to the explanations already given that the developed current remains of the same character during the time the coil passes from A to M; it becomes inverse from M to B and from B to M'; again changing to direct from M' to A.*

In other words, the current set up in a coil continues in the same direction from one neutral point to the other; if it is direct above that line, it is indirect below it. The line M M' may be called the *line of division*, and it is perpendicular to the line of the exciting magnet's pole NS. The line of division in Clarke's machine is that of the magnet's poles.

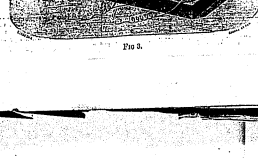

FIG 3.

* To thoroughly understand that the direction of the current from M to M' is the same as that from M' to M, it must be remembered that the direction of a current is reversed when the bobbin is turned round, as represented by dotted circles on the "Plan of the Machine" in the upper part of Fig. 3; if the bobbin pass first from N to A and afterwards from MM' to M', the two circles thus indicated will oppose themselves.

Spring Dynamometers

IN a former brief communication of mine on the subject of dynamometers (NATURE, vol. xiii. p. 383), suggested by an incidental remark made by Mr. Bottomley, I observed that "about three years ago Prof. Ball when introducing the C. G. S. system of units into the course of mechanics in this College had a series of dynamometers in students museum specially constructed for him." In reference to this statement, Dr. Ball's successor in the Professorship of Applied Mechanics has sent, in a letter to NATURE (vol. xiii. p. 466), that "this system is not employed in nor that referred to by your correspondent. I generally employ the kilogram, metre, and second, and accordingly have the foot, pound, and second, to measure a dynam or unit of force." It is, however, evident that the few words in my former letter did not question the merits of any particular system, or unit; whether the use of a united system of kilogram-metres and foot-pounds be an improvement upon a system now generally coming into use is a matter of opinion. And though the subject can hardly be one of much interest to your readers, I may, perhaps, remark that so far as my statement concerns Dr. Ball it is perfectly accurate; he was in the habit of using the C. G. S. system in his classes here, and I was aware no change had been made in this respect, the following statement occurring in Prof. Hennessy's own syllabus for the present as well as last session:—"The unit of force employed is the 'dyne,' or that force which, acting uniformly upon one gramme for one second, will give it a velocity of one centimetre a second." Even if Dr. Ball's syllabus had been made to Prof. Hennessy, one would naturally have concluded that the printed syllabus, authorised by the Department, was the one actually employed."

Passing on to Dr. Ball's statement, Prof. Hennessy remarks that "they cannot be depended upon to results within the tenth of a kilogramme"—how reading when a closer result could, no doubt, be taken by the eye, but that is really a matter of indifference for the makers, and the special purpose for which these instruments were designed: then follows the strong assertion that "spring dynamometers are totally unfit for measuring units on the C. G. S. system." As several instruments of precision depending on the tension of a spring occur to one's mind, instruments that only require proper precautions to yield extremely delicate and trustworthy results, it would be interesting to know upon what grounds Prof. Hennessy bases his emphatic and reiterated assertion. If it be merely a question of individual opinion, upon this subject hardly any authorities that could be quoted would carry much weight as Sir W. Thomson and Prof. G. Tait, who speak thus in their treatise on "Natural Philosophy," p. 122. "Spring balances we believe to be capable of carefully constructed, of rivalling the ordinary balance in accuracy, even for men, sophisticians they far surpass it in sensibility and quickness."

Royal College of Science, Dublin W. F. BARRETT

[2096.] — Magneto-Electric Machine. — No doubt a Jar could be discovered, but may be the smallest of this species which the Electrical Machine would require. To observe effects of the Electric Jar, by a longer discharge than the Spark, would be done by connecting one ball to the outside of the Jar coating, and the other ball to the inside coating.—

quées au bénéfice de cette statue vivante qui éternisera son nom malgré ses envieux, et qui est le système télégraphique de prévision du temps.

MACHINE MAGNÉTO-ÉLECTRIQUE

de M. de Méritens

Le débouché commercial et industriel qu'a ouvert dans ces derniers temps la lumière électrique aux machines d'induction électro-magnétiques, a provoqué de toutes parts des recherches et des perfectionnements qui ont fait avancer considérablement le problème de l'éclairage par l'électricité. Tout le monde connaît aujourd'hui les belles machines que MM. Siemens, Gramme et Lontin construisent, et on croirait en les voyant qu'il serait difficile de les perfectionner davantage. Toutefois nous croyons que la solution définitive du problème n'est pas encore atteinte, et il est probable qu'd'ici à peu de temps nous verrons mieux encore. Déjà la machine que vient de construire M. de Méritens est un pas considérable fait en avant dans cette voie, et je suis autorisé à croire que cette machine, qui a déjà étonné ceux qui l'ont vue fonctionner, n'a pas encore dit son dernier mot.

Pour nous, qui avons suivi dès le début les progrès de ces machines, qui avons nous-même contribué aux premiers perfectionnements qui leur ont été apportés, nous voyons avec un véritable plaisir cette marche progressive de cette industrie qui est en quelque sorte née en France. Mais tout en les admirant, nous ne devons pas oublier que c'est à la compagnie l'*Alliance* et à son habile ingénieur M. J. Van Malderem que nous devons cette magnifique application de l'électricité.

A ce propos, nous croyons qu'il ne sera pas sans intérêt pour nos lecteurs de raconter brièvement l'histoire de ces machines.

En 1859 M. Nollet, constructeur belge, avait construit pour la galvanoplastie de grandes machines magnéto-électriques du système de Clarke qui donnaient déjà d'assez importants résultats pour provoquer la formation d'une compagnie qui voulut les exploiter dans le but d'extraire le gaz de l'eau. Cette idée était insensée, mais précisément à cause de cela, elle trouva des adhérents, et ce fut cette compagnie qui, sous le nom de l'*Alliance*, installa dès 1860 dans des bâtiments attenant à l'hôtel des Invalides, les premières grandes machines magnéto-électriques connues en Europe. Naturellement les résultats obtenus furent déplorables, et en 1870 la compagnie fut obligée de liquider.

Elle se réorganisa ensuite en 1872, et après avoir nommé pour son directeur, M. Berlier, elle chercha à tirer parti du matériel considérable qui avait été créé; ce fut alors que je fus consulté et que j'indiquai à M. Berlier les applications qu'il pouvait en faire à la lumière électrique et à la galvanoplastie; mais pour y parvenir, bien des perfectionnements devaient être introduits dans ces machines, et tous les électriciens de l'époque apportèrent chacun leur pierre à l'édifice.

Parmi ces perfectionnements, il en est un suggéré par M. Masson, alors professeur de physique à l'École centrale et que j'avais amené voir ces machines, qui permit instantanément de doubler les effets obtenus. Ce fut de supprimer le commutateur jusque-là employé dans toutes ces machines. Tous ces perfectionnements admirablement interprétés par M. J. Van Malderem, permirent, conjointement avec ceux qu'il y apporta lui-même, de faire arriver ces machines à une perfection qu'on n'aurait guère osé espérer dans l'origine, et qu'on croyait bien ne pas pouvoir être dépassée. Ce fut alors qu'on songea à en tirer parti pour l'éclairage des phares et pour l'illumination de la marche des navires; des expériences furent alors tentées conjointement avec MM. Reynaud et Degraud, et bientôt, en 1863, les phares de la Hève purent être éclairés de cette manière.

En même temps, on faisait pour l'application à la navigation des expériences qui n'eurent pas d'abord tout le succès qu'on pouvait en espérer, surtout à cause du mauvais vouloir qu'on rencontre dans la marine, mais qui devaient fournir plus tard des résultats dont on put apprécier l'importance. Ce fut la France qui précéda les autres nations dans cette double voie, comme c'est elle qui les précède encore pour l'éclairage public. Mais nous devons dire que c'est grâce à la compagnie l'*Alliance* et à la courageuse initiative de son intelligent directeur, M. Berlier, que le monde civilisé doit ces belles applications de l'électricité.

Ce tribut d'hommages rendu à une compagnie dont la fortune ne seconda pas les efforts, nous allons examiner les progrès accomplis dans ces derniers temps en dehors d'elle.

La machine l'Alliance était une machine magnéto-électrique, c'est-à-dire une machine composée d'aimants persistants et de bobines d'induction. Dans son dernier modèle, elle mettait à contribution 48 aimants et quatre couleaux mus chacun de 16 bobines d'induction; elle fournissait des courants alternativement renversés, et pouvait alimenter trois bougies Jablochkoff; elle employait comme force motrice environ trois chevaux, et marchait à une vitesse de 400 tours par minute. Aucun échauffement n'était produit dans la machine, et la force qu'elle fournissait était très-régulière.

Dans des conditions tout à fait exceptionnelles, ce rendement a été très-augmenté, et on a même parlé d'une machine pouvant alimenter six bougies; mais les machines ordinaires sont loin de fournir de pareils résultats. Or, la machine dont nous allons maintenant parler peut, avec huit aimants seulement (aimants de même grandeur que ceux de l'Alliance), illuminer de trois à quatre bougies Jablochkoff et fournir également les courants renversés qu'on regarde, avec raison, comme un élément favorable pour l'éclairage public!

Il est vrai que la vitesse de la machine est plus grande, car elle accomplit sept cents tours par minute; mais elle ne dépense, m'a-t-on assuré, que soixante dix-huit kilogrammètres de force motrice, c'est-à-dire un peu plus de un cheval vapeur, et ne s'échauffe presque pas. Ses dimensions sont très-petites, et les éléments de sa construction sont simples et faciles d'ajustement et de construction.

Les effets avantageux de ce genre de machines résultent de ce qu'aux courants d'induction déterminés dans l'anneau des machines Gramme, sont ajoutés ceux qui se produisent dans les machines magnéto-électriques ordinaires.

Pour qu'on puisse les comprendre, imaginons-

bars take in the frame and all cylinder increases this tendency, and these bearings cannot be made short, as any angular motion vertically of the lower bar moves the inner end of the bar, which is as far above it, horizontally as the bars are apart. The arrangement of spiral springs in compression under the bars is necessary, as there shall be more initial strain on them than tending to the tubes are adjustment and the more compressed formulæ and pad efficients describe! shown.

The smallness of range of the springs and integrated by the small motion of the cylinder, as the pressure is the same throughout, and the varied spring compression and rise (very little) are not appreciable.

The integrating disc requires a means of horizontal adjustment, and the oil cylinder has provided for this, as it leaves a direct pressure on the seams dead to all their inclinations, namely, that it could not work when sheathing cards, because the centre of the smaller integrated at the piston-rod end of the cylinder. The rod should be carried through both ends of the cylinder.

The changing of springs is a useless operation, as half of the working parts must be dismantled and readjusted afterwards, and the new springs must be tested, which is useless and troublesome. Springs have been taken to represent those of the integrator would be better with spiral springs in tension, and practice differ from their centres.

The Rose Dynamometer is so called partly to distinguish it in name from other instruments, and because it is mechanically similar to Prof. Rose's recent steam indicator (a figure or vehicle to be tested) was described in my letter of 14th April, page 307, and other details of the Society of Engineers, the Bedford Meeting of the Royal Agricultural Society in 1875, and the Kensington Meeting of the Society of Arts, for trying mowing machines, and will again come into requisition next year at the Bristol Meeting of the Royal Society, and also at the Exhibition of Scientific Apparatus at South Kensington.

This instrument was designed by Mr. W. Anderson and is the most perfect integrating instrument belonging to the Society, except the planimeter, having been taken to several of workshops and factories which had been settled in the working of precision instruments.

The ground principle of this dynamometer is, that it shall occupy the same position as a pressure gauge, or as the ordinary spring balance, and that the pressure in any case shall be shown by means of harness attached to the vehicle shafts in the usual manner. The harness is attached to the register bar, and the horse or motive power is caused to exert a horizontal strain which a horse would have to exert in drawing.

To determine the power which each horse is doing, a 16-hand cart horse was taken for the purpose, and a dynamometer was constructed to fit him for drawing these along straight and level roads, and was as near as possible to the centre of gravity of the horse, placed on the principle of harnessing horses, only more carefully, that the pressure for shafts, being equal. The adjustment of the weight in varying circumstances seems to be an important point, and this is easily effected by means of a cart horse, and for carting 6 cwt. and 1 cwt. on the back of the cart, and for carting 6 cwt. and 1 cwt. on the back of the cart, and for carting 6 cwt. and 1 cwt. on the back of the cart

La force électro-motrice d'un élément Daniell est de 1,079. Si par conséquent ce courant passe par un galvanomètre de tangente dont la résistance est de 1,079 ohms, le courant sera de 1 Weber par seconde. Le point où l'aiguille s'arrête sous l'influence de ce courant est le point de départ des divisions du galvanomètre, ce dernier indique par conséquent l'intensité du courant directement en unités Weber.

10. La boussole des tangentes de Bradley, par le Dr. G. Seelhorst. (Dinglers polytechn. Journal, vol. 215, page 121).

Elle se distingue des autres boussoles des tangentes par sa simplicité. L'aimant est un disque de deux centimètres de diamètre. Le multiplicateur se trouve entièrement au-dessous de l'aimant. Cette boussole n'est pas susceptible de mesures de grande précision, mais elle est facile à manipuler et ne se dérange pas aisément.

11. Nouvel électro-moteur, par C. Gaume. (Dinglers polyt. Journal, vol. 216, page 316).

C'est une machine pour développer la force nécessaire à faire tourner, par exemple, une machine à coudre. Les armatures, d'une forme spéciale, sont mobiles, les électro-aimants fixes. Les résultats sur les effets de la machine ne sont pas connus.

12. La machine magnéto-électrique de Gramme, par Alfred Niaudet-Bréguet. (Telegraphic Journal, vol. III, pages 186, 196, 223).

Pour rechercher les sources historiques de la machine Gramme, il faut remonter jusqu'à la découverte de la magnéto-électricité, par Faraday, en 1832. Pixii, Saxton, Clarke, Wheatstone, Wilde, Siemens et Ladd ont construit des machines magnéto-électriques. La machine de Gramme fournit un courant continu et de force constante. Les premières machines possédaient un aimant pour exciter le courant électrique. Dans les types plus perfectionnés cet aimant est remplacé par un électro-aimant qui reçoit son courant de la machine elle-même. Suivant que le fil qui forme bobine sur le noyau en forme d'anneau est fin ou gros, la machine fournit un courant d'intensité ou de quantité. Comme la machine engendre par le travail mécanique de la rotation un courant électrique, le même on peut l'employer en sens inverse et produire avec le courant d'une pile un travail mécanique. La machine devient ainsi une machine électro-magnétique. La machine s'adapte à des emplois très-divers. Elle peut servir comme étalon de la force électro-motrice, elle est très-employée dans les ateliers de galvanoplastie pour remplacer les piles. Une machine pesant 117½ kilogrammes et dimunant une force de 50 kilogrammètres ou environ ⅔ de force de cheval, produit un courant qui dépose en une heure 600 grammes d'argent. En outre, on peut employer la machine pour l'éclairage et pour la production de la lumière, par exemple dans les phares et sur les bateaux en mer. Finalement on peut se servir de la machine de Gramme pour transporter une force mécanique à une distance quelconque.

13. La machine magnéto-électrique de v. Hefner-Alteneck. (Electrical News, vol. I, pages 226 et 230).

Comme celle de M. Gramme, cette machine est construite sur le principe du professeur Pacinotti. Elle se distingue de la première en ce que les hélices d'induction ne sont pas roulées sur un anneau en fer doux, mais longitudinalement sur un cylindre creux en maillechort. Ce cylindre tourne avec les hélices allongées comme l'anneau de Gramme. Mais à l'intérieur du cylindre est placé un cylindre fixe en fer doux. L'extérieur du cylindre tournant est embrassé par les prolongations hémicyclopes de deux électro-aimants puissants. Le courant d'induction engendré dans les hélices tournantes parcourt aussi les hélices des électro-aimants. Cette machine est la plus puissante qui ait été construite jusqu'à présent, elle produit avec une vitesse du cylindre de 380 rotations par minute une lumière égale à celle de 14,000 bougies. Pour produire cet effet elle demande une force mécanique de 700 à 750 kilogrammètres par seconde (9 à 10 forces de cheval). Une lampe électrique est adaptée à cette machine qui, en conservant le mouvement du recul du système Foucault, n'est pas compliquée par un mouvement d'horlogerie.

14. Sur l'histoire des machines magnéto-électriques à courant continu, non renversé, par le Dr. Ed. Zetzsche. (Dinglers polyt. Journal, volume 216, page 491).

La première machine de ce genre figurait à l'exposition de Londres en 1851. Elle avait été inventée et construite par MM. Siemens et Halske de Berlin et avait pour effet de transformer le faible courant d'une petite pile en courant de haute tension. En 1860, le Dr. Antoine Pacinotti, de Pise, construisit une autre machine avec électro-aimant transversal. Viennent ensuite les inventions de Wilde à Manchester en 1866, et de Ladd en 1867. En 1871 les principes de Siemens et Pacinotti ont été appliqués par Gramme dans la machine qui porte son nom. La dernière invention est celle de v. Hefner-Alteneck qui figurait à l'exposition de Vienne en 1873. L'article réclame les droits de priorité pour les inventions de Siemens et Pacinotti vis-à-vis de Gramme.

15. Nouvelle horloge électrique, par Arzberger (Dinglers polyt. Journal, vol. 217, page 460).

4. Le duplex et le quadruplex système.

1. Double transmission avec courants continus. (Journal of the telegraph, vol. VIII. page 360).

Moses G. Farmer a le premier, en 1858, pris un brevet pour un système de double transmission avec courants continus. En 1873, George K. Winter a aussi pris des brevets pour deux systèmes de même nature. Ces systèmes sont tout-à-fait analogues à ceux que M. d'Infreville a fait breveter dans les Etats-Unis après Winter.

2. Explication de la méthode Schwendler pour la double transmission, par W. P. Johnston. (Electrical News, vol. I, pages 75 et 89).

Ce qui caractérise la méthode de Schwendler pour la double transmission en sens opposé, c'est essentiellement la présence à chaque station de deux ponts de Wheatstone, un pour le courant de départ, l'autre pour le courant d'arrivée. Pour le courant de départ, le récepteur ou un relais de Siemens ou d'Arlincourt se trouve dans la diagonale du pont, pour le courant d'arrivée cet instrument est placé dans une branche. L'avantage de ce double pont de Wheatstone consiste en ce qu'il n'y a que la résistance d'une seule des branches opposées à la ligne qui demande une correction si la résistance de la ligne varie et que chaque station peut établir l'équilibre des résistances indépendamment de l'autre station. L'article se termine par des indications concernant l'échange des dépêches sur les lignes à double transmission.

3. Le duplex système de M. Smith. (Telegrapher, vol XI, page 229).

L'inventeur s'est servi du diagramme employé par Poggendorff pour comparer les forces électro-motrices de deux piles. Le système se compose, comme celui de Stearns, d'un «sounder», d'un condensateur égal en capacité à la ligne et d'une résistance additionnelle. Le relais (ou le récepteur) a deux hélices. Chaque station est pourvue de deux piles, mais il importe peu que les deux stations aient les mêmes pôles ou les pôles de noms contraire en contact avec la ligne. Ce système aurait fourni de bons résultats quand il a été expérimenté entre New-York et Buffalo.

4. Le duplex télégraphe de d'Infreville, par Hugh Nelson. (Telegrapher, vol. XI, page 272).

Actuellement cinq différents systèmes de double transmission sont en usage dans l'Amérique du Nord, le système différentiel de Stearns, le système du pont de Wheatstone de Stearns et les systèmes de Haskins, Gerrit Smith et d'Infreville. Ce dernier n'a pas besoin de condensateurs, le courant de retour étant détruit par l'extra-courant d'un relais. Les manipulateurs sont simples et n'ont que deux points de contact. Les piles des deux stations doivent être opposées l'une à l'autre et d'égale force électro-motrice. Le système a été mis en fonction avec succès entre Toronto et Montreal sur une distance de 640 kilomètres. (Comme il ressort de l'article 1er, l'originalité de l'invention de M. d'Infreville est contestée).

5. Quadruplex télégraphie, par F. L. Pope. (Telegrapher, vol. XI, page 271).

Des différentes descriptions du quadruplex de MM. Edison et Prescott, c'est une des plus complètes, rendue encore plus intelligible par un dessin détaillé. L'auteur passe en revue tout l'historique de la double télégraphie en sens contraire et dans le même sens depuis Gintl en 1853, se continuant par Frischen, Siemens, Stark, Kramer, Bernstein, Boscha, Schreiber, Wartmann, Maron, Schaak, Stearns, Zetzsche et Henviside jusqu'à Edison et Prescott. La première idée de la télégraphie quadruple appartient à Stark en 1855. Il a montré qu'il n'était besoin que de trouver un système pratique de double télégraphie dans le même sens pour obtenir immédiatement la télégraphie quadruple par son application au système de télégraphie en sens contraire. La difficulté du problème de la quadruplex télégraphie repose donc uniquement dans la difficulté de trouver un bon système de télégraphie double dans le même sens. Si l'on emploie trois différentes forces de courant, il est presque impossible de donner au réglage des relais une sensibilité suffisante et, si l'on se sert de courants alternant en direction, l'un des relais subit une secousse qui trouble les signaux.

MM. Edison et Prescott ont complètement abandonné la voie suivie par les autres inventeurs. Un courant d'une force 1 traverse continuellement la ligne, quand il n'y a d'abaissé aucun des quatre manipulateurs des deux stations. Par le premier des deux manipulateurs d'une station on peut renverser ce courant, par l'autre on augmente la force du courant de 1 à 4 sans changer la polarité qui est toujours déterminée par la position du premier manipulateur. A l'autre station le courant parcourt deux relais, l'un polarisé, l'autre ordinaire, chacun ouvrant et fermant un circuit local. Le circuit local du relais polarisé est fermé quand le courant est renversé par le premier manipulateur, mais ce courant, de la force 1, est trop faible pour agir sur le relais ordinaire. L'armature de ce dernier est attirée à son tour, si la force du courant est augmentée par le second manipulateur de 1 à 4, quelle que soit la direction du courant. Ce double système est transformé en quadruple système par l'intercalation des deux relais dans la diagonale d'un pont de Wheatstone. Les mauvais effets du changement de polarité dans le relais ordinaire et du courant de retour sont paralysés par deux électro-aimants auxiliaires et par deux condensateurs à chaque station.

...E'S magneto-electric machine, devised by M. Nicolai Berquet, two horse shoe-shaped steel magnets are so fixed parallel at a certain interval that their planes are vertical, their branches horizontal, and their four poles in one plane. Beneath axis at right angles to the planes of the magnets, and midway between the poles, are twelve iron cores, parallel to this axis, arranged equally with reference to...

...ROTH.—The Gramme Machine.—The moment I did not give to there a description of this as of inferior quality, but I do not deny to do so now as impossible. [Our quality reader might wish not be able to judge. Ed.] Small machines, such as I was then using, are not to be compared to large ones, and I do not doubt a "Gramme" machine, and I doubt if even now a more simple one than that to my book is to be found when read as a part of the whole machine which excites the principles of all the machines of that class. I may, perhaps, be allowed to say that I have described the principle as efficient a very much simpler machine than ...ma, the Weston Dynamo-electric Machine.—BAMBA.

...ual, and polygonal shapes, either parallel or superior also be cut by this machine."

DYNAMO-ELECTRIC MACHINES.

[1283.]—I should much like to see a full description of the most improved form of these machines, with working diagrams, and descriptions of a sufficiently plain and simple manner to enable amateurs to construct one for themselves. Mr. Wilson-Barker or Mr. Lecomber would undertake, I am sure, to supply any parts difficult of construction, it would take pay them and gratify a large number of your readers. Such a machine could be worked by a model engine, and would be the most economical method of utilising the improved electric lamps that have lately been submitted to the public. W.

Improvement in Dynamo-Electric Machines.

It is stated by the *Bing. Ind. Jour.* that the firm of Schuckert, in Nurnberg, have lately been devoting attention to the improvement of dynamo-electric machines, for galvano-plastic purposes and the electric light. Their machines are like the Gramme, but the following points may be noted. The rotating iron ring, wound with copper wire, is a flat disc; thus the wires of the two long sides of the cross section come under the action of the flat-shaped magnetic poles, and the induced currents of the two sides combine having the same direction. The whole wire length is thus utilised. Centrifugal forces at high velocity does no injury. Again, the iron ring is not in one massive piece, but in several ring discs, separated from each other by ensulite, pasteboard, or the like, the whole ring being held together by brass rivets. The object here is to hasten the disappearance of remanent magnetism, in rapid changes of the poles, and to obtain the maximum of magnetization. This construction allows of the firing of the ring or metal without disturbing insulating section, since only a very small part of the wire is in contact with it, and the coil effects of a possible heating are obviated.

DYNAMO-ELECTRIC MACHINES.*

(CONTINUED.)

The Brush and Wallace-Farmer machines were accompanied by lamps or carbon holders, which were thought by their makers to present advantages, if not for all machines, at least to be especially adapted to the requirements of their own; the "Serrin" lamp, which is made by H. Deyrolle for the Gramme machine, did not accompany the latter. The results of the experiment, however, quickly established the suitability of the Brush lamp, with enclosed carbons, as the source of light from all the machines, and the same lamp, with enclosed carbons properly adjusted as to size, was used for the several trials.

This lamp consists of a helix of insulated copper wire, resting upon an insulated plate, upheld by the metallic post. Loosely lifted within the helix is the core, partially supported by the adjustable springs. The rod passes directly through the centre of pencil. A washer of brass surrounds the rod just below the core, and has one edge resting on the lifting finger attached to the latter, while the other edge is overhung by the head of an adjustable screw stop.

The metal post is supported and guided by a tubular post, secured to a suitable base plate. Attached to the lower end of the post, and passing out through a slot, is an arm supporting an insulated holder for the lower carbon.

If now one conducting wire, from the machine, be connected to the base plate, and the other to the lower carbon holder, the current of electricity will pass up through the posts, and through the helix, rod, and the carbons, thus completing the circuit. The axial magnetism produced in the helix will draw up the core, and the core, by means of the lifting finger, will raise one edge of the washer, which, by its angular disposition against the rod, clamps and lifts it to a distance controlled by the adjustable stop, but separating the carbons points far enough to produce the light.

As the carbons burn away, the increased length of the electric arc increases its resistance and weakens the magnetism of the helix, and, therefore, the coil, rod, and carbon move downward by the force of gravity, until, by the shortening of the arc, the magnetism of the helix is increased and the downward movement arrested. When, however, the downward movement is sufficient to bring the clutch-washer, *c*, *b*, to the support, *t*, it will rock, *t*, will slip through until arrested by the upward movement of the core, due to the increased magnetism of the helix.

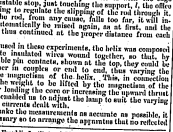

FIG. 8.

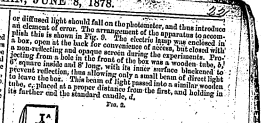
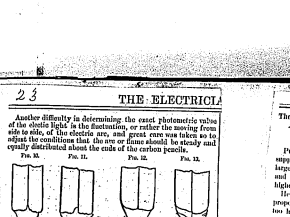
The normal position of the clamp-washer is with the edge under the adjustable pin just touching the support, in the effort of the core being to regulate the slipping of the rod through it. If, however, the rod, from any cause, fails too far, it will instantly and automatically be raised again, as at first, and the carbon points will remain at the proper distance from each other.

In the lamp used in these experiments, the helix was composed of two separate insulated wires wound together, so that, by means of suitable pin contacts, as shown at the top, they could be connected either in couples or end to end, thus varying the intensity of the magnetism of the helix. This, in connection with varying the weight to be lifted by the magnetism of the helix, either by loading the core or increasing the upward thrust of the springs, enabled us to adjust the lamp to suit the varying qualities of the current used with.

In order to make the measurements as accurate as possible, it was found necessary so to arrange the apparatus that no reflected or diffused light should fall on the photometer, and thus introduce plish this is shown in Fig. 9. The electric lamp was enclosed in a box, open at the back for convenience of access, but closed still fecting from a hole in the front of the box was a wooden tube, 5½ 6" square inside and 9' long, with its inner surface blackened to prevent reflection, thus allowing only a small beam of direct light to leave the box. This beam of light passed into a similar wooden tube, *c*, placed at a proper distance from the first, and holding in its further end the standard candle, *d*.



Another difficulty in determining the exact photometric value of the electric light is the fluctuation, or rather the moving from side to side, of the electric arc, and great care was taken so to adjust the conditions that the arc or flame should be steady and equally distributed about the ends of the carbon pencils.



Figs. 10 to 18 are full size, exact reproductions of the photographs taken, and fairly represent the average condition of the carbon when observations were made.

It was found that although there was a slow consumption of the negative carbon there was, at the same time, a constant "dodgeable" current of particles carried from the positive consumed different forms, as shown in the cuts, but no particles or shadows, except that the deposits on the negative carbon would become greater with increased current. These deposits would build up gradually until they had resumed the forms shown in Figs. 16 and 20; then growing narrower near the base, until, by a weakening of the current by this and the consumption of the upper carbon, the latter would readjust itself, and the piece would drop off. The effect of these growths on the intensity of the light was scarcely appreciable, except for a few seconds before and after the readjustment of the lamp.

[TO BE CONTINUED.]

NEW YORK, SEPT. 16, 1878.

The Pawtucket Curtiss Pumping Engine—A Practical Test and an Unexampled Performance.

Pumping engines to furnish a continuous supply of water are in use by most of our large cities and towns; their construction and adaptation calling for exercise of the highest engineering skill.

Heretofore the cost of first class engines in proportion to the actual work done has been too high for the resources of many towns exercising the need of them, and the pressure of our times has given rise to a demand for engines that may be relied upon to deliver more water with less original outlay and less cost of maintenance. The offers to meet this demand have been many; the general result disappointment.

Chanced to hear a short time since of a new style of pumping engine in course of trial at Pawtucket, R. I., and, being in that vicinity, made a visit in time to witness the conditions of that trial. The engine referred to was designed and built by George H. Corliss, of Providence, the inventor and builder of the Corliss Steam Engine, and who furnished the grand engine that ran the machinery at the Centennial Exhibition, who has given much study coupled with exhaustive experiments to produce pumping engines of higher prescribed duty than any others now in use. The trial showed a result considerably beyond the best heretofore on record, during a continuous run of 24 hours and a daily average, the precise coal working conditions being considered, never before equaled so far as we can learn, by any pumping engine in the world. To make the conditions of this test better understood by our readers we have procured a copy of the contract and specifications under which this engine was built for the Pawtucket Water Works, it will be observed from the following extracts that the requirements are unprecedented.

(1.) The engine is to be capable of raising with one three million (3,000,000) gallons of water in twenty-four (24) hours into a reservoir on Gimpy's Hill, two hundred and fifty (250) feet, more or less, above the level of the pump well. It shall force the water level through the pipes now laid in said street, and to pump directly into the distribution pipes during such time as the reservoir shall be under construction until its completion,

and thereafter, when required. It shall be able to do this under the varying conditions then ordinarily obtaining, and with the pressure corresponding to from 240 to 260 feet to the reservoir. It shall be able to do this with reasonable care, steadiness and safety.

(5.) The engine when completed and ready for service shall be subjected to trial each day and capacity; such trials to be conducted by the Chief Engineer of the Pawtucket Water Works and the Inspector, on the part of the party of the first part, with the co-operation of, and in concert with, such parties as the party of the second part shall see fit to appoint; One of said tests each day, and shall be twenty-four hours incessant duty, similar to the Lowell tests in June, 1876, with a similar provision in case of disagreement, as specified in Section 7 and 11 of the "Specifications for a Pumping Engine," hereinafter issued by said Water Commissioners. The other shall occupy two consecutive days, and shall consist of twenty-four (24) hours each day, as nearly as may be with the engines at such a speed as shall guarantee the delivery of 3,000,000 gallons in 24 hours. In this "every-day" running test, all the fuel shall be taken into the furnaces used until for kindling being reckoned as equivalent to 45 per cent. of its weight in coal. No allowance to be made for ashes or clinkers. The coal used in the tests shall be the best coal of the time, and the quantity of water delivered is to be ascertained by water measurement.

(6.) The sum to be paid by the party of the first part to said party of the second part in full compensation for all work and supplies indicated in this contract, is $23,000; provided that it shall appear that the duty of said engine on the 24 hours' trial, hereinbefore provided for, is at least 100,000,000 pounds per one hundred pounds of coal when delivering 3,000,000 gallons of water in 24 hours against a head of 250 feet, and that the duty on the two works "every-day running" test shall be at least 80,000,000 pounds per one hundred pounds of coal.

In consideration, however, that the duty of said engines is less on the every-day running test than hereinbefore stipulated, then said party of the second part shall pay said to a forfeiture on the contract price of one and a half (1½) per cent. of said price for each one per cent. of said deficiency; and if said duty shall not exceed 90,000,000 and 100,000,000 feet pounds, then said party of the second part agrees to allow said party of the first part to remain for the use of said Town of Pawtucket, without charge, for a period not exceeding six months from the expiration of said tests, in order that time may thus be given for the completion of another engine, after which it will remove it at its own cost, without claim for compensation in any way for the work it has done, or the expense it has been put to.

We know of no instance where a contract trial, *as exhaustive and as restricted to the conditions of every day work*, has ever before been demanded.

Its value, however, as showing what a pumping engine will do under the conditions of regular every-day practice, is not to be overestimated. As usually conducted trials last but a few hours, and the results are under exceptionally favorable conditions, *with no proper allowance for fuel used to start the fire*, far outstretch what they will accomplish in average running.

The Pawtucket Curtiss Pumping Engine embodies the important improvements which Mr. Curtiss brought out in the Centennial Engine, and they are here applied to the service of supplying towns with an economical system of water works. It is arranged to work on the compound principle, the high pressure cylinder 32" diameter, the low pressure cylinder 39" diameter. Each has a stroke of 30".

These vertical tubular boilers were used, of the precise plan and dimensions of those furnished by the same to the Centennial Engine, the only differences being in the greater thickness of shell to adapt the boilers to the very high pressure contemplated. Two boilers were used during the ten-hour daily running of the two weeks' trial at a pressure of 123 pounds, and the other for the night service during this trial, at a pressure of 100 lbs. No extra setting of elbows being work was employed. This arrangement be-

Bowman Mac

ing run continuously as the reservoir was not completed as was contemplated when the contract was made, and the town was dependent on continuous pumping night and day.

The two weeks' trial began Tuesday, August 6th, at 8.30 A. M., and was completed Monday, August 19th, at 8 P. M., thus including two Sundays instead of one only, as specified in contract. The coal used was Schuylkill (Shamokin) of the quality used for the current supply of the works, and was taken from the pile *without being picked or selected in any way*. The first day at 7.30 A. M., the fires under the two boilers, which had been left without banking or replenishing since 5 P. M. the previous day, were drawn, the grates cleaned, and at 8.07 new fires were built, using 161 lbs. of wood and shavings, and 220 lbs. of coal to kindle the fire. At 8.30 A. M. the engine was started and the trial began, the engine making an average of 21 revolutions a minute, steam at an average of 125 lbs., and delivering the water under head of 220 feet, including the estimated friction of the main, throughout the trial. A record was taken every ten minutes of the reading of gauges (water, steam, vacuum and receiver), the counter and the coal-scale from the center of the water gauge to surface of water in pump well. Every stroking of coal was weighted and time noted. The engine stopped at half-past six in the evening. The fires under the boilers were allowed to smolder until 7.30 next morning when they were banked, new fires built, and the trial proceeded with, continuously in this way, from day to day. It was found on Monday morning that an extra amount of coal was required to get up steam after an interval of 38 hours' rest against 14 hours of other days.

The coal taken from under the boilers was again used (after being sifted), no allowance being made for waste. An average of 85 lbs. of wood and shavings and 220 lbs. of coal was used every morning to start the fire under each boiler. The method employed of keeping an exact record of every pound of fuel used, both during the time of trial and in fi ing to make ready for trial, serves as *an effectual check to overstoking the fire*, as the fireman knows that when he commences a trial, where the record begins with starting of the engine, without allowance for coal piled upon the grate he is making ready. It often occurs, in computing the results, in trials of this kind, that no account is made of the wood used to kindle the fire, as less will be usually from 3 to 6 per cent. of the whole fuel used. In trials where the coal had been picked by hand, the apparent duty has been considerably increased. As shown by an expert, in his trial of the celebrated Lynn engine, in 1874, this excess of duty (as determined by the refuse) was 10.8 per cent.

At this trial each of the parties were represented by three practical men who took the records and carefully watched every detail.

The duty for the 15 days' trial, reckoning all the fuel used (wood at 45 per cent. of its weight in coal) *was not less than* 101,000,000 *foot pounds per* 100 *pounds of coal*. The duty for 21 hours *was not less than* 120,000,000 *foot pounds per* 100 *pounds of coal*. The Corliss during these tests delivered at the rate of 3,060,000 *gallons in* 24 *hours*. The representatives of both parties agree upon these results, which we hope to give entire in our next issue. We hesitate in saying that *no such results have ever before been achieved in a practical test of a pumping engine*. In comparing the work done by this engine with the best performances hitherto exhibited by others, it must be borne in mind that the rigor of the conditions under which this trial was made was such as to *preclude any species of manipulation to enlarge upon the ordinary duty performed*. Experts who were present while the trial was in progress, and who examined the methods employed, units in declaring it conducted with a degree of accuracy in every detail never before coming under their notice in testing a pumping engine. The most critical could find no feature to take exception to in any of the arrangements nor lack of scrupulousness in carrying them out. We had the pleasure of conversing with two of the experts here referred to, Mr. W. H. Odell, of Yonkers, and Mr. Thos. D. Stetson, of New York, (the former at one of the trials who expressed the belief that the performances of this engine was *beyond precedent*, and that a trial of such duration and care in checking possible error had never before taken place. Our own observations agree with this. The Pawtucket Curtiss Pumping Engine has been regularly working since the last day of January, and during the whole time there has been no failure of any part. Its operation is smooth and safe at very high speed, and no engineer has pointed out any liability to accident.

A number of special trials have been made in order to show what the engine will do under different conditions of water pressure from 69 to 117 lbs. These results will doubtless, in due time, be given to the public in detail. Efficient service has been performed by this engine in several cases of fire in the town. It has also been severely tried when architects have occured in the pipe mains where the pressure has been suddenly relieved, once by the blowing off of a 12-inch water gauge.

The tests that have taken place prove, beyond doubt, that Mr. Corliss has produced a pumping engine capable of much greater average practical duty, and at cost to the purchaser below what has heretofore been paid for engines of high duty, and which is calculated to work as great a revolution in water works engineering as the introduction of the Corliss Engine, thirty years ago, wrought in the application of power for manufacturing purposes.

We call attention to infringements of the WESTON DYNAMO-ELECTRIC MACHINES, in which Automatic Switches are used to prevent change of current.

The Weston Company are owners, by grant or purchase, of all forms of Automatic Switches for Electrotyping and Plating Machines. The adoption of these Machines will certainly lead to great loss to parties purchasing or using them.

Machines for Electro-Plating, Electrotyping, Electric Light, Telegraphing, etc.

Owing to the introduction of several new sizes of the WESTON DYNAMO-ELECTRO MACHINES, and the surprising results obtained from them by our customers, we have decided to issue the following price-list in advance of our complete catalogue.

The WESTON DYNAMO-ELECTRIC MACHINES have now been in successful operation for over two years, during which time we have sold over 800 Machines. The fact that all the early Machines are still working perfectly, and in most cases the Machines during the whole time of working not having cost $5.00 for repairs, will show their great economy over batteries. The new 14-inch Machines, which have been recently perfected, show the wonderful power peculiar to the Weston construction when increasing the size. A Machine only slightly larger than the 12-inch, developing three times the

THE BALANCE DYNAMOMETER.

Although many forms of dynamometers have been devised, none of them are more simple or more reliable than the one invented more than thirty years ago by Mr. Samuel Batchelder, of Boston.

This instrument, which is of great value in practical mechanics, is exceedingly simple and is fully adapted to its object. It is made of suitable dimensions and strength for the degree of power to be measured, and when it is used it is placed in the line of communication between the motor and the machinery to be moved, the power exerted on the machinery may be exactly measured by means of the steelyard and weight, which form a part of the machine. There is also connected with it an index to note the number of revolutions of the drum for a given time, which being observed, together with the weight, the data are obtained for computing the number of pounds which would be raised 1 foot high per minute by the power exerted at the time upon the dynamometer and transmitted through it to the working machinery.

Our large engraving represents the dynamometer in actual use in connection with dynamo-electric machines, while the cuts, Figs. 1 and 2, page 136, exhibit the details of construction. In these figures A A and B B are two pairs of belt pulleys, each pair consisting of a fast and loose pulley. The machine receives its power from the prime mover by a belt on the pulley, A, and the power is transmitted to the machine which is the subject of experiment by a belt from the pulley, B. The fast pulley, A, has the bevel wheel, D, are fast upon the shaft, C, which revolves in bearings, I. The bevel wheel, F, is connected with the pulley, B, by a sleeve, K, which is capable of turning on the shaft, C. The bevel wheels, D, F, are geared together by the bevel wheels, E, E, which run upon a cross shaft having a hose, G, through which the main shaft passes freely. It is evident that if this cross shaft is not retained in its place by some adequate force, the motion of the bevel wheel, D, will only cause the cross shaft to move round upon the shaft, C, and the wheels, E, will roll upon the wheel, F, without communicating motion to it, or to the pulley, B; but if the wheels, E, and the cross shaft are held stationary, the motion of the pulley, A, will be communicated to the pulley, B, through the bevel wheels, and the force then applied to retain the shaft, G, and wheels, E, in place will indicate the power transmitted through the dynamometer. The amount of power is ascertained by means of a graduated scale beam, H J, connected with the shaft of the wheels, E, by straps, a.

The weight, M, fastened to the shorter arm of the graduated beam by a set screw, affords a means of balancing the beam when the machine is at rest, and the weight, W, like that of a common balance, moved on the graduated arm of the lever, will indicate the strain upon the belt. The num-

BATCHELDER'S BALANCE DYNAMOMETER.

THE GRAMME DYNAMO-ELECTRIC MACHINE FOR PRODUCING ALTERNATING CURRENTS.*

Two recent improvement in the Jablochkoff system of electric illumination, and that which has given to it its present success, is the employment of an alternating current of electricity for establishing the electric arc between the carbon pencils. If the Jablochkoff candle is used with a continuous current, the positive carbon is consumed at twice the speed of the negative, but with a properly alternating current instead of a continuous one, the carbons are consumed at an equal rate, each being alternately positive and negative in the other, and an alternating current possesses this further advantage, namely, that each stick of carbon is kept beautifully pointed instead of rough and irregular, and this symmetrical consumption of the carbonaceous matter is a great source of steadiness in the light.

The Jablochkoff candle may be used with advantage with any dynamo-electric machine which produces an alternating current, or by a continuous current machine fitted with a commutator, by which the direction of the current is reversed every few seconds, but this arrangement for obtaining from a continuous current machine two currents in other dynamo-electric machines, can only be accomplished by great loss of electricity, and, therefore, of motive power; and it has been found much more economical and advantageous to use machines where currents are originally generated in alternating directions. Mr. Gramme, the inventor of Siemens' machine, and of many others, would appear, from the Scientific American, to have designed a machine for the purpose, to this new machine of M. Gramme which is shown in the engraving, and which is described in the Engineering. The electro-magnets, of which there are eight, are fixed radially to a central boss, *f*, revolving upon a horizontal steel shaft, *e*, running in suitable bearings attached to the framing, and an external pulley enables the machine to be driven by a band from a steam engine or other motor. The radial electro-magnets are alternately right and left handed in the direction in which their coils are wound, as that if they be numbered 1, 2, 3, 4, etc., up to 8, respectively, those represented by the even numbers are similarly wound in a current is sent through them all together, while those whose numbers are odd are wound in the opposite polarity. The poles of each of these magnets are, of course, of the magnets, are turned out so as to increase the size of the non-magnetic gap in which electric currents are induced in the coils of the ring.

In the old machine of M. Gramme, the electro-magnets were excited by the current from a special Gramme machine mounted on the same shaft as the two rings which generated the available current, and the current from the fine ring was exclusively devoted to exciting the electro-magnets. In further improvements upon his continuous current machine, M. Gramme dispensed with an extra and special ring for charging the magnets, and devoted a portion of the current from a single ring to that purpose, two coils being wound on the same ring. In the present machine, however, there is no self-contained apparatus for producing the current by which the electro-magnets are charged, although there is nothing to prevent an ordinary Gramme machine being attached to the same shaft. It is found more convenient, however, to use the new machine simply as an apparatus for dividing the current, and for giving to it a reciprocating nature, and, therefore, an altogether separate electro-motor is employed. An ordinary volute battery of sufficient power would answer the purpose, but in practice a small and separate Gramme machine of the continuous-current type is employed, driven by a separate strap, and the current from this machine being caused to traverse the coils of the rotating radial electro-magnets, they are magnetized to saturation with but a small expenditure of motive power.

Each of the eight sections of the induction-ring are made up of four sections, *a*, *a*, *a*, *a*, *a*, etc., all of which, in any one section, are wound in the same direction. By coupling the coils of these sub-sections in various ways, a division of the current may be made into 32, 16, 8, or only 4 circuits, and this is one of the most valuable qualities of the system.

From a consideration of the above description, it will be seen that all the sub-sections or coils marked *a* are influenced by the rotating magnets in precisely the same manner, for the influence of a north pole upon a coil wound in a positive direction is exactly the same as the effect of a south pole upon a coil wound in a negative direction, and similarly the currents induced in the coils marked *a* are similar in direction to one another, no matter what may be the position of the rotating magnets. In the same manner all the currents from the sub-coils marked *b* are homologous to one another, all that is necessary is to connect up the series of the coils marked *a* for the first circuit, all the coils marked *b* for a second circuit, all the coils marked *c* for a third circuit, and all the coils marked *d* for a fourth circuit. As the induction rings turn first, there is no difficulty in leading the current from the machine, and the apparatus is fitted with terminal screws on the exterior of the rings by which they can be collected, and by which variations in the method of coupling up may be made.

The current for the small machine is led to the rotating magnets through flat brushes composed of silk-worm gauze wire fixed to the frame work of the machine, and rubbing against two insulated drums or cylinders of copper, the two being connected to one end of the magnet-circuit and the second to the other.

When the shaft carrying the magnet is rotated, the expanded magnetic poles pass close to the coils of the induction-ring, and in so doing induce within them currents of electricity, the strength of which depends upon the intensity of the magnetic field through each coil, and, furthermore with the speed of rotation.

The new Gramme machine, as at present constructed, is made in three sizes. The largest is capable of supplying the current to 24 Jablochkoff candles, at a speed of 800 revolutions per minute, and absorbing a motive power of about 18 horse power, costs, with the smaller machines for charging the storage batteries, 10,000 francs (=£400), its length, including the steam engine, is 25 ins., its width 20 ins., and its height about 24 ins. The same; the total weight is a little over 1216 cwts. The second size machine requires 12 horse power to drive it, at a speed of 700 revolutions per minute, and supplies the light of 12 Jablochkoff candles, and costs, with its small machines, 5,000 francs (£200). It measures 22 ins. in length, 18 ins. in width, and 20 ins. in height, and weighs rather over 5 cwts. The smallest size actinetic, at a speed of 800 revolutions per minute, a Jablochkoff lights, and absorbs 4 horse power of motive power. Its dimensions are as follows: Length, 21 ins.; width, 16 ins.; height, 18 ins.; and its total weight is about 3½ cwts. In addition to these three Gramme, M. Gramme has a new machine in hand, which differs in construction, in several material points, from those to which we have referred, and from which he hopes to effect a saving in both the prime cost and the cost of working the machine. It is designed for use with 8 Jablochkoff candles.

It will appear from the above figures that the power absorbed is almost exactly one horse power for each candle, and the result of a year's working of the system at the Hotel and Magazins du Louvre very closely supports that estimate.

That M. Jablochkoff has solved the problem of producing a steady electric light, requiring but little attention, and suitable for street illumination of a very beautiful order, must be self-evident to all visitors to Paris at the present time.

Whether the system, however, is a success in an economical and commercial point of view, is another question altogether, and remains to be proved. We are rather inclined to the opinion that in its present stage it is rather costly, although light for light it will compare favorably with gas.

The whole system, much as it adds to the beauty and attractions of the city of Paris, must still be looked upon as in its childhood; it is rather more than a step, it is a long stride in the right direction, and we cannot but believe that further improvements, both in the construction of the machines for generating the electrical currents and in the apparatus for converting those currents into centers of illumination, will have brought all obstructions placed in its path.—*Journal Franklin Institute.*

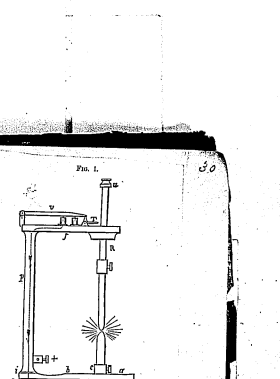
A NEW SYSTEM OF ELECTRIC LIGHTING AND A NEW FORM OF ELECTRIC LAMP.

By Profs. Elihu Thomson and Edwin J. Houston, of the Philadelphia Central High School.

HAVING been engaged in an extended series of experimental researches on dynamo-electric machines, and more especially on those for electric lighting, our attention has been directed to the production of a system that will permit the use of a smaller current for sustaining an electric light than that ordinarily required, or, in other words, the use, when required, of a current of sufficient intensity to produce a continuous arc. At the same time, our system permits the use of a powerful current, in such a manner as to operate a considerable number of electric lamps placed in the same circuit.

As is well known, when an electrical current, which flows through a continuous arc, or considerable length, is suddenly broken, a bright flash, called the extra spark, appears at the point of separation. The extra spark will appear, although the current is not sufficient to sustain an arc of any appreciable length if a point of separation is made.

In our system, one or both of the electrodes, which may be the ordinary carbon pencils, are caused to vibrate to and from each other. The electrodes are placed at such a distance apart that in their motion from each other they are gradually afterwards receive a distance apart which can be regulated. These motions or vibrations are made to follow one another at such a rate that the effect of the light produced is continuous, or, in other words, a light which does not flicker is produced by a rate greater than twenty-five in thirty per second, the electrodes being in a continuous circuit. The vibrations of one or both of the electrodes may be communicated to the electrodes by any suitable mechanism, such, for example, as mechanism operated by a rotating or reciprocating, or vibrating, armature, etc., but it is evident that the current itself fur-



nishes the most direct method of obtaining motion, as by the use of an automatic vibrator or an electric engine.

In practicing with this system in both electrical and we found it necessary to give motion to but one, and to have the negative electrode may be made of such size as to waste very slowly, motion is imparted to it in preference to the positive, which, of course, in practice may be formed by those of various substances of sufficient conducting power.

In this system, when desired, an independent battery circuit is employed to control the excitation and lighting of such lamps.

A NEW ELECTRIC LAMP.

The following is a description of one of the forms of electric lamp which we have devised, and used in connection with our system of electric lighting:

A frame, *a*, *a*, of metal is firmly attached at one of its ends to a pillar, *p*, and bears at its other end an iron armature, *a*, placed opposite the adjustable pole-piece of the electro-magnet, *m*. A metal collar, *c*, supports the negative electrode, *n*. The positive electrode being supported by an adjustable collar on the pillar, *p*. The pillar, *p*, is divided by insulation at *i*, into two sections, the upper one of which consists of the rod, *b*, again restores the contact. During the movement of the negative electrode, since it is caused to move many times per second, the positive electrode, though practically free to fall, cannot follow the rapid motions of the negative electrode; and, therefore, does not rest in permanent contact with it. The slow fall of the positive electrode may be insured either by properly proportioning its weight or by partly counterpoising it. The positive electrode thus becomes self-feeding.

The rapidity of movement of the negative carbon may be controlled by means of the right bar, *l*, which acts, practically, to shorten or lengthen the part vibrating.

In order to obtain an excellent but free contact of the arm, *a*, with the positive electrode, the rod, *b*, made of iron or other suitable metal, passes through a cavity, *s*, Fig. 2, filled with mercury, placed in electrical contact with the arm, *a*.

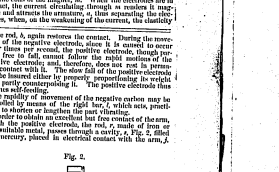


Fig. 2.

Since the mercury does not wet the metal rod, *r*, or the sides of the cavity, *s*, there is no danger of its overflowing, and the rod is allowed without any escape of the mercury. We believe that this feature could be advantageously introduced into other forms of electric lamps.

The electrical connections, occurring in the circuit, when the electrodes are connected, is traced, a, to the upper extremity of the rod, *b*, at such a distance that when the carbons are connected as much as is deemed desirable, it comes into contact with a tripping lever, *l*, which then allows the conducting plugs, attached to the bar, *r*, to fall into their respective mercury cups, attached, respectively, to the positive and negative binding-posts by a direct wire. This action practically cuts the lamp out of the circuit.—*Franklin Journal.*

THE BRITISH ASSOCIATION.

COMMENCED NOTICE.

On Tuesday, August 30th, the seventh day of the meeting, the business in Section G commenced by the presentation of the following reports of committees: "On Instruments for Measuring the Speed of Ships;" "On the Datum Level of the Ordnance Survey and on Tidal Observations in the English Channel." The first paper read was by Mr. J. N. Shoolbred "On Electric Lighting." This paper, which attracted a great many visitors to the section, and which we intend to publish *in extenso*, began by referring to the suggestion first made by M. Nollet, of Brussels, in the year 1810, of turning to account Faraday's great discovery of the induction of electricity from magnetism by the construction of magneto-electric machines. This suggestion, first taken up by Pixii, Clarke, and others, ultimately led to the construction of the Holmes and Alliance machines, which were used at the lighthouses of the South Foreland, Cape Grisnez, and La Hève. The paper then went on to refer to the researches of Siemens and Wheatstone and Varley, which led to the discovery of the reaction principle, the basis of all so-called dynamo-electric machines, which in Europe are represented by the machines of Siemens and Gramme, and in America by the Brush and Wallace-Farmer machines, descriptions of the Siemens, Gramme, and new Gramme machines being given. The paper next describes the systems for the subdivision of the electric light, the two most important of which at present are the Lontin system, now employed in London outside the Gaiety Theatre, and the Jablochkoff candle, which has been fully described in these columns.*

After describing some of the many forms of electric regulators for lamps, referring to the importance of obtaining carbon pencils of great uniformity of structure, the paper touches upon the question of horse power required to drive the apparatus, and concludes with a few remarks upon the cost of working under the different systems.

At the conclusion of the paper the president, Mr. Edward Easton, C.E., called upon Mr. J. N. Douglass, the engineer to the Trinity House, who opened the discussion by making a few remarks upon the application of the electric light to lighthouses, and referred to the experiments made for the Trinity House at the South Foreland by Professor Tyndall and himself, which were fully described in these columns nearly a year ago.† Mr. Douglass also referred to the establishment of the electric light to the two lighthouses which mark the southern extremity of the Lizard promontory.

Mr. J. H. Wigham said that from his experience of the Gramme machine, which had been considerable,

* See ENGINEERING, page 93 ante 125 ante.
† See ENGINEERING, page 93 ante.

ENGINEERING.

he had great confidence in it for the production of the electric light. He had had one which for months had been subjected to the roughest treatment, and which had kept in working order. He did not consider that the electric light would prove, for some time to come, any serious opponent to illumination by coal gas, so as to affect to any permanent degree the income of gas shares. He considered some doubt whether the electric light was any cheaper than gas, but there was a question to be decided whether the small intense light of the electric arc was superior for lighthouse illumination to the larger flame derived from gas or oil, that is to say, whether it possessed good fog-penetrating power.

Mr. Robert Briggs, of Philadelphia, U.S., said that he desired particularly to call attention to a recent report of a Committee of the Franklin Institute of Philadelphia, on dynamo-electric machines which, exhibited the relations of light, heat, and electric force with much completeness, as brought out by careful experiment and investigation for considerable time. Upon this Committee the speaker had the honour to serve, and he wished to give testimony to the diligence and labour expended by the several members during the three months of examination.

Every effort had been made to prepare a thorough and impartial report. (Mr. Shoolbred here said that this report was considered by him and had been abstracted to in his paper.) Mr. Briggs said that beside this report of the Franklin Institute, there had been a further inquiry into the subject of electric lighting, which had not been published up to the time that he left the United States. This inquiry was made at the instance of the exhibitor of the United States Capitol at Washington, Mr. Edward Clarke, who had, at the request of a Committee of the House of Representatives, referred to him the proposition to light the Hall of Representatives by the electric light by means of the dynamo-electric machine patented in the United States by Mr. Brush. The machine was one of those experimented upon by the Committee of the Franklin Institute.

The objects to be attained at Washington were first an abundance of light, secondly, removal of the heat emanating from gaslights, and, thirdly, the practical accomplishment of the first and second requirements with an expenditure which would compare favourably with the present cost for coal gaslighting. The experiments of the Franklin Institute, and a further practical illustration in the lighting of a railway station of the Pennsylvania Railroad at West Philadelphia, by a system of four separate sources of light from one dynamo-electric machine, satisfactorily demonstrated the feasibility of lighting the hall with regularity and with a quantity of light equal if not superior to what now proceeds from the gas burners over the ceiling. The experiments of the Franklin Institute gave with great exactness the quantity of heat given off, and permitted a direct comparison to be made with the heat accompanying the combustion of the gas. The cost was also determined with much certainty, for the power required and its commercial value in pence was readily estimated at well-known rates, and the attendance and repairs of apparatus, interest on plant, and a supposed substitution and renewal in two years, gave a good basis for the cost of maintenance and service.

It may be well, therefore, to quote the estimate of the cost of electric lighting in the case as compared with the present gas-lighting. The experiments of the Franklin Institute showed that about 14 ½ horse power would be consumed in driving dynamo-electric machines operating four lamps, each of 2000 candle power, and it was proposed to use three such machines, calling for 43 horse power in all. When:

	dols.
Taking 43 horse power for three hours' daily average use per day at 15½ cents per horse power	5.03*
One principal of electric lighting apparatus per day	5.00
Two assistants at 2.50 dols. per day	5.00
Carbons	1.35
Twenty per cent. of cost of apparatus 12,000 dols.=2400 dols.÷365 days ...	7.65†
Total approximate cost of lighting the Hall of Representatives by electric light, per day	24.00

* The above price is estimated at the rate of 125 dollars per year per horse power for ten hours per day, for 312 working days per year, which is a full profit rate for power supplied in small quantities.

† This percentage to cover interest, repairs, oil, &c., and 10 per cent. for supposed renewal of the whole each two years.

To effect the same purpose there are now at the present consumption of gas in the roof space about the glass ceiling of the hall, 1920 burners, each burning about 4½ cubic feet per hour, giving 8650 cubic feet per hour, or 16,600 cubic feet for three hours, assumed daily consumption. Taking thus 16,600 cubic feet at 3.200 dols. per M.=19.60 dols., or very closely twice as much as would define the cost of electric lighting. These values would vary in some degree by being estimated at English prices, but considering that the electric apparatus proposed is the most complete possible, and that the whole had been estimated at American prices, Mr. Briggs believed to think that a solution based on English prices throughout would be quite as favourable.

The report to Mr. Clark makes one comparison of the highest importance in this place with respect to the ventilation of the hall as to the heat evolved by the two systems respectively, and establishes the fact that only about one thirty-fourth part as much heat is given off by the electric light—that is to say by the arcs themselves—as is evolved by the gas burners, as they are now placed.

The total heat from gas-lighting of the whole of the upper level temperature of the escaping gases (omitting the latent heat of the water, which it is supposed is not condensed but diffuses as vapour) is nearly one hundred times that which proceeds from the arc giving equal quantity of light; but on the other hand the heat of the arc is only, according to the Franklin Institute experiments, about 31 per cent. of the total heat theoretically required for driving the dynamo-electric machines, the remainder being dissipated or conducted away either as heat or as electric current not utilised, so that the light-giving capacity of the electric light can be taken to be about thirty-one times that of a gaslight. With these facts in view Mr. Briggs protested against the assumption that as the light of the future the gaslight, as it is, occupies a strong place in the field of competition. We have long known that in the production of light by the combustion of oleaginous substances, hydro-carbons, of which coal gas is a good if not the most favourable type, a large amount of heat has been generated, a small portion only of which will have been expended in heating to incandescence, but a portion of the carbon, which will have been found in particular hydro-carbon gases (of the mixture known as coal gas) in the form of C_{14}, H_{12}. The heat proceeding from the burning of all the gas, except the C_{14}, which at most amounts to over 12 to 16 per cent. by weight, if so much) is expended in establishing the heat of incandescence, and maintaining it through a small flame, in the consumption of which the C_{14} also come to the air, and is consumed itself with the evolution of further heat.

Heat is force, and it was—said Mr. Briggs—not until the electric light, as produced by the dynamo-electric machine, gave us a measure of the force accompanying light, that we came to appreciate how unscientific, as regards the utilisation of heat, the gaslight is. We now know positively that by means of the electric light (not what may be the best result by any means) about 100 times as much heat will proceed from the theoretic combustion of coal gas as attends or is incident to the electric arc, that as a practical result 30 times as much heat is evolved from gaslighting as will impel a perfect heat engine to produce the electric light; and (taking the average best steam engine at 0.14 in useful effect as a heat engine) the heat from coal gas burning, as fuel, ought to give 4.2 times as much light through the intervention of the electric source of light with the apparatus of a dynamo-electric machine. Every showing is distinctive to the future of coal gaslighting in the competition, the advancement of science looks to the overcoming of the mechanical difficulties, and to the accomplishment of the fullest theoretic results. The absolute economy of electric lighting, as compared to gas-lighting, is so enormous that the time cannot be far distant when the former must take the latter's place for extensive illumination.

Mr. Denny Lane said that in his opinion the electric light would not be likely to take the place of gas. It was not the case that two systems of illumination occupied different ellerie, which in very few instances could be said to overlap one another, so as to dispute the same ground. In this view he was supported by Dr. G. William Siemens, with whom he had recently had a conversation on the subject. Light for light he believed the cost of electric illumination to be about one-half of that of gas, but it was impossible to produce by means of electricity, with any sort of economy, a single light of less illuminating power than that of a thousand candles, and there were many cases in which it would be better to have a hundred lights of ten candles power each, to one light possessing the concentrated illuminating intensity of the hundred distributed lights.

vivante qui électrisera, et qui est le révision du temps.

MACHINE MAGNÉTO-ÉLECTRIQUE

de M. de Méritens

Le débouché commercial et industriel qu'a ouvert dans ces derniers temps la lumière électrique aux machines d'induction électro-magnétiques, a provoqué de toutes parts des recherches et des perfectionnements qui ont fait avancer considérablement le problème de l'éclairage par l'électricité. Tout le monde connaît aujourd'hui les belles machines que MM. Siemens, Gramme et Lontin construisent, et on saisirait en les voyant qu'il serait difficile de les perfectionner davantage. Toutefois nous croyons que la solution définitive du problème n'est pas encore atteinte, et il est probable que d'ici à peu de temps nous verrons mieux encore. Déjà la machine que vient de construire M. de Méritens est un pas considérable fait en avant dans cette voie, et je suis autorisé à croire que cette machine, qui a déjà étonné ceux qui l'ont vue fonctionner, n'a pas encore dit son dernier mot.

Pour nous, qui avons suivi dès le début les progrès de ces machines, qui avons nous-même contribué aux premiers perfectionnements qui leur ont été apportés, nous voyons avec un véritable plaisir cette marche progressive de cette industrie qui est en quelque sorte née en France. Mais tout en les admirant, nous ne devons pas oublier que c'est à la compagnie l'*Alliance* et à son habile ingénieur M. J. Van Malderem que nous devons cette magnifique application de l'électricité.

A ce propos, nous croyons qu'il ne sera pas sans intérêt pour nos lecteurs de raconter brièvement l'histoire de ces machines.

En 1856 M. Nollet, constructeur belge, avait construit pour la galvanoplastie de grandes machines magnéto-électriques du système de Clarke qui donnèrent déjà d'assez importants résultats pour provoquer la formation d'une compagnie qui voulut les exploiter dans le but d'extraire le gaz de l'eau. Cette idée était insensée; mais précisément à cause de cela, elle trouva des adhérents, et ce fut cette compagnie qui, sous le nom de l'*Affluent*, installa dès 1855 dans des bâtiments attenant à l'hôtel des Invalides, les premières grandes machines magnéto-électriques connues en Europe. Naturellement les résultats obtenus furent déplorables, et en 1856 la compagnie fut obligée de liquider.

Elle se réorganisa ensuite en 1856, et après avoir nommé pour son directeur, M. Berlioz, elle chercha à tirer parti du matériel considérable qui avait été créé; ce fut alors que je fus consulté et que j'indiquai à M. Berlioz les applications qu'il pouvait en faire à la lumière électrique et à la galvanoplastie; mais pour y parvenir, bien des perfectionnements devaient être introduits dans ces machines, et tous les électriciens de l'époque apportèrent chacun leur pierre à l'édifice.

Parmi ces perfectionnements, il en est un suggéré par M. Masson, alors professeur de physique à l'École centrale et que j'aurais amené voir ces machines, qui permit instantanément de doubler les effets obtenus. Ce fut de supprimer le commutateur jusque-là employé dans toutes ces machines. Tous ces perfectionnements admirablement interprétés par M. J. Van Malderem, parvinrent, conjointement avec ceux qu'il y apporta lui-même, de faire arriver ces machines à une perfection qu'on n'aurait guère osé espérer dans l'origine, et qu'on croyait bien ne pas pouvoir être dépassée. Ce fut alors qu'on songea à en tirer parti pour l'éclairage des phares et pour l'illumination de la marche des navires; des expériences furent alors tentées conjointement avec MM. Teyssand et Degrand, et bientôt, en 1863, les phares de la Hève purent être éclairés de cette manière.

En même temps, on faisait pour l'application à la navigation des expériences qui n'eurent pas d'abord tout le succès qu'on pouvait en espérer, surtout à cause du mauvais vouloir qu'on rencontra dans la marine, mais qui devaient fournir plus tard des résultats dont on put apprécier l'importance. Ce fut la France qui précéda les autres nations dans cette double voie, comme c'est elle qui les précède encore pour l'éclairage public. Mais nous devons dire que c'est grâce à la compagnie l'*Alliance* et à la courageuse initiative de son intelligent directeur, M. Berlioz, que le monde civilisé doit ces belles applications de l'électricité.

Ce tribut d'hommages rendu à une compagnie dont la fortune ne seconda pas les efforts, nous allons examiner les progrès accomplis dans ces dernières temps en dehors d'elle.

La machine l'Alliance était une machine magnéto-électrique, c'est-à-dire une machine composée d'aimants permanents et de bobines d'induction. Dans son dernier modèle, elle mettait en contribution 18 aimants et quatre rouleaux munis chacun de 16 bobines d'induction; elle fournissait des courants alternativement renversés, et pouvait alimenter trois bougies Jablochkoff; elle employait comme force motrice environ trois chevaux, et marchait à une vitesse de 400 tours par minute. Aucun dégagement n'était produit dans la machine, et la lumière qu'elle fournissait était très-régulière.

Dans des conditions tout à fait exceptionnelles, ce rendement a été très-augmenté, et on a même parlé d'une machine pouvant alimenter six bougies; mais les machines ordinaires sont loin de fournir de pareils résultats. Or, la machine dont nous allons maintenant parler peut, avec huit aimants seulement (aimants de même grandeur que ceux de l'Alliance), illuminer de trois à quatre bougies Jablochkoff et fournir également les courants renversés qu'on regarde, avec raison, comme un élément favorable pour l'éclairage public!

Il est vrai que la vitesse de la machine est plus grande, car elle accomplit sept cents tours par minute; mais elle ne dépense, m'a-t-on assuré, que soixante dix-huit kilogrammètres de force motrice, c'est-à-dire un peu plus de un cheval vapeur, et ne s'échauffe presque pas. Ses dimensions sont très-petites, et les éléments de sa construction sont simples et faciles d'ajustement et de construction.

Les effets avantageux de ce genre de machines résultent de ce qu'aux courants d'induction déterminés dans l'anneau des machines Gramme, sont ajoutés ceux qui se produisent dans les machines magnéto-électriques ordinaires.

Pour qu'on puisse les comprendre, imaginons-

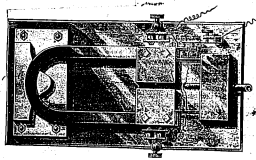
MOTEUR MAGNÉTO-ÉLECTRIQUE HARMONIQUE

DE M. EDISON.

Ce moteur magnéto-électrique se compose d'un aimant en fer à cheval de grandes proportions et



Moteur harmonique de M. Edison.

Les tiges mobiles possèdent des tiges qui pénètrent dans une boîte fermée où se trouve le dispositif destiné à recueillir le courant.

Le tube qui termine à droite l'appareil est destiné à laisser arriver l'eau d'une pompe que le moteur de M. Edison met en mouvement.

Il y aurait intérêt à savoir comment l'inventeur du phonographe s'y est pris pour recueillir des mouvements si rapides et à une si faible amplitude, mais il ne nous a point donné ce renseignement.

Jusqu'à plus ample information, nous ne voyons pas en quoi cette combinaison se distingue d'une multitude d'autres qui ont été tentées avec des succès toujours assez médiocres.

Pour que cette machine puisse marcher d'une façon satisfaisante, il faut que les deux branches oscillent bien d'accord. C'est de là que vient le nom de machine harmonique qui lui a été imposé.

DYNAMO-ELECTRIC MACHINES.

[15083.]—I should much like to see a full description of the most improved form of these machines, with working diagrams, and described in a sufficiently plain and simple manner to enable amateurs to construct a small machine themselves. If Mr. Wilmershurst or Mr. Lancaster would undertake this, and also supply one parts difficult of construction, I should be glad to subscribe for a number of your copies. Such a machine could be worked by a model engine, and would be the most economical method of utilising the improved electric lamps that have lately been submitted to the public. W.

MAGNETO-ELECTRIC MACHINES FOR LIGHTHOUSES.—The magneto-electric machine, adopted by MM. Sautter, Lemonnier, and Co., for the illumination of lighthouses, as shown by them at the Paris Exhibition, is a continuous current Gramme machine. When connected up "for tension," it gives a light equivalent to 2,500 Carcel burners, with an expenditure of 7 h.p., and 220 revolutions per minute; and, when arranged "for quantity," the light is equal to 4,000 of these burners, whilst 11 h.p. are expended, and the velocity is 550 revolutions per min. A similar machine constructed by the above-mentioned firm, and intended for the Planier lighthouse, was exhibited by the French Minister of Public Works. The reason for the adoption of the continuous current machine, instead of one with alternating currents is as follows:—In machines of the former class the light is concentrated on one of the carbons, whilst in those of the latter description it is equally divided between the two carbons, the distance between which, with the powerful currents now used, is from four to five millimetres at least. Now, if the middle of the arc be focussed in the lens, the horizon receives no light; whilst, if it be one of the two points, the light from the other is lost, being refracted either towards the sky or on to the sea in the vicinity of the lighthouse. The light furnished by a continuous current machine

is therefore better utilised than that produced by one with alternating currents. By varying the speed of revolution, and by the use of a commutator, the above machines allow of the intensity of the light being varied, according to the condition of the atmosphere, in the ratio of 1:4, the expenditure of motive power being proportionate to this intensity.

VOL. II., NO 1. NEW YORK, JANUARY 1, 1879. $1.00 PER ANNUM.

Electric Light Engine.

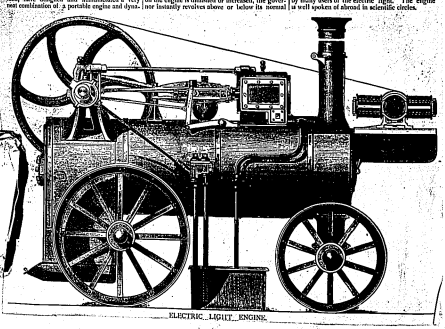
In the various trials which have lately taken place with electric lighting, says the *Engineer*, London, gas, steam, and even water have been used as motive power for driving the dynamo-electric machines; but when the machines have been attached to large fixed engines usually employed in factories, it has been found that the movement was not sufficiently regular, or that it was often necessary to keep a large engine at work at night simply to drive the electric light, an arrangement evidently somewhat wasteful in principle, and costly and unsatisfactory in practice. It has been generally admitted that when the electric light is employed, whether for permanent or temporary purposes, it is advisable to have an engine adapted specially for the purpose of driving the machines, not only on account of the economy in fuel and labor, but also from the greater regularity which can be ensured in the movement of the dynamo-electric apparatus.

Messrs. Ross, and Head, of Ipswich, England, have designed and manufactured a very neat combination of a portable engine and dynamo-electric machine on Siemen's, Gramme's, or other well known system, the whole being mounted on four wheels, and easily transported from place to place. The engine is fitted with a patent automatic expansion gear, which is very sensitive and capable of regulating the number of revolutions of the fly-wheel per minute with great accuracy—a matter of much importance to insure the proper action of all electrical machines.

This gear consists of two small eccentrics fixed on the crank shaft, and furnished with straps and rods, as usual in the usual manner. The ends of the rods are connected together by a small disk, which has two quick circular slots at the end of the bell-crank lever. The weight shall not be supporting and form the connection between the link and governor, which is on the former principle. The action of the whole is as follows:—The eccentric, which is attached to the lower end of the link, is fixed at such an angle in relation to the crank as to effect an early cut-off, whilst the eccentric attached to the top of the link is set so as to allow a late suppression of the steam. When the load on the engine is diminished or increased, the governor instantly revolves above or below its normal speed, and by the rising or falling of its arms and balls it shifts the link and brings the expansion valve more or less under the influence of the early or late cut-off eccentric, thus regulating the supply of steam to the altered load until the engine again makes its proper number of revolutions per minute.

The following diagrams will show the action of the automatic cut-off in the cylinder. They are from a ten-horse power engine with ten-inch cylinders, thirteen-inch stroke, making 140 revolutions per minute.

The electric machines are fixed on a platform in front of the smoke box, and a second fly-wheel can be attached when it is necessary to drive two machines for a double light. These engines are made of from four to twelve-horse power, and, if necessary, the wheels can be taken off and the boiler fixed to the ground. Several of these engines have been made for driving electric lights in various parts of the world, and we think we may commend the design as a practical one, and likely to supply a want which has long been felt by many users of the electric light. The engine is well spoken of abroad in scientific circles.



ELECTRIC LIGHT ENGINE.

CIRCUMSTANCES INFLUENCING THE EFFICIENCY OF DYNAMO-ELECTRIC MACHINES.*

By Profs. Edwin J. Houston and Elihu Thomson.

During the recent competitive trials made at the Franklin Institute, as to the relative efficiency of some different forms of dynamo-electric machines, the authors have been entrusted with the work of determining the relations between the mechanical power consumed, and the electric and thermic effects produced, took the opportunity thus afforded, to make a careful study of many interesting circumstances which influence the efficiency of these machines.

It is proposed in the present paper, to select from the many circumstances thus noticed, a few of the more interesting, reserving the others for a future consideration.

It will readily be understood, from the comparatively new field in which we had been working, no reliable data of the electrical work of these machines having before been obtained, that difficulties constantly arose owing to necessary conditions of operation, and new developments as to the behaviour of the machines under varied conditions, were constantly met.

A convenient arrangement of the particular circumstances we are about to discuss may be, 1st, Those affecting the internal work of the machine; 2nd, Those affecting the external work, and 3rd, The relations between the internal and external work.

The mechanical energy employed to give motion to a dynamo-electric machine is expended in two ways, viz., 1st, In overcoming friction and the resistance of the air; and, 2nd, In moving the armature of the machine through the magnetic field, the latter of course constituting solely the energy available for producing the electrical current. The greatest amount of power expended in the first way was noticed to be about 17 per cent. of the total power employed. This expenditure was clearly traceable to the high speed required by the machine. The speed, therefore, required to properly operate a machine is an important factor in ascertaining its efficiency.

The above percentage of loss may not appear so great, but when it is compared with the total work done in the arc, as heat, constituting as it did in this particular instance over 50 per cent. of the latter, and about 23 per cent. of the total work of the circuit, its influence is not to be disregarded.

In another instance, the work consumed as friction was equal to about 80 per cent. of that appearing in the arc as heat, while in the Gramme machine experimented with, this percentage fell to 20 per cent. of that which appeared in the arc as heat, and was only about 7 per cent. of the total power consumed in driving the machine.

In regard to the second way in which mechanical energy is consumed, viz.: in overcoming the resistance necessary to move the armature through the magnetic field, or in other words, to produce electrical current, it must not be supposed that all this electrical work appears in the circuit of the machine, since a considerable portion is expended in producing what we term the local action of the machine, that is local circuits in the conducting masses of metal, other than the wire, composing the machine.

The following instances of the relation between the actual work of the circuit, and that expended in local action, will show that this latter is in no wise to be neglected. In one instance an amount of power somewhat more than double the total work of the circuit was thus expended. In this instance also it constituted more than five times the total amount of power utilized in the arc for the production of light. In another instance it constituted less than one-third the total work of the circuit, and somewhat more than one-half the work in the arc.

Of course work expended in local action is simply thrown away, since it adds only to the heating of the machine. And since the latter increases the electrical resistance, it is doubly injurious.

The local action of dynamo-electric machines is analogous to the local action of a battery, and is equally injurious in its effects upon the available current.

Again, in regard to the internal work of a machine, since all this is eventually reduced to heat in the machine, the temperature during running must continually rise until the loss by radiation and convection into the surrounding air, are eventually equal to the production, and the machine will at last acquire a constant temperature. This temperature, however, will differ in different machines according to their construction, and to the power expended in producing the internal work, being, of course, higher when the power expended in producing the internal work is proportionally high.

If therefore a machine during running acquires a high temperature when a proper external resistance is employed, its efficiency will be low. But it should not be supposed that because a machine when run on no supposed resistance, that is on short circuit, without external resistance, heats to a great degree, that therefore its inefficiency is shown thereby. On the contrary, should a machine remain comparatively cool when a proper external resistance is employed, and heat greatly, when put on short circuit, these conditions should be regarded as an index of its efficiency.

As a rule the internal resistance of dynamo-electric machines is so low that to replace them by a battery, the latter, to possess an equal internal resistance, would have to be made of very large dimensions, so that the efficiency of Dynamo-Electric Machines, cannot be stated in terms of battery cells as ordinarily constructed.

In regard to the second division, viz., the external work of the machine, this may be applied in the production of light, heat, electrolysis, magnetism, &c.

Where it is desired to produce light, the external resistance is generally that of an arc formed between two carbon electrodes; the resistance of the arc is therefore an important factor in determining the efficiency. To realize the greatest economy, the resistance of the arc should be low, but nevertheless should constitute the greater part of the entire circuit resistance.

In some of our measurements the resistance of

* Paper read before the American Philosophical Society, Nov. 1st, 1878.

the arc was surprisingly low, being in one instance 54 ohms, and in another 79 ohm. It was, however, in some instances as high as 218 ohms.

It may be noted as an interesting fact that where the greatest current was flowing, the resistance of the arc thereby produced was low. This is undoubtedly due to higher temperature and increased vaporisation from the carbons. In this latter case also the greatest amount of light was produced.

The amount of work appearing in the arc as measured by the number of foot pounds equivalent thereto, is not necessarily an index of the lighting power. In two instances of measurement, the amount of energy thus appearing in the arc was equal, while the lighting powers were proportionately as three to four. This apparent anomaly is explained by considering the resistance of the arc, it being much less in the case in which the greater light was produced. The heat in this case being evolved in less space, the temperature of the carbons, and therefore their light-giving powers, was considerably increased.

A few remarks on the economical production of light from an electrical current may not be out of place. The light emitted by an incandescent solid will increase as its temperature is increased. In the voltaic arc the limit to increase of temperature is in the too rapid vaporisation of the carbon. Before this point is reached, however, the temperature is such that the light emitted is exceedingly intense. No reliable method of measuring the temperature of the arc has as yet been found.

A well known method of obtaining light from electrical currents is by constructing a resistance of some material such as platinum, having a high fusing point and heated to incandescence by the passage of a current. When platinum is employed as the limit to its increase of temperature is the fusing point of the platinum, which is comparatively but a fraction of the temperature required to vaporise carbon. Were the fusing off in the amount of light emitted merely proportional to the decrease in temperature, the method last described might be economical. Unfortunately, however, for this method, many facts show that the decrease in the light emitted is far greater than the decrease of the temperature. Most solids may be heated to 1000° F. without practically emitting light. At 2000° F. the light emitted is such that the body is said to be at a bright red. At 2000° F. the amount of light will have increased far more than twice, probably as much as four times that emitted at 2000° F.? It is reasonable to suppose that with a further increase of temperature the same ratio of increase will be observed, the proportionate increase in luminous intensity far exceeding the increase in temperature.

It would therefore appear that the employment of a resistance of platinum, or other similar substance, whose temperature of alteration of state as compared with that of carbon is low, must be for economical than the employment of the arc itself, which as now produced has been estimated as about two or three times less expensive than gas.

Indeed it would seem that future improvements in obtaining light from electrical currents will rather be by the use of a sufficient resistance in the most limited space practicable, thereby obtaining in such spaces the highest possible temperature.

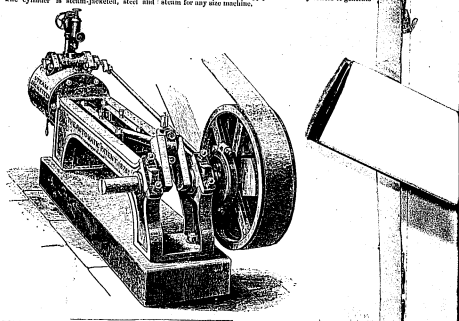
Perhaps the highest estimate that can be given of the efficiency of dynamo-electric machines as ordinarily used, is not over 50 per cent. Our measurements have not given more than 38 per cent. Future improvements may increase this proportion. Since the efficiency of an ordinary steam engine and boiler in utilising the heat of the fuel is probably over estimated at 20 per cent., the apparent maximum percentage of heat that could be recovered from the current developed in a dynamo-electric machine, would be over estimated at 10 per cent. The economical heating of buildings by means of electricity may therefore be regarded as totally impracticable.

Attention has, long ago, been directed to the use of dynamo-electric machines for the conveyance of power. Their employment for this purpose would indeed seem to be quite promising. Since in this case one machine is employed to produce electrical currents, to be reconverted into mechanical force by another machine, the question of economy rests in the perfection of the machines and in their relative resistances.

In respect to the relations that should exist between the external and internal work of dynamo-electric machines, it will be found that the greatest efficiency will, of course, exist where the external work is much greater than the internal work, and this will be proportionately greater as the external resistance is greater. Our measurements gave in one instance the relation of 72 ohm. of the arc to 49 ohm. of the machine, a condition which indicates economy in working. The other extreme was found in an instance where the resistance of the arc was 1·98 ohms, while that of the machine was 4·60 ohms. a condition indicating wastefulness of power.

THE MOTIVE POWER TO DRIVE DYNAMO-ELECTRIC MACHINES.

In our last number we described an engine designed by Messrs. Rasmusens, Sims, and Head. It is not, however, always necessary to have so complete an apparatus. In many cases, and especially in this the case in large factories, there is a sufficient boiler power to generate the steam, so that more boiler power is not wanted for the special engine required for lighting purposes. Instead, therefore, of going to the expense of obtaining a boiler and engine, in such cases the engine only is required. If there is the slightest doubt as to the supply of steam, we should advise in all cases a good margin on the safe side. The supply of steam being provided for, the engine has to be obtained and fixed. An The manufacturers of the engine call it "The Automatic," and claims several advantages for it. One of the most important for electrical engineers to consider is the governor. The makers state that the "automatic variable expansion," which governs of steam by admitting the exact amount required by a varying load, and thus keeping the machine running with extreme steadiness. As will be seen from our illustration, the engine is extremely simple, and no endeavour has been made to compensate in our engine the most important improvements of recent years. The cylinder is steam-jacketed, steel and phosphor bronze are used instead of wrought iron and brass, so that the wear of bearings may be reduced to a minimum, and that the maximum strength may be obtained from the use of the least weight of material. According to the statements of Messrs. G. Russell and Co., the 10-horse power nominal, with 60 lbs. boiler pressure, works to 30-horse power indicated. The diameter of the cylinder of this engine is 10in., length of stroke 10in., diameter of fly-wheel 42in., making 120 revolutions per minute. Supposing a small Gramme to be driven direct from the fly-wheel without any intermediate shafting, we should obtain some 880 revolutions of the dynamo machine per minute. This would be about the number of revolutions the machine would be required to make under ordinary circumstances. At the experimental shed on the Embankment the small Gramme does not make so many revolutions as this, but in other cases it is required to make 900 or 1,000 revolutions per minute. It would be well, perhaps, to caution engineers against too high a rate of speed. The dynamo machine will, like other pieces of mechanism, heat if driven too fast, and just a certain point the wires will fuse, rendering the machine useless. In fixing the engine to drive the machine, as well as in fixing the machine itself, it is necessary that great care should be taken to have a good firm foundation. Messrs. Russell make the engine we have then briefly mentioned of nine varying from 1 to 10-horse power. If required, Messrs. Russell supply the necessary boilers to generate steam for any size machine.



SIEMENS' BROTHERS' DYNAMO-ELECTRIC LIGHT APPARATUS.

[CONCLUDED FROM PAGE 40.]

CONDUCTING OR LEADING WIRES.

The leading wires are usually of copper of high electrical conductivity. They must be insulated from one another throughout their length, and not placed too close together. As their resistance affects the intensity of the light very much, the greatest care is usually exercised in the distance of the wires from the machine.

The total practical result is obtained when their resistance, together with that of the lamp, is equal to the total internal resistance of the dynamo machine. Wires of various sizes are therefore required. The following is one type adapted to a distance of 220 yards between the machine and lamp :—

It consists of a strand of 19 copper wires, No. 16 B.W.G., covered with layers of cotton tape and india-rubber.

The increase in strength of the current caused by a leading wire of low high resistance can be overcome by a higher velocity, which is obtained only by increased motive power, but if the power is much too small it will become heated. The proper remedy is to increase the sectional area of the leading wire.

Sufficient sparks should never be allowed to appear at the commutator and brushes, as sparks result from a rapid burning of the metallic parts. They can easily be avoided by properly adjusting the two arms which carry the brushes.

The position of the brushes yielding the least spark at the commutator is that giving the highest intensity of light in the electric arc.

The commutator should, while in motion, be freely oiled to prevent the brushes wearing away too rapidly. The sticky oil would from time to time, be removed by washing with paraffin oil or petroleum.

WEAR AND TEAR.

The chances of stoppage so common to the old forms of electric light apparatus have in this form been reduced to a minimum. It now do not exceed those that arise with machines generally. The Trinity House Report states that the Siemens machine worked well for a month without any necessity for stopping. The brushes are the only parts which wear away, and they are very easily replaced.

Some experiments were made at Fort Monckton on behalf of the British Government in July, 1878, with the Siemens, the Gramme, and the Wilde machines. The results are given in the minutes of the Institution of Civil Engineers for 1878, and they show the great superiority of the Siemens machine over other machines of its class. Since that, during a series of experiments made at the South Foreland Lighthouse for the purpose of selecting the electric apparatus for the Lizard lighthouse, the Siemens machine was proved to be the cheapest, lightest, smallest, and of most powerful. (See Trinity House Report, in which a full account is given.) Six of these machines are now erected in the Lizard, and they give a very excellent light. They are arranged that they can be worked either single, during the daytime or in pairs during thick weather.

The reason for coupling them in pairs and connecting them in what is called parallel circuit (or "quantity," as for "tension") is because it has been found that when they are so arranged the density of the electric light produced exceeds by some twenty per cent. the intensity of the sum of the two when worked separately. Then the Siemens machine, giving respectively a power of 4,846 and 6,063 when worked separately (total 10,909) gives when coupled up in parallel circuit a light equivalent to 13,710 candles; just as in telegraphy it has been found that the rate of signalling can be increased from 20 to 25 per cent. when the apparatus is coupled up in parallel arc. For this reason it is usual to employ two machines of medium size, instead of one machine of large size. The intense light so produced is also much more uniform than from one large machine.

AUTOMATIC ELECTRIC LAMP.

Automatic electric lamps have been produced, actuated by clockwork to enable the carbons to approach each other at a certain point, when, by means of an electro-magnet, the clockwork is checked, and the carbon points are allowed to burn away through a distance that, by the decrease of current, the clockwork released and the process caused to approach again. With both lamps the clockwork has been a source of trouble, and it is liable to get out of order.

The lamp to be here described is actuated without clockwork; also automatically separates the carbons as they burn away, checked long electric arc, or touch each other; and, by this combination of several well-known principles, a perfectly self-regulating lamp is produced.

The working parts are represented in the diagram Fig. 6, and Fig. 8 represents the largest size lamp, such as is employed for lighthouse illumination. Two smaller sizes of lamp, adapted for general purposes, are also manufactured.

E (Fig. 6) is the horse-shoe magnet with the armature, A, placed a short distance in front of its poles. A regulating screw *b* with the rubber spring *f* is attached to the lever A', forcing it against the stop *d*, and withdrawing the armature from the poles of the electro-magnet. When a current traverses the coils of the latter of sufficient strength to attract the armature and overcome the tension of the spring *f*, contact is made at *c*, which diverts the current from those coils. The consequent release of the armature breaks contact at *c*, the armature is again

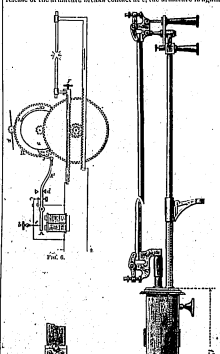


FIG. 6.

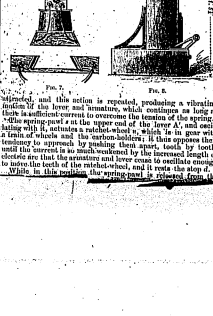

FIG. 7.

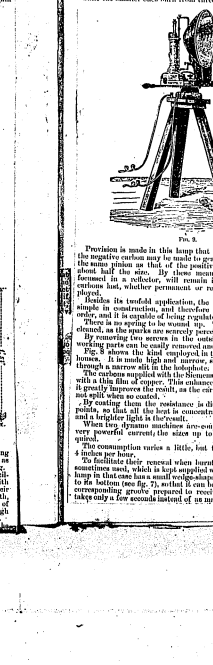

FIG. 8.

attracted, and this action is repeated, producing a vibrating motion of the lever and armature, which continues as long as there is sufficient current to overcome the tension of the spring.

The spring-rod *r* at the upper end of the lever A', and oscillating with it, actuates a ratchet-wheel *w*, which is in gear with 4 train of wheels and the carbon-holders; it is thus opposes their tendency to approach by pushing them in apart, tools by tooth until the current is so much weakened by the increased length of electric arc that the armature and lever cease to oscillate enough to move the teeth of the ratchet-wheel, and it rests the stop *d*.

While in this position the spring-rod *r* effected from three

crease of current follows decrease of resistance, the armature again oscillates, and this cycle of action is continuously repeated.

When in action the movements of the carbons are scarcely perceptible, but when, by any external cause, the carbons are separated so as to extinguish the light, they immediately run together until they touch, when they ignite and separate to a proper working distance by means of the electro-magnet above described.

The only operation requiring attention in the use of this lamp is the adjustment of the tension of the spring *f*. When this tension is once regulated to the current at disposal, the lamp will continue to give a steady light as long as the current remains uniform.

The relative rate of consumption of the two carbon points differs. The positive carbon burns away rather more than twice as quickly as the negative carbon.

The duration of the light depends mainly on the lengths and sizes of the carbons. The large lamp will burn for ten hours, while the smaller ones burn from three to four hours.

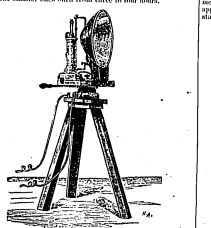

FIG. 9.

Provision is made in this lamp that the rack which supports the negative carbon may be made to gear either with the teeth of the same pinion as that of the positive carbon, or into one of about half the size. By these means the light, when once focussed in a reflector, will remain in focus as long as the carbons last, whether permanent or renewed currents are employed.

Besides its twofold application, the lamp is very compact, is simple in construction, and therefore not likely to get out of order, and it is capable of being regulated with great precision.

There is no spring to be wound up. The contact need not be cleaned, as the sparks are scarcely perceptible.

By removing two screws in the outside casing, all the chief working parts can be easily removed and inspected.

Fig. 8 shows the kind employed in the lighthouse of lighthouses. It is made light and narrow, so that it can be inserted through a narrow slit in the lighthouse.

The carbons supplied with the Siemens Patent Lamps are coated with a thin film of copper. This enhances the cost somewhat, but it greatly improves the result, as the carbons burn longer and do not split when so coated.

By rendering them the resistance is diminished, except at the points, so that all the heat is concentrated in the electric arc, and a brighter light is the result.

When in use, dynamos are coupled together to give a very powerful current, the size up to 20 unit diam: are required.

The consumption varies a little, but the average is from 3 to 4 units per hour.

To facilitate their renewal when burnt short, a spare lamp is sometimes used, which is kept supplied with fresh carbons. The lamp in that case has a small wedge-shaped contact-slide attached to its bottom (see fig. 7), so that it can be inserted quickly into a corresponding groove prepared to receive it. The process thus takes only a few seconds instead of as many minutes.

In the cabin shops at Siemens Brothers' telegraph works at Woolwich, where the electric light has for the past two years taken the place of gas, and has been thoroughly tested, this economical machine, to be at 2 to 1 in favour of electricity, taking it under most unfavourable circumstances, as regards cost of coal, and with interest on first cost at 25 per cent.

The advantage would, however, be much greater in favour of electricity if the light intensities were compared, for in the above case the electric light is three times as powerful as the gas formerly used. The ratio thus becomes 6 to 1 against gas light.—*Ed.*

Two kinds of concentrating apparatus are supplied in combination with the automatic lamp, both of which are capable of giving a powerful parallel beam which will reach to an enormous distance, and are well adapted for naval, military, and other purposes. The one kind consists of a parabolic reflector of silvered metal, its concave surface being silvered and burnished. The apparatus is mounted with a ball-and-socket joint upon a wooden stand, as shown in fig. 9.

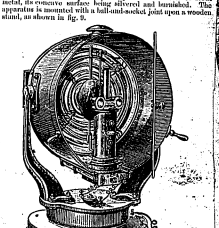

FIG. 10.

The other kind is the Pecenel Catadioptric lens or Holophote (see fig. 10) which may be substituted for the reflector, and gives a more powerful beam than one given by reflection. The lens is surrounded by a metal case or lantern, in which is placed the electric lamp upon a slide for focussing. Behind the carbon-points a hemispherical reflector is placed to catch all the back rays and reflect them back through the lamp focus. The entire lantern is capable of revolving on horizontal friction rollers upon pivots. Two handles are placed at the back to manipulate it.

As the electric arc is much too bright to be looked into with the naked eye, both concentrating apparatus are supplied with a hood, called a dome or lume observer, by means of which an image of the burning carbons is thrown upon small screens at the back, so that the lamp can be easily adjusted without fatigue to the eyes. The fresh observer is shown on the lamp in the Holophote, fig. 10.

HOW TO MAKE A DYNAMO-ELECTRIC MACHINE WITH WORKING DRAWINGS ONE-HALF ACTUAL SIZE.

By Geo. M. Hopkins.

Probably the most important invention following the discovery of magneto-electrical Induction is the dynamo-electrical machine, which is now made in many forms, all of which are based on the same general principle, viz.: that rotation, within the influencing powers of the poles of a magnet, of a soft iron armature surrounded by one or more helices, an electrical current being produced in the helices by the rapid magnetization and demagnetization of the soft iron armature.

While several of the principal machines seem to stand on about the same footing in regard to efficiency, none of them can be more easily made than the Siemens; and I do not think a small machine of any other type would give better satisfaction than the ones described in this article.

It is not necessary to use permanent magnets in this machine. Electro-magnets may be employed, the slight residual magnetism left in the soft iron cores serving to excite the armature, which in turn excites the magnet, thus multiplying the magnetic induction until a strong current is realized.

In the accompanying engravings, which are exactly one half size, Fig. 1 is a perspective view of a dynamo-electric machine having electro-magnets and a Siemens armature. Fig. 2 is a vertical transverse section taken on line $x\ x$ in Fig. 3. Fig. 3 is a horizontal section, taken through the electro-magnet looking toward the forward. Fig. 4 is a vertical longitudinal section of the armature and its commutator, taken on line $z\ z$ in Fig. 3. Fig. 5 is a transverse section of the commutator and commutator strips, taken on line $z\ z$ in Figs. 3 and 4. Fig. 6 is a perspective view of a dynamo-electrical machine employing permanent magnets. Fig. 7 is an end elevation of the same, and Fig. 8 is a perspective view of this machine, showing the manner of adjusting it. As the dimensions of either machine may be obtained from the engravings, I shall omit them in the description.

The electro-magnet is, for the sake of convenience, composed of two pieces, A B, which are exactly alike consisting of the connecting piece, C, in cast with the pieces, A. These pieces, A, are planed at their joinings at the top, and secured together by two bolts which pass through the part C. The lower ends of these parts are also planed to receive the base plate, E, which is secured in place by dowels and screws, two of each entering each part. The cylindrical cavity which receives the armature, G, is bored out truly

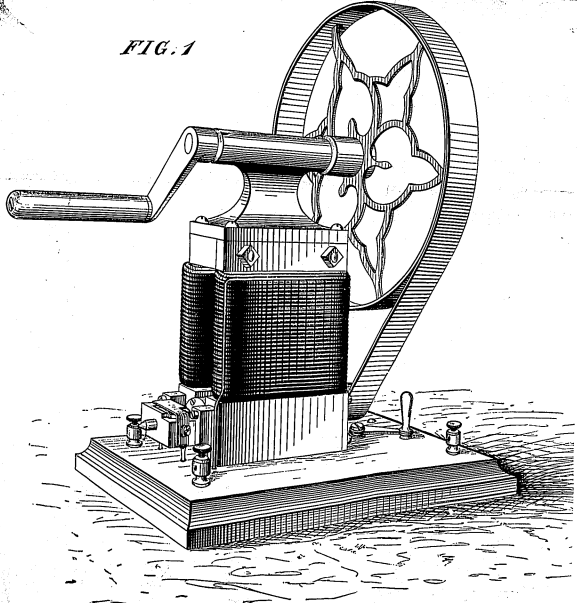

FIG. 1

HAND POWER ELECTRIC MACHINE.—Half Size.

and smoothly of a uniform caliber from end to end. The edges of that portion of the electro magnets around which the wire, D, is wound are rounded, as shown in Fig. 5. Before winding a piece of cotton factory cloth should be wrapped around each core; upon this is wound several layers of No. 16 gutta-percha-covered copper wire. The finished magnets should be wound in opposite directions, or in such a way that when the two portions, A B, are placed end to end, one coil would be simply a continuation of the other. The inner ends of the coils are connected together, while their outer ends are of sufficient length to run downward through the base, and leave room for the curved iron bar, E, secured with the binding posts, *a* and *a*.

The armature, G, consists of a cylindrical piece of soft cast iron grooved longitudinally, and across the ends, and wound with No. 16 cotton or silk covered copper wire. It is, in fact, a very short and wide bar electro magnet, having enlarged and elongated ends of the form of a segment of a cylinder. In diameter the armature is only a very little less than that of the cylindrical space between the parts, A B, of the electro magnet, and its length is a little less than the width of the electro magnet. In Figs. 2 and 4, G' is the core of the armature around which is wound the wire, H. To opposite ends of the armature are fitted the brass heads, J J, into which are screwed the shafts, *b c*. It will, of course, be understood that the armature needs filing around the core, G', and that the heads and shafts must be fitted to the ends of the armature before it can be turned and fitted to the cylindrical space in the electro magnet. The shaft, *b*, is journaled in a brass support, L, which is attached by screws to the edges of the parts, A B, of the electro magnet. The shaft, *c*, is journaled in a similar support, M, which is secured to the opposite side of the electro magnet. Outside of the bearing, L, upon the shaft, *b*, is secured the pulley, *d*, and between L and the support, M, and the head, J, the commutator is placed upon the shaft, *c*. The commutator consists of a vulcanite cylinder, *e*, having upon its periphery a copper or brass ferrule, which is slit longitudinally at diametrically opposite points, forming the insulated segments, *f g*. These are secured to the vulcanite cylinder by small brass screws, and the slits are placed exactly opposite the center of the longitudinal grooves in the armature. The commutator is prevented from turning on the shaft by a set screw, and with the segments are connected the terminals of the armature coil, H. The terminal wires pass through holes in the head, J, which are lined with an insulating material.

To opposite sides of the support, M, are secured the copper commutator springs, *k l*. The spring, *k*, bears forward over the commutator and bears upon it with a constant pressure. The spring, *l*, is bent so that it touches the side of the commutator at a point diametrically opposite the contact point of the spring, *k*. The spring, *k*, is connected, by a wire (No. 16) insulated, and extends downward through the wooden base of the machine to a similar wire runs from the spring, *l*. As the design of the machine is such that its magnet may be connected with a battery, that all of the current from the armature may be utilized, instead of allowing a portion of it to pass through the helices of the magnet, two extra binding posts, *r s*, and a switch, N, are added.

The connections under the base are as follows: The terminals, *a a*, of the electro magnet are connected with the binding posts, *a a*. The commutator spring, *k*, is connected by the wire, *i*, with the binding post, *r*; the commutator spring, *l*, is connected with the switch, N, by the wire, *t*. The switch button, *r*, is connected with the binding post, *p*, by a suitable wire, and the switch button, *s*, is connected with the binding post, *n*, by the wire, *t*. All of these connections should be made with No. 14 wire. A support, O, for the shaft, P, is secured to the top of the electro magnet. The shaft, P, has at one end the driving wheel, Q, and at the other end a crank for operating the machine. A one inch belt, R, runs around the pulley, *d*, and the wheel, Q.

When the machine is driven by power the pulley, *d*, may with advantage be larger. The size of the wire on the magnets and armature may be varied for some special purpose, but for general use the sizes here given are recommended. The slit in the commutator should be made slightly angular, so that one section of the copper ferrule will touch the spring before the other section leaves it. The armature should fit in as nearly as closely as possible without rubbing. The parts mentioned as brass or copper should be made of those metals, as a magnetic insulation is required wherever they are used.

To run the switch, N, is in the position shown in the drawing, the binding posts, *s r*, being connected by a wire, the current passes from the post, *n*, through the commutator and the armature, thence by the wires, *f g*, through the commutator and through the button, *r*, and by the wire, *i*, to the post, *p*, thence through the electro magnet to the post, *n*, through the switch, N, and by the wire, *t*, to the post, *s*. Here the machine is arranged in this manner, the wires leading from the machine are taken from the posts, *a a*. The full force of the machine is developed on Sistari after the connection of the posts, *r s*.

By moving the switch, N, so as to make contact with the button, *s*, and connecting *r* and *n* by a wire, and using eight Bunsen elements with the posts, *a p*, the magnets are excited without disturbing from the power of the armature, and the current from the latter is taken through the wires, as before, to the post, *s*, but the wire, *t*, is now in electrical connection with the binding post, *n*, through the switch, N, button, *s*, and wire, *t*; therefore the current is taken away from the machine by inserting wires in the posts, *s n*.

Wires not connected with a battery this machine will vent from four cools inches of No. 26 platinum wire. It will rapidly and impressive water by slipping the coils of the wire in water slightly acidulated. It will run as induction coil and produced a small electric light between two fine carbon points when arranged same as in the apparatus described in SUPPLEMENT No. 149. The machine affords a current sufficiently intense to give strong shocks by connecting it with a bells or electro magnet, small permanent magnets may be charged, and it answers an admirable purpose for ringing large gongs. The effect may sometimes be increased by interposing a resistance of two or three coils between the binding posts, *s n*. This is especially the case when the apparatus with which it is connected is of low resistance kind. It may be connected with a small electric motor, thus affording a striking example of the convertible of force into electricity and of the development of power from the electricity thus produced. For many purposes this machine will be found equal to six or eight Bunsen cells.

When a battery is employed to excite the electro magnet the effect is very much increased. For example, it will run with twelve inches of platinum wire instead of four or six inches, and it will afford a current sufficient for a strong electric light.

The speed has much to do with the efficiency of the machine. The writer advises a speed of from 1,000 to 1,500 turns of the armature per minute. The drive wheel in the example given may with advantage be made much larger, say two feet in diameter, where space is not considered. The construction of the machine shown in Figs. 6, 7, and 8 will be readily understood after what has already been said.

The armature is precisely the same as in the other case, and so is the commutator, the only difference being that the armature is wound with No. 32 wire and the slits in

PERSPECTIVE SHOWING HAND CRANK ARRANGEMENT FOR DRIVING ELECTRIC MACHINE.

to project them upon a screen, and to obtain copies of them by photography.

Taking up the subject where others had left it, Dr. Silvanus P. Thompson, Professor of Experimental Physics in University College, Bristol, has, during the last two years, elaborated this method of magnetic and electro-dynamical investigation to an extent and to a degree that he may be said to have brought it to a new and practical result. The subject was first brought by Dr. Thompson before the Physical Society of London in February last, and a second communication was made by him to the same society in the month of June, when some of the figures with which the article is illustrated were projected upon the screen. At the meeting of the British Association which was held at Dublin in August last, Professor Thompson brought the research before Section A, in a paper "On Some New Magnetic Figures," which was illustrated by a very large number of magnetic and electro-dynamic figures fixed upon glass for use in a projection lantern, as well as a number of photographs from them and from others of a similar nature. These figures, some of which we now reproduce, illustrate in a very beautiful manner not only lines of magnetic force and the mutual attraction and repulsion of voltaic currents passing within what may be called "electro-dynamical range" of one another, but also the phenomena of electro-magnetic rotation and the forces at work in the action of such physical instruments as galvanometers dischoding, of course, all needle telegraph instruments) and magnetometers. Since that time Dr. Thompson has still further elaborated the system so that he is enabled by it to demonstrate and illustrate nearly all the laws of magnetism and electro-dynamics. The method which he adopts is to coat plates of glass about 2½ ins. square with a solution of gum arabic, to which a small proportion of gelatine is dissolved to prevent the film cracking off in flakes; when this is dry it is perfectly smooth transparent laid coating is given to the glass plate. The wires or magnets having been placed below, finely sifted filings of wrought iron are dusted over the plate from a muslin bag, the plate being gently tapped with a light glass rod until the figures are formed. A gentle stream of steam from a small boiler is then directed on to the plate by a flexible tube, the effect of which is to soften the gum, into which the filings sink without being displaced, and are found to be firmly adhered to the glass when the plate is dry. A glass cover plate, upon which the positions of wires, poles, magnets, etc., are marked by means of opaque paint or black paper, isthen fastened over the edges to the plate carrying the figure, and can then be photographed either as a transparent plate for projection on the screen, or as a negative for printing upon paper.

If the end of a small bar magnet be placed below a card or a plate of glass, a fitting figure formed around it would consist of radiating lines crowding a star, of which the end of the magnet would be the center, and this would be the case whether the magnet were presented to the under side of the plate, but if the end of a second magnet be placed against the plate within the influence of the first, that is to say, so that the magnetic lines of both magnets would overlap, the filing figure between greatly changes. If the end of the second magnet be of the same character as the first, mutual repulsion will ensue; this will be shown by the lines which radiate from the one magnet turning away from as if avoiding those from the other, and the effect will be to form a sort of bend on each side of the line joining the poles, more of the lines from the one pole coalescing with or running across any of those from the other. But if an opposite polarity be substituted for that of similar polarity, attraction will take place, which will be illustrated by the running together of the lines of force radiating from both magnets, so as to form between them a bundle of elliptic loops connecting the one pole with the other. If instead of placing the end of a magnet against the glass, whereby lines of magnetic force are formed, a hole be drilled through the plate, and a wire be passed in a direction normal to its surface, through which a strong voltaic current is passing, the lines of force instead of radiating from a center will be found to consist of more or less concentric circles of which the wire is the center; this effect is illustrated in Fig. 1. Were it not for the necessary imperfection of the process by which they are formed these circles would be perfectly circular and perfectly concentric, and the distances between any circle and its nearest neighbor would be proportional to the squares of their distances from the central wire. The circles would, in fact, illustrate a section through a sectsoid supposed at surfaces described about an electrified point in space.

Fig. 1 represents the effect of a current passing in a wire upon a plate below which there is a wire conveying an electric current in a direction parallel to the plane of the plate. In this figure the filings arrange themselves in a series of straight lines perpendicular to the direction of the wire and at equal distances from one another, and may be looked upon as a number of repetitions of Fig. 1, strung upon the wire at equal distances apart and looked at edgeways.

Fig. 2 represents the effect of a crossed loop or large "kink" formed in the wire. This figure illustrates very well the mutual attraction of two currents flowing in opposite directions; as well as the corresponding repulsion of currents whose direction is the same, and it also exhibits the electro-magnetic effect within one turn of a helix, through which a voltaic current is passing; in that case the lines of magnetic force would be perpendicular to the plane of the loop, and the filings under their influence could only form themselves (as far as the plate will allow them) into lines perpendicular to the plane of the paper, and therefore seem, for from above they appear simply as isolated dots or points.

Fig. 4 shows the effect of two currents crossing one another at right angles; here again mutual attraction and repulsion are well illustrated, loops being formed in one pair of corners, and lunules in the other pair, showing at the same time a tendency of the two currents to set parallel. These attractions and repulsions are beautifully shown in Figs. 5 and 6, in which the two white dots represent wires passing through the glass plate in a direction perpendicular to its plane, and through which voltaic currents are passing. In Fig. 5 the currents in the two wires are in opposite directions, the one being up, and the other down, while in Fig. 6 the currents are in the same direction. These two latter figures are interesting as illustrating Faraday's conceptions of the physical action of lines of force, which were (1) that lines of force have a tendency to "shorten" themselves; (2) that when lines of force meet one another "end on" they either attract and coalesce, or else they repel and part, according as they are "unlike" or "like;" and (3) that when like lines of force run parallel to one another, they are mutually repelled. The first of these phenomena is well shown in Fig. 6; the annular lines of force around one of the wires have a tendency to run into those surrounding the others, so as to become elliptic curves round the two wires, while in Fig. 5 mutual repulsion takes place, brushes being formed between them.

Fig. 7 represents not only the lines of force radiating from a magnet shown as a small black square and the concentric circles formed around a wire, but it illustrates the influence which the one has upon the other when brought into proximity. Here the lines of force show the tendency of an electric current to rotate round the pole of a magnet, and that of a magnet to rotate round a current, the radial lines from the magnet and the circular bands round the wire attracting and coalescing on the one side, and mutually repelling on the other. Fig. 8 is an exceedingly interesting electro-dynamical figure in which the influence of an electric currents upon a magnetic needle, free to rotate about its center, is beautifully illustrated. In this figure the forces pulling the needle round and round can be seen at work, and the pictorial action of the lines of force brought into play in the action of the galvanometer and of all other instruments is well illustrated. Dr. Thompson has still further elaborated this experiment by passing the wire sometimes to the current over the needle and down through a hole on the opposite end, with greatly increased effect; the duplicating of the lines of force are repeated at the opposite end and on the opposite side of the needle, forming a couple tending to turn the needle about its center.

The experiment of which Fig. 9 is a diagram was designed to illustrate the lines of electro-dynamic and magnetic force brought into play in the induction of magnetism in an iron bar when an electric current is sent through a wire coiled round it. It represents a small electro-magnet showing four turns of its coil. In the actual experiment the bar was a strip of fernstype iron, and the wire carrying the current was threaded through the eight holes, four being on one side of the bar and four on the other.

One of the most beautiful results of Professor Thompson's experiments is shown in Fig. 10, and illustrates at a glance the phenomena of the rotation of a magnetic pole round itself under the influence of a voltaic current. We have seen that the lines of force around the pole of a magnet are simply radial straight lines forming the figure of a star of which the pole is the center, and that lines around a current are, as shown in Fig. 1, of the nature of concentric circles. If now these two influences be combined, if a current of electricity be sent vertically upward through a magnet, what would be the effect upon the lines of force generated around the pole by the rotation of the current and its magnet? The filing figure shown in Fig. 10 answers the question exactly in the manner that might be expected. Just as the influence is a combination of the magnet and the current, so are the effects a combination of the radiating lines of the magnet figure with the concentric circles of the current, and a spiral figure is produced, represented in the figure, which is somewhat similar in form to the great spiral nebula in Orion discovered by Lord Rosse. When either the direction of the current or the pole be reversed, a similar spiral is formed, but the striating curves turn in the opposite direction; in other words, with one polarity, the spiral is left-handed, and with the opposite polarity the spiral is right-handed. Here, then, is a clear graphical illustration of the phenomenon of electro-magnetic rotation, and to Dr. Thompson belongs the credit of being the first to discover a proof of the fact that even when the magnet is fixed the lines of force are rotated when a current is sent through it.

In these experiments, Dr. Thompson employs wires of silver 0·8 mm. in diameter, using a current from a Grove's battery of either ten or twenty cells. He has produced a very large number of figures, some of which are of the greatest possible interest, illustrating as they do the action of the various magnetic and dynamo-electric machines, as well as other magnetic motions and the action of different physical instruments which depend for their action upon electro-dynamic currents or upon magnetism.—*Engineering.*

ENGINES FOR WORKING ELECTRIC LIGHT MACHINES.

I.

Messrs. Robey and Co.'s Patent Fixed Engine.

THE question of the engine power required for driving dynamo-machines employed in producing the electric light has received considerable attention lately, and many engineering firms have manufactured engines which are remarkably well adapted for the purpose.

Before proceeding to describe any of these engines, we would draw attention to the cause of the large discrepancies which exist when comparisons are made from the popular accounts of electric light trials, the discrepancies we mean as regards the horse-power required to produce the light. This almost entirely arises from *nominal* horse-power being confounded with *actual* or *indicated* horse-power. Now there is almost always a very wide difference between these quantities. The *actual* horse-power is often a *third* times the *nominal* horse-power. As the former quantity is the only true index of the work done in producing the light, it should always be the one employed in making calculations for comparisons. The *actual* horse-power is calculated with great facility. Thus, if we have given

Length of stroke in feet $= l$;
Diameter of cylinder in inches $= d$;
Pressure of steam in lbs. per square inch $= p$;
Number of revolutions of fly-wheel per minute $= n$;

Point of stroke at which steam is cut off $= x$; then

$$\text{Actual H. P.} = \frac{d^2 \times .7854 \times l \times 2n}{33000} \times$$

$$p\,x\,(r_2 \log \frac{1}{x} + 1)$$

Thus if the length of stroke were 1 ft., diameter of cylinder 6 in., number of revolutions of fly-wheel per minute 100, pressure of steam 60 lbs., and the steam was cut off when the piston had moved through $\frac{1}{4}$ of its entire stroke, that is $x = \frac{1}{4}$, then

$$\text{Actual H. P.} = \frac{36 \times .7854 \times 1 \times 200}{33000} \times$$

$$60 \times \tfrac{1}{4}\,(r_2 \log 4 + 1) = 10, \text{ very nearly.}$$

The *nominal* horse-power of an engine is calculated from the formula

$$\text{Nominal H. P.} = \frac{d^2\sqrt{l}}{156}$$

Taking the values we have given to d and l, we get

$$\textit{Nominal} \text{ H. P.} = \frac{36 \times 1}{156} = r_3, \text{ which is very}$$

considerably less than the *actual* horse-power.

We cannot too strongly insist upon the necessity in all trials of the electric light of the *actual* or *indicated* horse-power of the engines being given and not the *nominal* horse-power; and we are inclined to think that if this was done, the results of some of the trials would be by no means so favourable to the light as one is led to suppose, although as regards the engines the results would prove highly creditable to the engine makers.

The engine of which we give an illustration, is manufactured and designed by Messrs. Robey & Co., of Lincoln. It is admirably adapted for driving the dynamo-machines, and is especially remarkable for the small space it occupies, its regularity of speed, large margin of power, and regularity in running; this latter point is especially valuable, as upon it depends very much the steadiness of the light.

The locomotive type of boiler employed enables about 20 per cent. more water per lb. of coal to be evaporated than would be the case in one of the Cornish or egg-ended form. There is no loss due to the leakage or radiation from steam pipe and other large surfaces. The boiler working with an artificially strong draught, as inferior, and therefore cheaper class of fuel can be used.

The engine parts are fitted up with all modern improvements, the cylinders are steam-jacketed, and the valve gear is arranged to work with variable degrees of expansion.

The result of the whole being an economy of fuel, as proved by actual comparison with the old type of engine doing the same work, of from 20 per cent. to 30 per cent.

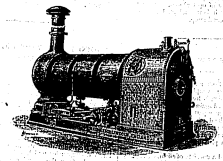
As will be seen, the entire engine is erected on a massive cast-iron bed-plate, so that the boiler is relieved of all strain due to the engine, and is confined to its legitimate purpose—that of raising steam.

The base-plate is formed at one end into an ash-pit, with damper doors, and is made suitable for receiving the fire-box end of the boiler—the other end of which is carried by a crutched-shaped casting fixed over the cylinders.

The end of the base-plate under the cylinder is formed into a feed water tank, into which the cylinder cocks discharge all condensed water, and into which a portion of the exhaust is so directed as to heat the feed water to nearly boiling point before going into the boiler.

The whole of the parts of both engine and boiler being included on one foundation or base-plate, heavy and expensive foundations are dispensed with—the weight of the boiler and its contained water acting as an extra weight to assist in keeping the whole machinery in rigid position.

The 16 "Jablochkoff" lights recently employed for lighting the Billingsgate Market were produced by a dynamo-machine, driven by one of Messrs.



Robey's *so nominal* horse-power engines; the boiler pressure being 60 to 80 lbs., the point of cut-off one-half, and the *indicated* horse-power 23.

It will be noticed that in this case, the indicated horse-power was but very little in excess of the nominal horse-power. The form of engine is capable, if necessary, of working up to 60 indicated horse-power.

General Science.

ENGINES FOR WORKING ELECTRIC LIGHT MACHINES.

Engines of Messrs. Ransomes, Sims, and Head.

Messrs. Ransomes, Sims, and Head, of Ipswich, have devoted a great deal of attention to the subject of motive power for electric-machines of various kinds.

Their engines have already for some years been used for electric light for lighthouses in Russia, New Zealand, and also for other purposes. At the Exhibition of Scientific Apparatus, held at South Kensington, in 1876, Messrs. Ransomes supplied one of their engines for driving the electric-machines shown in operation, and it gave the most universal satisfaction, on account of the perfect regularity of its motion.

It is well known that, in all cases, the greatest regularity in speed is required in the motive power for all electric-machines, and for this purpose Messrs. Ransomes recommend their Patent Automatic Governor Expansion Gear, which will regulate the movement of the engine to such a nicety, that the revolutions will remain without any perceptible fluctuation, even when the entire load is suddenly put on or thrown off. As it has also been found better in all cases to employ a small separate steam engine for the electric light, rather than to drive the machinery from the main engine or running shafting of the factory, Messrs. Ransomes have been induced to pay great attention to the adaptation of their portable engines for electric purposes.

The engraving (fig. 1) represents one of Messrs. Ransomes, Sims, and Head's portable engines, which has been recently designed, and is specially

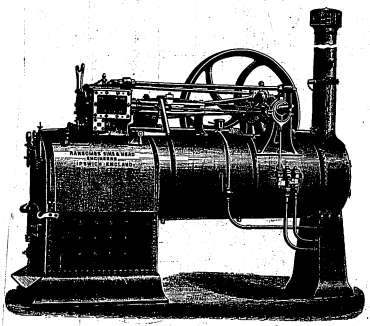


Fig. 1.

arranged for driving a dynamo-machine. The electric-machine is carried on a bracket extended beyond the smoke-box, so that the whole apparatus, motive power, and electric-machine is self-contained, and being mounted on the four wheels of the engine, it is readily transported from place to place. The

platform can be arranged, when required, to carry an exciter and distributor, so that, by fitting on a second fly-wheel, both machines may be driven at one time.

It will be noticed that in this arrangement the cylinder has to be placed next the funnel, and the crank-shaft over the fire-box; but Messrs. Ransomes have also supplied engines of their standard pattern, in which a bracket for the dynamo-machine is fixed on the side of the fire-box, or they can attach a bracket to each side of the fire-box, so as to drive two machines at the same time.

The 6 horse-power machine, which we illustrate, has a cylinder 8½ in. in diameter, with 12 in. stroke, and a speed of 150 revolutions a minute. With a steam pressure of 60 lbs. per square inch, cut off at about half-stroke, this engine will develope about 30 indicated horse-power, and the coal consumed under ordinary circumstances would not be more than about 3 lbs. per indicated horse-power per hour, according to quality of coal.

For the experiments now being carried on by the Metropolitan Board of Works in lighting the Thames Embankment by electricity, Messrs. Ransomes have supplied a 30 horse-power portable steam engine, which is fitted with the patent automatic governor, and has been much approved, and the excellent working and regularity of motion in this engine has contributed greatly to the success which has thus far attended the experiments in question.

This engine has two cylinders each of 10 in. diameter, with 12 in. stroke, and makes 140 revolutions a minute. It is mounted on cast-iron pedestals or saddles, instead of wheels, which gives great steadiness.

The engraving (fig. 2) shows one of Messrs. Ransomes' simple cylinder engines on pedestals, and fitted also with the patent, automatic, governor expansion. These engines are made from 4 to 20 horse-power, and they may all be had either on wheels or on pedestals.

The engraving, fig. 3, shows Messrs. Ransomes' Traction Engine (as used for agricultural purposes) arranged for driving an electric light for railway purposes. The ordinary wheels have been replaced by flanged wheels to suit the rails and the engine, which is of very light but strong construction, and can be run from place to place at speeds of 12 or 3 miles an hour. This arrangement of railway engine and light will be found most useful for lighting up works at night on the permanent way, or for repairs, or inspection of tunnels. The dynamo-machine is fitted to the front part of the boiler between the cylinder and furnace, and is driven by strap from the fly-wheel. The light which may be of any system preferred, is intended to be placed in front of the smoke box at a height most convenient.

When the engine is travelling on the line the dynamo-machine is driven by the strap from the fly-wheel as before mentioned, and the light is diffused along the road. When, however, it is necessary to stop in order to direct the light to some particular spot, the driving wheels are readily thrown out of gear, so that the engine ceases to be locomotive, the power being employed only for driving the dynamo-machine.

During the day the engine can be used for driving saws or pumping, or any other description of work.

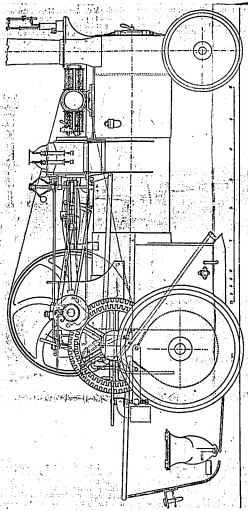

FIG. 2.

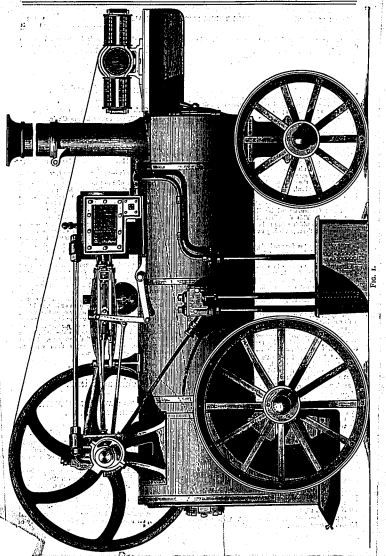

FIG. 3.

SCHUCKERT'S DYNAMO-ELECTRIC MACHINE.

THE improvement, introduced by Mr. S. Schuckert, consists in the construction of dynamo-electric machines with the most advantageous arrangement for utilizing the induction wire or conductor on the revolving iron armature so as to reduce the warming of it to a minimum.

For this purpose the armature is ring-shaped, and composed of several short-iron discs. Both side faces as well as the outside are brought under the influence of the magnetic poles, and these poles are arranged with the highest intensity of magnetism directly opposite the side faces of the ring.

The flat ring is made up of a number of short-iron discs, which are magnetically insulated from each other, which serve to reduce eddy-currents in these discs when the ring is in working; because in these single short-iron rings of small volume, the pole changing goes on with little resistance, and the electrical interpolation is easily destroyed. The warming

TEMPERING THE ELECTRIC LIGHT.—It has occurred to J. Pumphrey that, as clouds temper the brightness of the sun, so an imitation of clouds, by wadding and strips of glass fibre, would temper the electric light; and by using screens of glass wadding instead of opaline or clouded shades he reduces the loss of light from 50 to 25 per cent.

We have received Mr. Killingworth Hedges' pamphlet entitled "Useful Information on Practical Electric Lighting" (E. and F. Spon, publishers). It is designed as a guide to the unscientific public, who wish to make use of the new illuminator, and in the best of its kind we have seen.

MR. EDISON has exhibited the working of his incandescent light in the basement of his laboratory and factory with excellent results, furnishing 14 of the new lamps, each with 16 to 20 candle power, on one circuit, giving a steady white light, much superior to the carbon, and equivalent to the number of gas jets. The generator was a Gramme machine of 24-horse power. Mr. Edison states that he can now supply light for practical domestic use at less than half the cost of gas, but is experimenting for further improvements in the lamp and economy in the generator. —*Daily News*, March 28.

THE Metropolitan Board of Works have decided to continue the Jablochkoff lights for three months longer on the Thames Embankment, at a reduced cost.

JABLOCHKOFF'S candle was tried on March 19, in the theatre of the Royal United Service Institution, as a means of illumination for facilitating surgical operations and examinations in dull weather or after dark. Mr. Balmanno Squire, Senior Surgeon to the British Hospital for Diseases of the Skin, exhibited a remarkably small, light, and portable hand-lantern, which, he says, may be projecting from the back of a bibliokeeper, and be served also as a handle for the lantern) a fitted to the tube the burning end of the electric candle could be advanced forward into the lantern as the candle gradually burnt back. This, with two connecting screws for attachment. The electric wires, formed the whole blue glass placed at the side of the lantern formed the means of ascertaining from time to time the exact position of the burning end of the electric candle. He

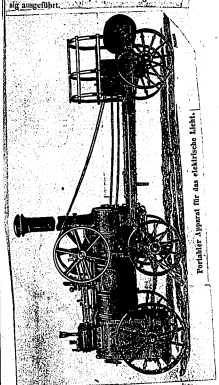
Portbarer Apparat für das elektrische Licht.

Unbestreitbar wird Interesse mehr für die praktische Einführung und Verwendung des elektrischen Lichtes gethan als — im praktischen Amerika... Wien, Paris und London sind hierin New York weit, weit voraus. Namentlich in England trachtet man nach einer praktischen Anwendung desselben nach jeder Richtung hin. Davon gibt uns wieder die hier abgebildete portable Dampfmaschine einen Beweis, welche von Messrs. Marshall, Sons & Co. zu Gainsborough im Auftrage der Ingenieure für Elektricität, Messrs. Crompton & Fawkes, hergestellt worden ist, um — sie Contractoren oder Anderen auszuleihen, welche des temporären Gebrauches kräftigen elektrischen Lichtes bedürftig sind.

Das Arrangement besteht aus einer portablen Dampfmaschine von 6 Pfkr. mit zwei Triebrädern mit eigens schweren Kränzen und ist mit dem wohlbekannten Hartnell'schen automatischen Expansionsventil-Geschirre versehen, welches vom Regulator controllirt wird. Dieses Geschirr gibt nämlich eine merkwürdige Gleichförmigkeit der Schnelligkeit unter verschiedenen wechselnden Lasten und ist insbesondere deshalb sehr geeignet für den irgend welcher Neigung, zu pulsiren oder zu trudeln, eine Neigung, welche gewöhnlich allen Regulatoren eigen ist, welche auf das Dreschwerk wirken, die aber in jeder Beziehung zweckmässig ausgeführt.

Der vorbeschriebene Apparat ist an einen Contractor eingeliefert worden, der die neuen Bauten der „Stanton Iron Works" zu Nottingham herzustellen hat. Acht Arbeiter vermochten, ohne einander im Wege zu stehen, bei'm Lichte dieser bedeutenden Lampen begonnen zu arbeiten und so schnell zu mauern, als am Tage; Am Tage wird die Dampfmaschine behütet, um eine Mörtelmühle zu treiben, und Contractor und Bauherren waren wohl damit zufrieden und wussten besonders die wirksame Eigenschaft des damit erhaltenen Lichtes zu schätzen, das obendrein durch die Nebenvergünstigkeit der Dampfmaschine sich als billig herausstellte.

Wie aus der Abbildung zu ersehen ist, nimmt sich das ganze Arrangement der einzelnen Theile an diesem Apparate für elektrisches Licht gefällig aus und ist es auch in jeder Beziehung zweckmässig ausgeführt.



Portabler Apparat für das elektrische Licht.

Das Ausleihen, Herrichten, Verbinden mit den Lampen, um die erforderliche volle Beleuchtung zu geben, erfordert nur eine Stunde.

Die hier verwendeten Lampen sind Modificationen des Serrin'schen Regulators und sollen die Vorzüge dieses Systems sämmtlich eine Form in sich schliessen, welche in den Stand setzt, die Theile derselben vermittelst gewöhnlicher Maschinenwerkzeuge zu verdoppeln, auf welche Weise die ersten Herstellungskosten um die Hälfte verringert werden.

Der Telegraph

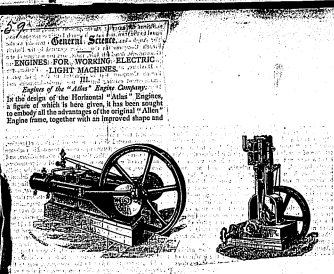
4076. ELECTRIC APPARATUS FOR GENERATING AND MEASURING ELECTRIC CURRENTS, &c. F. Jacques.—Dated November 24, 82.

In one type of machine the poles each of the inducer system are composed of a horseshoe core of iron of the magnetic field magnet system, or horseshoe core of iron of the magnetic field magnet system, being [illegible] and the [illegible] of the same [illegible] of the same [illegible] of the same

GENERAL SCHEME OF ENGINES FOR WORKING ELECTRIC LIGHT MACHINES.

Engines of the "Atlas" Engine Company.

In the design of the Horizontal "Atlas" Engines, a figure of which is here given, it has been sought to embody all the advantages of the original "Atlas" Engine frame, together with an improved shape and



finish in the details. Thus, while the guide bars, front cylinder, cover and main carriage are cast in one with the bed, the bed is carried out with a square shape so as to facilitate foundations and ensure a more even distribution of the bearing surface and of the holding-down bolts. The square bars have been retained, as the crosshead is of improved design, with slippers adjustable by means of a wedge and screw so that it can be slipped on in any position. With the exception of the guides and the outline of the slide-valve spindle, which the feed-pump plunger provides the former with the short form of radius on the right hand, and has also the advantage of throwing only a "sensional" strain on the eccentric rod.

In the "Atlas" Vertical Engines the vertical tubular frame merges into a square hollow base in which are cast two carriage or slide-valve crank shaft. The guides are cylindrical, form part of the frame, and are cast with set bosses opening outside the frame. Both horizontal and vertical engines are made to gauges, so that any part can be easily replaced at any time.

The "Atlas" Engine Company have been trying several kinds of governors, with a view to fixing out the best, and hope to introduce shortly a very superior one.

When combined with vertical boilers the "Atlas" engines are fixed on a hollow foundation plate, forming a tank, in which the feed water is admitted and is warmed by the heat of the under part of the furnace.

We may mention that "Atlas" Engines were selected to drive the Dynamo-Electric Machine at Aston, near Birmingham.

The current from a dynamo-electric machine of Mr. Field was recently applied to telegraphy in the working of fifteen large circuits.

DYNAMO-ELECTRIC MACHINES.

By Profs. Edwin J. Houston and Elihu Thomson.*

During the recent competitive trials made at the Franklin Institute as to the relative efficiency of some different forms of dynamo-electric machines, the authors, having been intrusted with the work of determining the relations between the mechanical power consumed and the electric and thermic effects produced, took the opportunity thus afforded to make a careful study of many interesting circumstances which influence the efficiency of those machines.

It is purposed in the present paper to select from the many circumstances thus noticed a few of the more interesting, reserving the others for future consideration.

It will readily be understood that, from the comparatively new field to which we have been working, no reliable data of the electrical work of those machines having before been obtained, difficulties constantly arose, not only from the conditions of operation, and new developments, as to the behavior of the machines under varied conditions, were constantly met.

As a certain arrangement of the particular circumstances we are about to discuss may be, 1st, those affecting the internal work of the machine; 2d, those affecting the external work; and 3d, the relations between the internal and external work.

The mechanical energy employed to give motion to a dynamo-electric machine is expended in two ways, viz., 1st, in overcoming friction and the resistance of the air; and 2d, in imparting motion to the armature of the machine. The magnetic field, the latter, of course, constituting solely the energy available for producing electrical current. The greatest amount of power expended in the first way was noticed to be about 17 per cent. of the total power employed. That expenditure was clearly traceable to the high speed required by the machine. The speed, therefore, required to properly operate a machine is an important factor in ascertaining its efficiency.

The above percentage of loss may vix appear great, but when it is compared with the useful work done in the machine, as here, consuming as it did in this particular instance over 80 per cent. of the latter, and about 38 per cent. of the total work of the circuit, its influence is not to be disregarded. In another instance the work consumed as friction was equal to about 80 per cent. of that appearing in the arc as useful work in the former machine experimented with this percentage fell to 20 per cent. of that which appeared in the arcs as heat, and was only about 7 per cent. of the total power consumed in driving the machine.

In regard to the second way in which mechanical energy is consumed, viz., in overcoming the resistance necessary to drive an armature through the magnetic field, or, in other words, to produce electrical current, it must not be supposed that all of the energy thus spent is lost in the circuit of the machine, since a considerable portion is expended in producing what we term the local work of the machine, that is, heat developed in the conductors of the machine, that is, local wire, exposing the machine.

The following instances of the relation between the actual work of the circuit, and that expended in local action, will show how that latter is to be considered. In one instance an amount of power somewhat more than double the total external work of the circuit was thus expended. In this instance also it constituted more than five times the amount of power utilized in the arc for the production of light. In another instance it constituted less than one-half the total work of the circuit, and somewhat more than one-half the work in the arc.

Of course, the work expended in local action is simply thrown away, since it adds only to the heating of the machine. And since that adds to the internal electrical resistance, it is doubly injurious.

The local action of dynamo-electric machines is analogous to the local action of a battery, and is equally injurious in its effects upon the available current.

Again, in regard to the internal work of a machine, since all life is eventually reduced to heat in the machine, the temperature during running must continually rise, until the loss by radiation and convection into the surrounding air equal the production, and thus the machine will acquire a constant temperature. This temperature, however, will differ for different machines according to their construction and to the power expended in producing the internal work, being, of course, higher when the power expended in producing the internal work is proportionally high.

If, therefore, a machine during running acquires a high temperature when a proper external resistance is employed, its efficiency will be low. But it should not be supposed that because a machine heats when run without external resistance, that is, on short circuit, it must equally inefficiency be shown thereby. On the contrary, should a machine thus easily consumption, and when a proper external resistance is employed, and keep greatly within it, on short circuit, these conditions should be regarded as a proof of its efficiency.

As a rule the internal resistance of dynamo-electric machines is so low, that to replace them by a battery, the latter, to possess an equal internal resistance, would have to be made of very large dimensions, so that the efficiency of dynamo-electric machines cannot be stated in terms of battery cells as ordinarily constructed.

In regard to the second division, viz., the external work of the machine, this may be applied in the production of light, heat, electrolysis, magnetism, etc.

Where it is desired to produce light, the external resistance is generally that of an arc formed between two carbon electrodes; the resistance of the arc is, therefore, an important factor in determining the efficiency. To realize the greatest economy, the resistance of the arc should be low, but, nevertheless, should constitute the greater part of the entire circuit resistance.

In some of our measurements the resistance of the arc was surprisingly low, being in one instance .34 ohm, and in another .29 ohm. It was, however, in some instances, as high as 2·18 ohms.

It may be noted as an interesting fact that, where the greatest current was flowing, the resistance of the arc thereby produced was low. This is undoubtedly due to higher temperature and increased vaporization from it. In some of the latter case also the greatest amount of light was obtained.

The amount of work appearing in the arc, as reason, by the number of foot pounds equivalent thereto, is necessarily an index of the lighting power. In two instances of measurement the amount of energy thus appearing in the arc was equal, while the lighting powers were proportionately as three to four. This apparent anomaly is explained by considering the resistance of the arc, it being much less in the case in which the greater light was produced. The heat in this case being evolved in less space, the temperature of the carbons, and, therefore, their light-giving powers, was considerably increased.

A few remarks on the economical production of light from electrical current may not be out of place. The light emitted by an incandescent solid will increase as its temperature is increased. In the voltaic arc the limit to increase of temperature is in the rapid vaporization of the carbons. Before this point is reached, however, the temperature is such that the light emitted is exceedingly intense. No reliable method of measuring the temperature of the arc has as yet been found.

A well known method of obtaining light from electrical currents is by constructing a resistance of some material, such as platinum, having a high fusing point, and heated to incandescence by the passage of a current. The platinum is employed, the limit to its increase of temperature is the fusing point of the platinum, which is unquestionably but a fraction of the temperature required to vaporize carbon. Were the fusing off in the amount of light emitted merely proportional to the decrease in temperature, the method last described might be economical. Unfortunately, however, the method, many facts show that the decrease in the light emitted is much greater than the decrease in the temperature. Heat sufficient to produce 1,000 °C. without practically emitting light. At 2,000° C. the light emitted is such that the body is said to be a bright red. At 4,000° C. the amount of light will have increased more than twice, probably as much as four times, that emitted at 2,000° C. It is reasonable to suppose that, with a further increase of temperature, the same ratio of increase will be observed, the proportionate increase in luminous intensity for exceeding the increase in temperature.

It would, therefore, appear that the employment of a resistance of platinum or other similar substance, whose temperature of alteration of state as compared with carbon is low, must be far less economical than the employment of the arc itself, which, as now produced, has been estimated as about two or three times less expensive than gas.

Indeed, it would seem that future improvements in obtaining light from electrical currents will rather be by the use of a sufficient resistance in the most limited space incandescent, thereby obtaining in such space the highest possible temperature.

Perhaps the highest estimate that can be given of the efficiency of dynamo-electric machines, as ordinarily used, is not over 50 per cent.; our measurements have not given more than 38 per cent. Future improvements may increase this proportion. Since the efficiency of an ordinary steam engine and boiler in utilizing the heat of the fuel is probably overestimated at 10 per cent., the apparent maximum percentage of heat that could be recovered from the current developed in a dynamo-electric machine would be overestimated at 10 per cent. The economical heating of buildings by means of electricity may, therefore, be regarded as decidedly improbable.

Attention has long ago been directed to the use of dynamo-electric machines for the conveyance of power. Their employment for this purpose would, indeed, seem to be quite promising. Since in this case one machine is employed to produce electrical currents, to be reconverted into mechanical force by another machine, the question of economy rests in the perfection of the machines and in their relative results.

In respect to the relations that should exist between the external and internal work of dynamo-electric machines, it will be found that the greatest efficiency will, of course, exist where the external work is somewhat greater than the internal work, and this will be proportionately greater as the external resistance is greater. Our measurements gave in one instance the relation of 82 ohm of arc to 32 ohm of the machine, a condition which indicates economy in working. The other extreme was found in one instance where the resistance of the arc was 1·93 ohm, while that of the machine was 4·00 ohms, a condition indicating wastefulness of power.

---

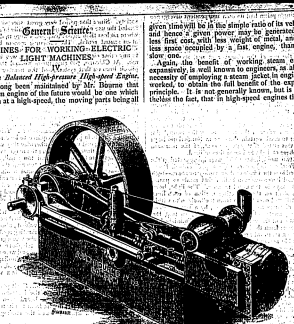
ENGINES FOR WORKING ELECTRIC LIGHT MACHINES.

IV.

Bourne's Balanced High-pressure High-speed Engine.

It has long been maintained by Mr. Bourne that the steam engine of the future would be one which is driven at a high-speed, the moving parts being all



designed so that no unbalanced momentum may cause a tremor.

The benefits which this high-speed system possess are numerous; not only is the noise and complication of gearing avoided, but, as an engine with any given pressure of steam will generate a given amount of power at each stroke, whether the strokes per minute be many or few, it is clear that the amount of power generated by a given engine in a given time will be in the simple ratio of its velocity; and hence a given power may be generated with less first cost, with less weight of metal, and with less space occupied by a fast engine, than by a slow one.

Again, the benefit of working steam engines expansively is well known to engineers, as also the necessity of employing a steam jacket in engines so worked, to obtain the full benefits of the expansive principle. It is not generally known, but is nevertheless the fact, that in high-speed engines there is a further benefit arising from the inability of the cylinder to become sensibly heated and cooled at each stroke, from the shortness of the time given for that process, and in such engines the cylinder approaches to the condition of a non-conductor, which is known to be favourable to the economical generation of power. Then, in the case of all high-pressure engines, it is easy to see that a considerable pressure must be more beneficial than a lower

pressure. To raise a given quantity of water into steam takes just the same quantity of heat, whether the evaporation is effected at the pressure of the atmosphere or at six or eight times that pressure. But at the low pressure the steam will not generate any power, whereas at the high pressure it will generate much power. A very high pressure of steam, however, is inconvenient, as it involves a correspondingly strong and heavy boiler, an extra strong and heavy engine, and separate expansion gear, which is not compensated by the small amount of increased economy obtained from excessive pressure. A pressure of about eight atmospheres is found to be, on the whole, the most eligible that can be adopted.

The figure shows one of Mr. Bourne's high-speed engines, employed in generating the electricity for the electric light at the Polytechnic Institution, in Regent Street.

The proportions of these engines for all powers is as follows:—

Extreme length of engine, about 3 times the length of stroke.

Extreme breadth of engine, about 3 times diameter of cylinder.

Breadth of fly-wheel for strap, about 14 times diameter of cylinder.

Diameter of vertical boiler, about 8 times diameter of cylinder for small, and 6 times for larger powers.

Height of boiler, about 22 times its diameter.

Working pressure in boiler, 120 lbs., tested to 240 lbs.

Water required for feed, about 4 cubic ft. per *indicated* horse-power per hour.

Coal consumed, about 3½ lbs. per *indicated* horse-power per hour.

In addition to the engines, which have been already described, those manufactured by several other firms are worthy of notice, as being especially adapted for driving electric-light machines, amongst others, the engines of Messrs. Marshall, Sons, & Co., of Gainsborough, and also Messrs. Tangye, of Birmingham. Messrs. Marshall's engines are fitted with patent automatic expansion gear, which insures the greatest regularity in the working.

ENGINES FOR WORKING ELECTRIC LIGHT MACHINES.

IV.

The Otto Silent Gas Engine.

The first practical gas engine was, it is believed, introduced by M. Lenoir, of Paris, now nearly twenty years ago. In this engine the ignition of the explosive mixture of gas and air in the cylinder was effected by the passage of an electric spark, obtained from an induction coil worked by a battery. This arrangement, although effective, had many manifest inconveniences, and M. Hugon and others improved upon the idea by effecting the ignition by means of a small gas flame placed opposite a slight aperture in the cylinder, which was opened and closed by a valve. This device has been adopted in all the engines subsequently invented, and answers the purpose most effectually.

The progress of the electric light has given an impetus to the manufacture of gas engines, and at the present time a large number are employed for the purpose of driving dynamo-electric machines.

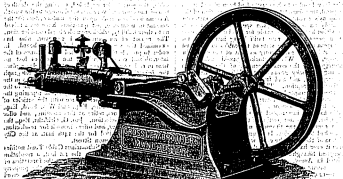
The general appearance of the Otto and Lenoir gas engine, as manufactured by Messrs. Crossley Brothers of Manchester, is shown by the cut on the following page.

The principle of combustion in these gas engines is entirely new. In them an explosion does not take place in the ordinary meaning of the term. A small part only of the charge is combustible, which on ignition serves to expand the remainder, thus avoiding shock and effecting great economy. The engines have also the peculiarity of igniting their charges at the *beginning* of the stroke, having *the whole* of the stroke for effective expansion of the gases, instead of merely a fraction as in obsolete constructions.

Every part of these engines is now made to gauge,

and is therefore easily replaced. The wearing portions are also of the simplest and most inexpensive patterns; for instance, the working barrel of the cylinder itself can be supplied for about 11 per cent. on the first cost of the engine, and being strictly gauged, can be put in with great facility in a few hours.

By this system the engine may be kept permanently almost equal to new for a certain annual expenditure.



The pistons are of great length—of which the peculiar construction of the engine readily admits, and being also as light as possible, ride on the oil with the least degree of wear.

The slides valves keep in excellent condition with proper care; but, as far as possible, to prevent risk of stoppage even from neglect, they are supplied in duplicate with each engine without extra charge.

These engines will run with extreme smoothness and regularity of speed, and have very few working parts. They possess the great and sometimes indispensable advantage, as compared with steam engines, of starting at full power at once on the gas being lit, and, starting on boiler, they avoid all the dangerous and pecuniary risks, annoyances, expensive repairs and attendance which a boiler frequently entails. The cost of a chimney, the nuisance of smoke, coal, ashes, and water must also be considered when a boiler is used. Where work is intermittent, trouble with a steam boiler and engine is at its maximum, but with a gas engine the reverse is the case.

The smallest engine capable of driving a Gramme "A" machine, is one 3½ H.-P. *nominal*, or 5½ H.-P. *indicated*. The 8 H.-P. *nominal* will *indicate* 14 H.-P. These will drive 3 Gramme "A" machines and 4 Siemens "A" machines. The gas consumed by these engines per *indicated* H.-P. is four 21 to 25 cubic feet, the engine running at 160 revolutions per minute.

LES NOUVELLES MACHINES
A LUMIÈRE DE M. SIEMENS

M. Siemens est, comme on le sait, le premier inventeur des machines dynamo-électriques sans organe excitateur spécial, et dès l'année 1867 il avait employé ces sortes de machines dans beaucoup d'applications électriques, notamment pour le tir des mines. Depuis les résultats avantageux obtenus par les appareils d'induction pour la lumière électrique, il a cherché lui aussi à combiner des machines dynamo-électriques capables de fournir [illegible]

[illegible] peuvent de la manière la plus heureuse. On connaît les expériences si curieuses faites en Angleterre, à South Foreland, sur la valeur réciproque des différents générateurs imaginés dans ce but, et on doit se rappeler que les machines de M. Siemens du petit modèle avaient été classées en première ligne. Nous devons toutefois faire observer qu'à cette époque les machines Gramme qui avaient été essayées étaient loin d'être aussi perfectionnées qu'elles le sont aujourd'hui. Toujours est-il que les machines Siemens passent encore comme excellentes et nous croyons devoir d'autant plus les étudier sérieusement qu'elles sont généralement peu connues en France.

Aujourd'hui, MM. Siemens ont établi à Paris, rue Picot, n° 8, un grand établissement de construction de ces machines, dirigé par M. Boistel, et que nous avons visité récemment avec un véritable intérêt. On y construit en ce moment un assez grand nombre de types différents, depuis les machines à génération de courants de grand et de petit modèle, jusqu'aux machines à division de lumière qui sont établies pour quatre, pour huit et pour seize foyers lumineux. Ces dernières machines n'emploient, m'a-t-on assuré, que trente chevaux de force, y compris la mise en marche de la machine génératrice. Ce serait une force motrice moindre que celle nécessaire par les machines Gramme à division. Mais des expériences comparatives devront évidemment être faites pour que l'on puisse être fixé à cet égard. En ce moment, nous ne voulons rien préjuger, mais seulement faire connaître ces dispositions nouvelles, qui sont vraiment très-intéressantes.

La machine génératrice de M. Siemens a été décrite dans notre ouvrage sur *l'Eclairage électrique* et, avec plus de détails, dans notre *Exposé des applications de l'électricité*, t. V; il y a cependant été apporté dernièrement, pour le petit modèle, certaines modifications que nous croyons devoir rappeler.

Dans cette machine, l'inducteur est constitué par deux électro-aimants à noyaux plats et larges, opposés l'un à l'autre par leurs pôles semblables, et réunis ensemble de manière à former un épanouissement assez étendu recouvrant en une sorte de demi-circonférence. Les parties creuses de ces demi-circonférences sont opposées l'une à l'autre, et c'est dans le cylindre ainsi constitué que se trouve placée la bobine induite. Cette bobine est constituée par un cylindre de cuivre recouvert de taffetas gommé, sur lequel sont enroulées, dans le sens de sa longueur, une série d'hélices disposées comme des multiplicateurs galvanométriques, lesquelles se trouvent réunies en tension et dont les fils de jonction aboutissent à un collecteur comme dans la machine Gramme. A l'intérieur de ce cylindre se trouve, mis une carcasse de fer immobile, soit une série de fils de fer disposés comme dans les machines d'induction électro-magnétiques et qui, tout en servant d'excitateur au système électro-magnétique de l'inducteur, contribuent eux-mêmes à l'induction comme dans les machines de Rukmkorff et autres. Deux poignes de cuivre, appuyant sur le collecteur servent la région neutre du système électro-magnétique, recueillent le courant et le distribuent au circuit.

Dans le grand modèle, l'inducteur est horizontal et la bobine induite est pourvue de la carcasse de fer dont nous avons parlé. Dans le petit modèle, au contraire, l'inducteur est placé verticalement et la bobine induite est remplie de fils de fer; c'est ce petit modèle, dont les dimensions ne dépassent pas celles de certaines machines d'induction de cabinets de physique, qui sert d'organe générateur pour mettre les machines à division et à inversion, et on est très-étonné qu'un organe excitateur aussi petit puisse déterminer des effets aussi considérables.

Les machines à division sont fondées toujours sur le principe du système Lontin, mais dans des conditions tout à fait différentes et en mettant à contribution des effets électriques entièrement nouveaux. Si nous prenons par exemple le modèle pour seize bougies, nous voyons que l'inducteur, au lieu d'être mobile comme dans les systèmes Lontin et Gramme, est constitué par deux couronnes verticales d'électro-aimants fixés parallèlement l'un devant l'autre et entre lesquelles tourne le système induit qui est composé d'autant de cadres galvanométriques qu'il y a d'électro-aimants dans chacune des deux couronnes. Les électro-aimants de l'inducteur, qui sont à deux branches, sont disposés les uns à la suite des autres, mais sans se toucher et de manière à présenter des intervalles égaux entre les noyaux magnétiques. Ils sont naturellement isolés du bâti de fonte qui les soutient au moyen de lames d'ébonite, et ils sont reconnus de manière qu'un pôle nord se trouve toujours entre deux pôles sud, et un pôle sud toujours entre deux pôles nord. Comme on le comprend facilement, les électro aimants, pris vis-à-vis sur l'autre bâti, sont de polarités contraires; par conséquent, un cadre galvanométrique qui viendra s'introduire entre deux noyaux consécutifs de ce double système inducteur se trouvera impressionné sur quatre points opposés; d'abord sur les deux faces du multiplicateur, et en second lieu sur les deux parties opposées du cadre galvanométrique.

Le système induit se compose d'une roue en bronze à l'extrémité de laquelle sont fixés les 16 multiplicateurs galvanométriques dont nous nous parlé; ces multiplicateurs sont contenus sur deux chevalets de bois fixés entre deux lames de cuivre percées de trous et ayant la forme de secteurs allongés. Chaque multiplicateur se compose de 23 rangées de spires, au nombre de 17 par rangée, et le fil a 18 dixièmes de millimètre de diamètre; il n'y a d'ailleurs aucun moyen de fer dans chacun d'eux, et ils ont exactement l'aspect d'un cadre galvanométrique; c'est par leurs joues que tous ces multiplicateurs sont fixés sur la roue de cuivre, et ils s'y adaptent avec une telle précision, que l'on croirait la roue munie de deux larges circonférences métalliques présentant sur ses bords extérieurs des découpures circulaires correspondant à chaque multiplicateur. Les trous dont sont pourvues ces joues métalliques ont été pratiqués pour permettre à l'air de refroidir les fils des multiplicateurs enfermés au dedans, précaution négligée en France, mais que l'on prend toujours dans les machines construites à l'étranger.

La partie centrale de la roue du système induit est occupée par une forte planche circulaire, sur laquelle sont fixés les fils de communication des bobines entre elles et avec le collecteur. La combinaison de ces fils est, du reste, très-simple : les multiplicateurs sont répartis comme dans la machine Gramme, en quatre séries, et les multiplicateurs de chaque série sont réunis entre eux en tension. L'un des bouts homologues de chacune de ces séries aboutit à un anneau métallique fixé sur l'axe de rotation de la roue, et les autres bouts aboutissent à quatre autres anneaux isolés les uns des autres et sur lesquels appuient des frotteurs en communication avec les lames d'attache des quatre circuits correspondant aux lampes électriques, lesquels circuits sont complétés par une communication avec un frotteur appuyant sur l'anneau commun à tous les multiplicateurs. Le courant de la machine excitatrice qui est placée à côté correspond d'ailleurs aux 32 électro-aimants des deux couronnes de l'inducteur, lesquels sont tous réunis en tension et sont composés chacun de cinq rangées de spires ayant 32 spires en fil de 2 millimètres.

Ce qui est remarquable dans cette machine, c'est le peu d'échauffement qui est développé en elle. Les électro-aimants de l'inducteur n'ont guère plus de 30° de température, les multiplicateurs sont un peu plus échauffés, mais je n'ai pu me rendre compte du leur degré de chaleur.

D'après M. Boistel, la force motrice employée pour faire fonctionner le système à seize foyers serait de 13 chevaux; la vitesse de rotation de la machine à division est de 590 tours par minute, et celle de la machine excitatrice est de 1373 tours. Dans le modèle destiné à alimenter huit foyers, la force employée est de 7 chevaux, la vitesse de rotation de la machine à division est de 550 tours, et celle de la machine excitatrice de 1373 tours. Dans le modèle pour quatre foyers, la force employée est de 4 chevaux, la vitesse de rotation de la machine à division est de 660 tours, et celle de la machine excitatrice de 1100 tours.

Avec de légères modifications, M. Boistel pense que l'on pourrait disposer la machine à quatre foyers pour 6 et la machine à huit foyers pour 12.

Le principe des machines de MM. Siemens repose uniquement sur les réactions d'induction produites par le passage des spires des multiplicateurs devant un inducteur électro-magnétique et sans l'influence d'un mouvement tangentiel : ce n'est pas exactement l'effet produit dans l'expérience classique de Faraday, et lesdits deux courants engendrés entièrement différent de ce qu'il devrait être, d'après les idées que l'on se fait généralement de l'induction. J'ai étudié longuement ces différentes sortes d'inductions dans un Mémoire présenté à l'Académie le 23 février 1879, et ce mémoire est, du reste, résumé dans une des Notes qui terminent notre volume sur l'Eclairage électrique.

TH. DU MONCEL.

APPAREIL DE LUMIÈRE ÉLECTRIQUE

DE M. JAMIN.

On appelle fort justement *lampes électriques* les appareils pourvus d'un mécanisme automatique, plus ou moins simple, destiné à maintenir à bonne distance les deux charbons entre lesquels jaillit un arc voltaïque, malgré l'usure inégale de ces charbons et les variations du courant.

On appelle *bougies électriques* les appareils dans lesquels, par des artifices convenables, on fait jaillir l'arc voltaïque entre les pointes de deux charbons placés côte à côte, sans mécanisme aucun. Le premier appareil de ce genre est dû à notre ami, M. Jablochkoff; nous avons eu occasion de le présenter aux lecteurs de *la Nature* en 1877 et d'y revenir en 1878 pour constater l'immense succès qu'il a obtenu, succès parisien d'abord, puis européen et universel.

M. Wilde, de Manchester, a proposé une seconde bougie électrique, appareil qui avait été essayé à Paris, à l'insu du physicien anglais, par M. Nysten, neveu et collaborateur de M. Gramme.

M. Wilde place les deux charbons parallèlement, mais l'un des deux est mobile autour d'un axe, de telle sorte qu'en repos ils se rapprochent et se touchent par leurs extrémités; au moment où le courant est lancé dans l'appareil, il passe par le point de contact, un électro-aimant est actionné qui écarte le charbon mobile et l'amène au parallélisme exact avec l'autre, l'arc voltaïque apparaît et se maintient.

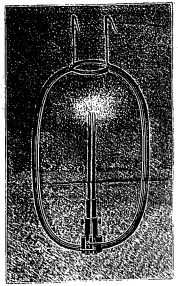
L'arc persiste entre les deux extrémités des charbons dans des conditions et avec des irrégularités que nous indiquerons tout à l'heure.

M. Jamin vient de réaliser un appareil, représenté par la figure ci-jointe, qui résout d'une façon singulièrement élégante le même problème.

Les deux charbons, plantés parallèlement dans le chandelier, sont entourés d'un fil dans lequel le courant même qui fournira la lumière, circule et circule parallèlement. L'appareil étant ainsi établi, touchons les deux charbons au milieu de leur longueur avec un troisième charbon, qui sert ici d'*allumette* ou, si on veut parler moins familièrement, d'amorce au courant en lui offrant un passage.

On écarte l'allumette et l'arc voltaïque apparaît, mais loin de rester où on l'a produit, il se transporte avec une extrême rapidité jusqu'au bout des charbons où il reste.

Toute l'idée de M. Jamin est dans ce transport, déterminé par l'action directrice de courants qui enveloppent l'appareil. Il faut donc nous y arrêter un instant.



Appareil de lumière électrique de M. Jamin.

Le courant, avons-nous dit, circule parallèlement dans les charbons et dans les fils enveloppants; cela veut dire que si le courant monte par le charbon de droite et descend par celui de gauche, il monte également par les fils de droite et redescend par ceux de gauche.

Il résulte de là que l'arc voltaïque, qui est comme un élément mobile du courant, se transporte dans le sens indiqué par les lois d'Ampère.

Il est à la fois attiré vers le haut par la partie du courant qui passe au-dessus et qui agit en vertu de l'attraction des courants parallèles et, de même sens, — repoussé vers le haut par la partie du courant qui passe au-dessous et qui agit en vertu de la répulsion de courants parallèles et de sens contraire — poussé vers le haut par la tendance du courant de droite à faire tourner le courant mobile dans le sens qui l'amène au parallélisme, — poussé également vers le haut par la tendance du courant de gauche à faire tourner le courant mobile dans le sens qui l'amène au parallélisme.

Les quatre actions sont concomitantes, exactement comme dans un galvanomètre, les quatre parties du fil (deux verticales et deux horizontales) concourent à faire dévier l'aiguille.

L'énergie de cette action peut être variée à volonté; il suffit, en effet, de multiplier le nombre des spires de fil qui entourent l'appareil pour aug-

DEPREZ'S ELECTRO-MAGNETIC ENGINE.

BY THE COUNT DU MONCEL.

ACCORDING to Count du Moncel (writing in *Le Lumière Électrique*) M. Marcel Deprez has succeeded in solving the problem of making an electro-magnetic motor capable of doing useful work, and which can compete with the steam-engine in point whether the new motor can compete with even a water-motor as regards economy, to say nothing of gas and steam-engines; but, according to Du Moncel, Deprez's apparatus is barely 8m. long, by ten thin rods in breadth; it weighs about 60lb., and can supply a power of nearly 8 horse-power, or 8 times that of the best electromotors. This (says Du Moncel) is really an extraordinary result, and one which could scarcely have been anticipated a few years ago. Under these conditions saving machines may with perfect ease be worked by electricity without any exorbitant expenditure. This ingenious system consists of a horse-shoe electro-magnet, about 1m. in length, between the pulsed which is introduced a little more than one-third open by the magnet over a length of 0m. 25. Up to the present time no one has ever thought of causing magnets or electro-magnets to act otherwise than by their polar extremities; and all the engines devised hitherto have been arranged on this principle. M. Deprez, however, thinking that under these conditions the whole of the magnetism that can produce a magnet was not utilized, endeavoured to cause the whole of the sufficiently-magnetised portions of the magnet engine to act upon the mobile system to be influenced; that is to say, in the present case, the branches of the magnet nearly 0m. 25 in length. The electro-magnetic armature, instead of being placed transversely to the magnet, is arranged longitudinally and parallel to it. Under these conditions the attraction and repulsion exercised on this armature is found to be considerably augmented, as is perceptible from the difference of force necessary in producing rotation; and this increase of force may give an idea of the considerable advantage which the employment of motors, which work by the effect of attraction, presents over those which work by the effect of attraction, reversals of the current. Everybody knows that a horse-shoe magnet is a kind of galvanometer frame, of which one side constitutes the two poles of a straight electro-magnet, and the other, that core, broader than it is long, upon which the wire is wound. The axis of this electro-magnetic frame is the thread of wire in the magnetising helix, and, consequently, to the axes of the magnet. At one end of this axis is a pivot communicated, and at the other end is a projecting axis with a pinion which gears into a wheel of 60 teeth, communicating 60 times greater. When the apparatus is properly regulated, the armature makes 90 revolutions per second, and, consequently, the wheel which it moves makes three revolutions. It is upon the axis of this wheel that is fixed the friction transmitting the movement, and from the axis of which is caused inwards either a saving-contact or a motive-contact, by the intervention of a sort of rocking lever. In order to render the working of this apparatus perfect, M. Marcel Deprez has adopted to it an extremely ingenious regulator, the action of which is very effective, and the work of which is fixed by one of its extremities to one of the branches of the armature. By means of a screw this tension can be given to any given velocity of the engine is given to the spring. The transmission of the current from the collector to the wire of the armature is effected with great difficulty by this spring, as in the case of all frictional contacts; but, again, a certain velocity is greater than that which is required, a centrifugal force is brought into action which the moment the engine reaches a slackening of the speed, and then there is a reversal of the circuit, which up again before when the velocity again becomes too great. These alternations occur with such immense power is somewhat higher than a second. Thus, first a continuous spark is seen which is essential to the regulating spring is to continue apparent, while, in reality, it is not continued, but by means of great inertia. In fact, may be retarded by trying to stop the pulley, the direction of the current is not changed. With five Bunsen elements at which this engine can be effected only with great difficulty; there is, however, a peculiarly electro-magnetic a little upon the subject of motors, a stoppage by pressing the finger upon the pulley. Count du Moncel does not say what is the cost of five Bunsen elements, nor whom they are to be placed when employed in working a sewing-machine in a lady's boudoir.

Electro-magnetic Railway. — One of the novelties in the Berlin Exhibition is an electric railway for Lichterfelde and Halbke. The electrical power is supplied by a dynamo-electric machine worked by a steam-engine, to another dynamo-electric machine, which sets in the wheels of an electric locomotive. The train is to run at a way at 20 miles per hour, carrying three metres (or second; the same time that will be tried at the Scientific Exhibition at the Palais Bourbon, Paris. Deprez's motor, which is very promising. A new gramme, and with twelve Bunsen elements giving seven kilogrammetres power. This result of Marcel Deprez's exhibiting now at Lille, on the Exposition of 1878 (we hoped that it will have been exhibited at Paris). It is actual help of breaking and directing without any sacrifice of ballast and escape of gas.—*Nature*.

Le mois de mars 1879 est particulièrement intéressant à ce point de vue. Les 18 dépressions signalées sur toute l'étendue du continent, 11 sont venues de l'océan Pacifique et ont abordé la côte par l'Oregon et le Territoire de Washington ; le plupart ont marché sensiblement dans la direction de l'est, leurs centres se déplaçant le long du 45e parallèle. C'est sans doute à ce manière exceptionnel de heurtmques qu'il faut attribuer l'excès de température que tous les observateurs ont signalé ; cet excès semble croître avec la hauteur du lieu au-dessus du niveau de la mer ; c'est ainsi que le plus grand écart (+ 21,5) a été constaté au sommet du Pike's Peak, dans le Colorado. Pendant les premiers jours du mois, il est tombé dans le nord de la Californie des pluies considérables à la suite desquelles le Sacramento a rapidement grossi, détruisant les digues et submergeant les rivières. Par contre, les cultivateurs se plaignent de la sécheresse dans l'Utah, le Kansas et le Texas. La débâcle des glaces sur les rivières a permis à la navigation intérieure de reprendre son cours, interrompu pendant les mois d'hiver. Sur le Mississipi, le premier steamer de la saison passait à Saint-Louis de fer 1er mars, le Keokuk le 8, à Burlington le 16, à La Crosse le 23 ; à cette date la rivière était encore prise en amont de Saint-Paul, c'est-à-dire au nord du 45e degré de latitude. A la fin du mois, la navigation sur les Lacs n'était pas rétablie, mais la fonte des glaces s'effectuait activement.

TH. MOREAUX.

MACHINE MAGNÉTO-ÉLECTRIQUE

DE MÉRITENS[1].

A en juger par le nombre de langues électriques que cette machine peut allumer, on pourrait croire qu'elle constitue le générateur magnéto-électrique le plus puissant pour une force motrice donnée. Elle pourrait, en effet, avec une force motrice ne dépassant pas un cheval-vapeur, maintenir allumées indéfiniment trois bougies Jablochkoff, sans exiger de la part du moteur une vitesse de plus de 200 tours par minute et sans produire d'échauffement appréciables. Mais la lumière fournie par ces bougies ne semble pas être aussi forte que celle des bougies alimentées par les machines Gramme, et jusqu'à ce que des mesures précises soient données, on ne peut préjuger définitivement de la puissance relative de ce générateur. Cette machine est magnéto-électrique et fournit comme celle de l'Alliance des courants, renversés, mais elle ne demande pour produire le même effet, que huit aimants d'Arvarre au lieu de quarante-huit et seulement un quart de la force motrice, c'est au moins ce que dit M. de Méritens.

Les effets avantageux de ce genre de machine résultent de ce qu'aux courants d'induction déterminés dans l'anneau des machines Gramme, sont ajoutés ceux qui se produisent dans les machines magnéto-électriques ordinaires.

Pour qu'un puisse la comprendre, imaginons un anneau Gramme (fig. 1) divisé par exemple, en quatre sections, isolées soigneusement l'une du l'autre et constituant par conséquent quatre électro-aimants acquis, placés bout à bout. Imaginons que le noeud de fer de chacune de ces sections soit terminé à ses deux extrémités par une pièce de fer A B, formant comme un quatuor-cement de ses pôles, et supposons que toutes ces pièces réunies par l'intermédiaire d'une pièce de cuivre C b, constituent un aimant solide autour duquel sont disposés des aimants permanents N, S, N, Save leurs pôles alternés de l'un à l'autre. Examinons ce qui se passera quand cet anneau accomplira un mouvement de rotation sur lui-même, et voyons d'abord les effets qui résulteront, par exemple, du rapprochement du pole épanoui B, quand marchant de gauche à droite il s'approchera de X. A ce moment il se développera dans l'hélice électro-magnétique de A B un courant induit d'aimantation, comme dans une machine de Clarke. Ce courant sera instantané et de sens inverse aux courants particuliers d'Ampère de l'aimant inducteur, il sera très énergique en raison de la proximité de B du pôle X ; mais l'anneau en s'avançant va déterminer entre le pôle X et le noyau AB une série de déplacements magnétiques, qui donneront naissance à une série de courants d'intersection polaires, qui se manifesteront de B en A ces courants seront directs par rapport aux courants particuliers de X, mais ils ne sont pas instantanés et vont encroissant d'énergie de B en A. A ces courants se joindront simultanément les courants d'induction dynamique résultant du passage des spires de l'hélice devant le pôle X. Quand A abandonnera X, un courant de désaimantation se produira, égal en énergie et de même sens que le courant d'aimantation.

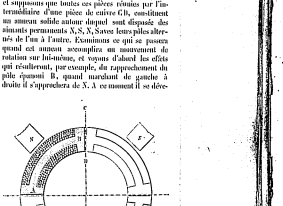


FIG. 1. — ANNEAU GRAMME.

[1] M. du Moncel vient de publier dans la *Bibliothèque des Merveilles* (librairie Hachette) un volume très complet et d'un *excellent* d'actualité particulier, sous le titre *l'Éclairage électrique*. Nous empruntons la description de cette machine, dont on a beaucoup parlé, à cet intéressant ouvrage.

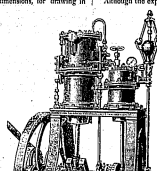
General Science.

ENGINES FOR WORKING ELECTRIC LIGHT MACHINES.

VI.

Simon and Sue's Gas Engine.

This engine has two cylinders, one for driving and the other, of smaller dimensions, for drawing in



the combustible mixture of gas and air, and for transmitting it into the driving cylinder. This gaseous mixture passes into the cylinder through a network of metal gauze, and is ignited on the driving cylinder side of it; the result of this arrangement is that the expansive union of the gaseous mixture, which drives the piston, takes place gradually, as the mixture is forced through the gauze, and on the principle of the safety lamp, the combustion cannot be communicated to the opposite side of the gauze, which would have the effect of causing the combustion before it is required.

The valves and governor, which regulate the admission of the gas and the exit of the products of the combustion, are very simple and effective.

Although the expansive effect of the combustion of the gas and air is a motive power employed in working the engine, it is not the only motive power, and to this point the engine differs materially from others. Each cylinder is water-jacketed, and between the cylinders and the jackets water flows continuously, the source being derived from a bucket or other small receptacle, whence it is pumped by the engine itself. These water-cavities are in communication with each other. Now the expansion and combustion of the gaseous mixture necessarily generates heat, and this is communicated to the water surrounding the cylinders, moreover, the spent gases are also very hot, and these being caused to pass through a vessel containing a network of tubes through which the water circulates adds additional heat to the water, so much so that the latter very soon begins to boil and generate steam; this steam is allowed to pass into the driving cylinder, and adds greatly to the motive power. When spent it passes out with the spent gases, adding what heat remains in it to the incoming steam, so that a uniform supply of the latter is maintained. The advantages of this type of engine are numerous. First, no water-vessel to cut the cylinder is required; indeed, the hotter the cylinder the better the engine works. However, the greater part of the heat is utilized in generating steam. Next the utilization of the steam overcomes another difficulty. The dryness of many explosions is destructive to cylinders, and soon destroys the lubrication which has consequently to be renewed. In Simon's engine no such difficulty occurs, as the steam preserves the lubricating qualities intact. Also the pressure of the expanded gas does not exceed 40 lbs., which puts but very little racking strain on the machinery.

There can be no doubt but that this engine, of which we give a general view, is a step in advance.

We learn that by a recent improvement, Messrs. Simon have obtained a gain of 20 per cent. in the power of their engine without any increase in the consumption of the gas used.

LIGHTING BY ELECTRICITY.—No. I.

During the past few weeks several events of a public nature have occurred which have had the effect of giving a fresh impulse to the interest taken in the question of lighting by electricity, a question which must before long occupy a far more important position that it does at the present time. The most noteworthy of these events, as indicating the advance which the subject has made in the way of official recognition, has been the appointment and session of the Select Committee of the House of Commons on Lighting by Electricity, which has been sitting twice a week for more than a month, and before whom independent scientific witnesses have been examined as well as others, who, although

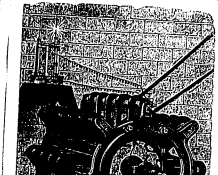


FIG. 1.

interested for or against one or another system of illumination, gave evidence none the less valuable for the purposes for which the committee was appointed.

While this committee was sitting at Westminster, not only was the electric illumination of the Victoria Embankment extended from Waterloo Bridge to Blackfriars, opening up an unbroken line of electric lights extending from Westminster to the Bank—a distance of more than a mile—but the very excellent report to which we have already referred in a previous issue* has been issued by the Metropolitan Board of Works, which shows that the finally good results the Jablochkoff system is not, by a long way, as costly as previous experience would seem to indicate.

Immediately after this followed the exhibition of electric lighting apparatus at the Royal Albert Hall; an exhibition which, from the splendid support accorded to it by the representatives of special systems, as well as by manufacturers of apparatus, proved to be one of the most complete and instructive illustrations of the present position of the science of electric lighting that had ever been brought before the public; and, owing in a like harmful way in which the exhibition was got up, and the still more harmful manner in which it was closed within three days of its being opened, a grand opportunity was thrown away and lost, and one, we fear, such as is not likely to present itself again.

Again, the lighting of the Albert Hall by the Siemens light during great musical performances, and the illuminations of the South Kensington Museum and Horticultural Gardens on occasions of conversazziones and fêtes, have each and all contributed to keeping alive public interest in the electric light, and have shown that, for such purposes, it has become a practical and recognised application of science to useful purposes. We do not think, therefore, that there could be a more fitting occasion than the present for running over in brief review the general question in a new strain, remodelling our renders as we go of the principle and construction of the various electric generators employed, of the characteristic features of the different systems for utilising the currents so produced, and of such necessary instruments and apparatus as are employed in the regulation, measurement, and general investigation of these currents.

Passing over the history of the subject from the

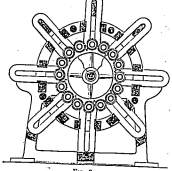

FIG. 2.

first discovery of the electric arc by Sir Humphry Davy in the year 1810, and the early magneto-electric machines which followed Faraday's brilliant discovery of magneto-electric induction, all of which have been described in these columns, and over and over again elsewhere, we will confine our attention to those generators of electricity which are actually used at the present time for the production of the electric light, and to those lamps and regulators which have stood the great battle of competition and experience, and which by their survival have proved themselves to have some claim to be reckoned among the fittest.

VOLTAIC BATTERIES.

Of voltaic batteries only two that are ever used for the production of the electric light are now in common use, and these are Grove's and Bunsen's carbon battery used to the exclusion of all others on the Continent. The zinc of the acids employed and of the size consumed in both these combinations render them both completely unfitted for the economical generation of electric currents of such strength as are required for the electric light, and batteries are only now employed for very special cases, such as lectures, public entertainments, and such occasions where it is inconvenient to employ the more cumbrous mechanical generators or where expense is no particular object, but even for such special purposes batteries are now giving way to dynamo-electric machines, which are very easily transported from place to place and installed even only for a few hours' use.

MAGNETO-ELECTRIC MACHINES.

The earliest forms of mechanical electric generators which have been used successfully for the production of the electric light were the magneto-electric machines of Professor Holmes, which for many years illuminated the lighthouse of Dungeness and the South Foreland, and the machines of the Société l'Alliance, of Paris, which have been in use at the lighthouse of Cape Grisnez, La Hève, and at several other Continental stations. These machines are identical in principle and very similar in construction, and it will be sufficient for our purpose to describe the latter arrangement which is shown in perspective in Fig. 1, and in cross section in Fig. 2. It consists of a framework of cast iron carrying four horseshoe steel magnets arranged radially and symmetrically around a central axis in right angles of five magnets each, their poles all being directed towards this axis. The four spaces between the magnets revolve upon a horizontal axis four bronze discs wheels, each carrying sixteen soft iron bobbins, each of which consists of a tube of soft iron wound with insulated copper wire, all being wound in the same direction. The magnets are so arranged around the machine that opposite poles meet each other both in each circular series as well as in each horizontal row, so that at each revolution of the machine, the core of each of the sixty-four bobbins has its magnetic polarity reversed sixteen times, and as it is impossible to reverse the polarity of a magnetised bar without reversing the direction of an electric current induced in a wire wound round it, it follows that at each revolution of the machine no less than 1024 electric impulses, alternating in direction, are transmitted into the external circuit of the machine.

Professor Holmes also designed a machine in which, like the early machine of Pixii, the inducing bobbins were fixed, and the magnets moved in front of them, but he constructed a machine of this type in which electro-magnets were substituted for the permanent magnets, part of the current produced being utilised to excite them. This was therefore a dynamo-electric machine, and in principle of working, and of distributing the coils, it bore some resemblance to the more recent machines of M. Lontin, to which we shall refer further on.

For many years the Holmes and Alliance machines divided the field between them, and for lighthouse illumination, where economy was not so great an object as power and efficiency, they served their purpose well, but they were of too costly form in prime cost and in expense of working to be in any way applicable to general purposes, and they were moreover subject to all the inconveniences and faults to which machines which have their commutators permanent magnets are liable.

The very important invention made by Dr. Werner Siemens in the year 1854 of the longitudinal induction bobbin, or Siemens armature, as it is called, and which has been described in these columns,† resulted in the production by Messrs. Siemens Brothers, of Berlin, of a magneto-electric machine possessing a very high degree of efficiency, although not specially applicable to the production of the electric light, was the first machine of any considerable size to which the invention by Mr. Wilde, of Manchester, of a very important principle of working as being the first brought before the public in which permanent magnets were employed instead of the more powerful electro-magnets, and still more interesting in connection with the history of the subject as furnishing an important and specially characteristic link between the early magneto and dynamo machines what are now called dynamo-electric machines, to which, with one exception, all the modern electric light-producing machines belong. Mr. Wilde's apparatus consisted of a large magneto-electric machine having powerful fixt electro-magnets in the place of the compound permanents usually employed, and these magnets were charged by the current generated by a subsidiary Siemens shuttle magneto machine, which for comparisons was mounted on the top of the larger machine, and was driven at a higher velocity by a separate belt. With this machine very powerful effects both calorific and illuminating were produced. This double machine has by some been classed among dynamo-electric machines, but it clearly has no claim to be so reckoned, for it occupies a distinct position of its own. It might be called an electromagneto magneto-electric machine whose electro-magnets are excited by the current from a magneto-electric machine instead of from a voltaic battery.

SMALL DYNAMO-ELECTRIC MACHINES.

[15462.]—So many queries appear in our columns asking for information about the above, that I think the following description of one I made may interest our readers. My machine was got a Gramme armature, of which the dimensions are as follow:—Iron ring width 2½, diameter inside 3½, outside 6.

The coil is in thirty divisions made of No. 18 cotton-covered copper wire, total diameter 9mm., outside diameter 12mm. The coil is embraced by the horns from the electro-magnets above and below; these last are made so as to shape these poles into the centre where the horns are fixed. The cores of field magnets are 35mm. diameter, having a length of 140mm. on each side of horns, and are wound with No. 16 wire. So far this appears to be all right, but although I am able to drive the armature at a speed of 1,200 revolutions per minute, still I am unable to get more than the smallest trace of current from it.

If, however, I connect three or four Bunsen cells to the terminals of my machine (turning it into an electro-motor), it will then get reverse rotation of the armature, which with five cells runs about 1,100 revolutions per minute. Further, if I connect the coils of field magnets to a battery, having them separate from the armature circuit, I can get a powerful current from the armature, when the horns showing that if my magnets were permanent, the machine would work all right. If any of our correspondents have been successful in making a machine of this class, I shall, for their rewards, as the above case will be interesting, theoretically a small machine ought to act upon the same principle as the large ones, and as I have had some trouble in studying them last I am sure my case, &c., are all correctly made.

As a small machine like this would be useful for experimental work, I trust some one will be able to help me.—Ohm.

[15193.]—Siemens' Armature.—Our present knowledge of magneto-electric induction is very limited indeed, as many of our readers, no doubt, have succeeded in producing a dynamo-machine that could be worked by hand. The success of these machines made requires at least 2½ h.-p. to drive. Hand magneto-machines have been made, but, however, they all do not come up to our expectations. To enjoy the action of your own instrument, one requires steel magnets of great strength.—Wimshurst.

THE New York correspondent of the *Daily News* telegraphs as follows:—"Mr. Edison has obtained a dynamometer of sufficient delicacy to measure every one-hundredth of horse-power. With this instrument he can calculate the cost of the electric light to the minutest detail. He has demonstrated that from 80 to 90 per cent. of energy is converted into light, and that six electric lights are supplied from one horse-power at one-third the cost of gas. He estimates that the problem of applying the electric light to domestic use has been practically solved, but admits that a great mass of detail remains to be worked out. He has satisfied himself that platinum can be supplied in large quantities so as to reduce the expense.

THE Society of Control Work [illegible]

RESEARCHES WITH PROFESSOR HUGHES' AUDIOMETER.

By BENJAMIN WARD RICHARDSON, M.D., LL.D., F.R.S.*

PROFESSOR HUGHES having done me the honour to show me first his newly invented instrument for the measurement of hearing, and having supplied me with an instrument for the purpose of testing the application of it for physiological and practical purposes, I have been enabled to make a considerable number of experiments, on which I venture to submit the following preliminary report:—

The instrument, as it has been used, is before the Society. It consists of two Leclanché's cells for the battery, a new and simple microphonic key connected with the cell and with two fixed primary coils, and a secondary or induction coil the terminals of which are attached to a telephone. The induction coil moves on a bar between the two fixed coils, and the bar is graduated into 200 parts, by which the readings of sound are taken. The graduated scale is divided into 20 centims., and each of these parts is subdivided into 10, so that the bearing may be tested from the maximum of 200 units to 0—zero. The fixed coil on the right hand contains 5 metres of wire; the fixed coil on the left hand contains 100 metres. By this means a long scale from the left hand coil is produced. The secondary coil contains 100 metres of wire.

In using the instrument, one Leclanché's cell has been found sufficient, as a general rule, but two have been used in instances where the hearing of the person under test has been very defective. The Leclanché cell was selected by Professor Hughes as affording a reliable current for the purpose he had in view, and for standard comparisons. In using the instrument, the induction coil is moved along the scale from or towards the larger primary, as may be required, and the degrees or units of sound are read from the figures on the scale, the

* Paper read before the Royal Society May 15.

will be in contact with the bare place on the lowest turn of wire on the bobbin, consequently the major portion of the current conveyed by the wires connected to the two terminals on the bobbin flows from the bare spot on the wire, up the lever, and thence through the electro-magnet back to the second terminal. The armature being consequently attracted, the curved lever is made to rock or roll on the bared surfaces of the wires, thus making contact with turns of the wire higher up the bobbin; but when this is so, the current entering the lower terminal has to traverse all the turns up to the turn with which the lever may be in contact, and the current is thus weakened. Hence it is easy to see that when the spring *s*, is adjusted to a certain tension, the current flowing will, by pulling the armature *c*, pull the lower lever on to such a turn of the wire on the bobbin as will introduce an amount of resistance sufficient to produce equilibrium, and if the current weakens or strengthens, the lever will move backwards or forwards until the resistance adjusted by the decreased or increased number of turns in the circuit again produces equilibrium.

To adapt the apparatus for alternating currents, the electro-magnet is replaced by a bar or wire, which expands by the heating effect of the currents.

For dynamo-machines, the apparatus is arranged to be worked by the machine itself. This is done by connecting the rocking lever to a Watts's governor. Under these conditions the apparatus regulates the velocity of the machine, and not the strength of the current.

It is hardly necessary to call attention to the utility of the invention, but the importance may be well understood when we consider that the apparatus bears the same relation to the regulation of the electric currents as the Watts's and other governors, or to the regulation of the flow of steam in steam engines.

PACCINOTTI'S DYNAMO-ELECTRIC MACHINE.

THE novelty in the magneto-electric machine invented by Dr. Antonio Paccinotti of Pisa, in 1860, which we illustrate below, is the peculiar shape of

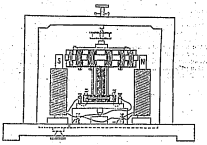

FIG. 1.

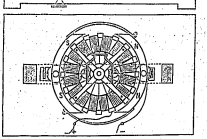

FIG. 2.

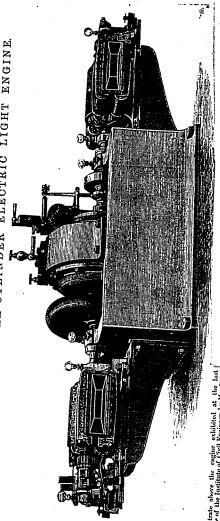
the rotating electro-magnet, which is an iron ring, whose induced poles during rotation move constantly from one point to the other without interruption. About this iron ring coils of isolated copper wire, *a*, fig. 1, were placed, which were connected with each other so as to form a continuous wire. From each connection a conducting wire was brought to metallic pieces *b* of the same number, laid parallel to, and insulated from, each other around the shaft carrying the ring.

The ring was arranged horizontally, and on each side of the diameter was placed one pole of a powerful electro-magnet ending in elongations of soft iron *s s*, fig. 2, inclosing about one-third of

BROTHERHOOD'S THREE-CYLINDER ELECTRIC LIGHT ENGINE.



We illustrate above the engine exhibited at the last conversazione of the Institute of Civil Engineers, which is described at length in another column. The shaft of the engine drives a dynamo-electric machine of the Siemens type, constructed for Messrs. Siemens Bros. cable-ship Faraday.

Vol. II.—No. 7. Manufacturer & Builder JULY, 1879. ELEVENTH YEAR.

Weston's Electric Light Generator.

Mr. Edward Weston, of Newark, N. J., who has earned a great reputation as the inventor and manufacturer of the dynamo-electric machine, now used in many electroplating and electrotyping establishments, both here and abroad, has for some time given his attention to the construction of a similar machine, especially adapted for the production of electric light, and of the lamps used in connection with the same. In the adjoined engravings Fig. 1 represents the machine, Fig. 2 the lamp exteriorly, Fig. 3 another form of lamp, showing details of carbon carriers and of electro-magnet and armature regulating their position, and holding the sliding rod with a clamp, which automatically releases and keeps the light steady. This is one of Mr. Weston's latest improvements to the electric lamp. Fig. 4 represents the iron armature of Fig. 1, without its coils.

The machine (Fig. 1) is constructed with a view of keeping it in continuous operation without heating it to such a degree as to necessitate its stoppage so as to allow it to cool off, a feature in which many machines of this kind have failed. For this purpose the large stationary soft iron electro-magnets are, where they are not covered by the coils, perforated by slits. Fig. 4 shows these slits in the center of the top and on the sides, and when in motion the hand can feel the currents of air pass out of these slits, being propelled from the rotating center to the circumference by the centrifugal tendency, on the same principle as the action of a rotary fan blower. This continuous current of air, taken in cool at the center, and blowing out at the circumference, is most effective in keeping the machine cool, which, without this provision, loses much of its effectiveness, as the magnetic power of iron decreases when the temperature rises, and the conductivity of the coils for electric currents diminishes from the same cause. Therefore, even if a machine does not become hot enough to necessitate its stoppage, it is of importance to keep its temperature at as low a degree as possible, so as to secure its maximum efficiences.

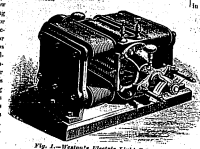


Fig. 1.—Weston's Electric Light Generator.

The power required to drive these machines is from two to twelve horses, and depends on their size, at which the price varies from $200 to $1,200, the larger ones being capable of furnishing several lights. They are commencing to be largely used for brilliant illumination purposes in New York and vicinity, for instance, on the new iron pier at Coney Island, which we have described in a previous number.

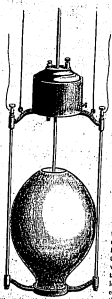

Fig. 3.—Weston's Electric Lamp.

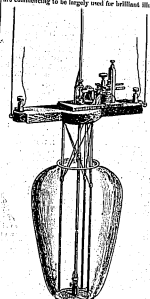

Fig. 2.—Details of Electric Lamp.

These machines excel in simplicity and compactness; they appear to be eminently durable, and are claimed to be the most powerful for their size and cost of any in the world, as it is reported that actual tests showed them to yield more than double the amount of light per horse-power absorbed, than that obtained from any other machine built in this country.

The ability of the company to execute satisfactorily any orders for electric light, can be inferred from the fact that they have now in successful operation nearly seven hundred dynamo-electric machines among the largest manufacturers in this country and in Europe.

Figs. 2 and 3 represent lamps with ground glass globes, seen below, and which contain the carbons, the lower one being fixed to the bottom and the upper one suspended from the conducting rod, which is capable of sliding downward, but this down-sliding motion is arrested and regulated by a small clamp, worked by an electro-magnet, situated in the cylinder seen in Fig. 2, and its interior arrangement in Fig. 3; Fig. 4 shows the revolving armature, placed inside Fig. 1. The little electro-magnet in Fig. 3 is charged by the current; when its magnetism becomes too strong by a too close proximity of the two carbon electrodes, its attraction draws the clamp and draws the rod upward, separating the carbons. When the current, by this separation, suffers resistance enough to become weaker and cause the electro-magnet to relieve the armature by diminished attraction, it allows, by relieving the clamp, the rod to slide down and bring the carbons closer together. This simple device works so well that we have watched the light for hours and did not notice any perceptible change in it.

Fig. 4.—Armature of Light Generator.

We advise parties desiring the use of electric light, before ordering a machine, to communicate at the manufactories full particulars in regard to the buildings and localities to be lighted, to give, for instance, the size of the rooms or areas, the amount of power disposable, where it is located, etc. They can be sure that the manufacturers, the Weston Dynamo-Electric Machine Co., of 292 Washington street, Newark, N. J., will without delay give all particulars as to cost of machines, etc.

Messrs. Cordli, Hassan & Van Winkle, the agents for the Weston Dynamo-Electric Machine Co.'s plating machinery, have opened an office at 22 and 24 Liberty street, New York, where information as to the light machine can also be obtained.

25 Manufacturer & Builder July 1879

NOTICE.

NEW YORK, June 1st, 1878.

The trade is hereby cautioned against infringing the Letters-Patent of the Weston Dynamo-Electric Machine Co., for certain improvements in Dynamo-Electric Machines, or either selling or using machines embodying those improvements. We are the owners of the Letters-Patent, and will promptly prosecute all persons or parties proceeding against all who shall be detected in infringing them in any way. Proceedings have already been commenced against the more prominent infringers.

DUNNAKER & DUNNAKER, Counsel for W. D. E. M. Co.

WESTON DYNAMO-ELECTRIC MACHINE CO

Machines for Electro-Plating, Electrotyping, Electric Light, Etc., Etc., Made under Letters-Patent of the United States, and are beg to refer to the following houses: HORTON BRITTAIN, Co.; HOWELL & EDMUX M'F'G Co.; HERR & HATTON; HATH-AWAY BROS.; ROBERT WARNER & Co.; THE ELECTRO-PLATING & OX. 1 PLATING WORKS; ROGERS' CUTLERY CO.; CHAS. HOERES BRASS; EDWARD MILLER CO.; MOUSELL, YALE & TOWNE; THE HOTCHKISS MFG. CO.; THE N. Y. LOCKSMITHING COMPANY; MARTINEZ CO., Philadelphia; MERRIAM, CHAMBERLAIN CO., SIMPSON & HARRIS; FISHER & SON; and over 500 others. Works for Silvering, Silvers, Bronze Platers, Etc. The two highest CENTENNIAL AWARDS, and the CENTENNIAL GOLD MEDAL, were awarded to us.

Prices from $192 to $500.

☞ New Catalogue just issued.

Room 4, over West of Broadway.

Engineer July 1879

One of the most interesting novelties in the Berlin Exhibition is the construction of an electrical railway by Siemens and Halske. The electrical power is says *Nature*, supplied by a dynamo-electric machine, which works the wheels of an electric locomotive. The length of the way is 300 metres, the velocity three metres per second; the number of engines three, and passengers twenty. The same experiment will be tried at the Scientific Exhibition at the Palais de l'Industrie, with Marcel Deprez's motor, which is very promising. A new model has been constructed, weighing seven kilogrammes, and, with twelve Bunsen elements, can give a man-power.

Engineer July 1879

4505. APPARATUS FOR OBTAINING ELECTRIC CURRENTS, &c., *C. F. Brush*.—Dated 25th December, 1878. 2½.

Upon a revolving shaft are placed as many electro-magnets in the circumference of a circle as the circumstances require. The shaft is then arranged that the one pole of one of the electro-magnets terminates in the reverse pole of the next electro-magnet in the length of the shaft; but in the circumference of the circle the same pole. The coils are to an electric lamp, and extends to the manufacture and application of circular or spiral carbon pencils.

Edison's Dynamometer.—An Improvement

Sc. Am. Aug 9 1879

To the Editor of the Scientific American:

Noticing in your last issue the dynamometer invented by Mr. Edison, it occurred to me whether odd for him to adopt such coarse devices for measuring power, however effective they may be. Why did he not apply the principle of the tasimeter to this purpose? It seems feasible enough to a layman. Suppose the driving and driven shaft to be placed suitably in line, but not connected, provide each with an arm, allow the arms to overlap each other at the ends, and place between the ends of the arms a carbon button having electrical connections as in the tasimeter. The button would be pressed more or less, according to the power consumed by the driven shaft, and its electrical conductivity would be changed with every variation of pressure.

To insure accuracy in the indications of the galvanometer, another tasimeter arranged to receive a variable amount of pressure should be connected with a switch, so that it could at any moment be thrown into the electrical circuit in place of the button carried by the arms.

If the tasimeter is so sensitive and so accurate for exceedingly small pressures, why should it not be more accurate in indicating heavy pressure?

X.

The Edison Dynamometer.

To the Editor of the Scientific American:

In your issue of July 26th, you remark that Mr. Edison's new dynamometer is "in principle something like other dynamometers." Are you aware how much it is like one devised by Mr. Horatio Allen and used in the government experiments on steam expansion in 1855?

As described by Prof. Fairman Rogers, at a meeting of the Franklin Institute, March 19th, 1860, and published in my report as secretary, it appears as follows (see *Journal of the Franklin Institute*, vol. 40, page 201):

"The shaft, being cut between the engine and, the first fan, a grooved pulley is keyed upon the engine shaft and one exactly similar upon the fan shaft. An endless rope is laid over these two pulleys in such a way that the light of the rope hangs down before and behind. In these lights are long two grooved pulleys of a diameter equal to the distance of the large pulleys apart, and to these smaller pulleys equal weights, so that the rope is held tightly in the grooves of the large pulleys. The engine pulley being turned by the engine, sufficient extra weight is added to the hanging pulley on the driving side of the rope to equal the strain on the rope, which represents the resistance of the fans, when the whole system will be in equilibrium, and the amount of power to drive the fans will be measured by the tension of the rope, and consequently by half the extra weight which has been added.

"If the resistance of the fans increases by any means, the weight rises; if the resistance diminishes, the weight falls, and a spring balance is fastened to the weight and to the floor to take up these irregularities.

"A rod attached to the weight and carrying a pencil, moving over the surface of a cylinder running from the shaft, serves to register the power required to run the fans.

"By the apparatus the friction of the fan shaft can be measured and any change in the resistance from varying density of the air is immediately indicated."

Another part of the invention relates to means for storing the electric current or energy so that it may be utilized as used as required. This is done by the use of secondary batteries, and there are devices for shifting the connections from one secondary battery to another, especially so that one may be in use while the other is being charged from the main circuit. The secondary batteries are of any desired construction. Mr. Edison prefers two sheets of lead wound together into a spare or spiralform and immersed in dilulated water in a closed case. The main line is connected with any magneto-electric machine or other source of electric energy, and by wires to the secondary batteries, and the return wires are through a switch to the earth connection.

Engineer July 1879

EDISON'S CHALK CYLINDER BATTERY, DYNAMOMETER, AND NEW ELECTRIC LAMP.

THE uses of the chalk cylinder in Edison's receiving telephone have been sufficiently explained in our pages, but it appears that in the course of some experiments with the electro-chemical telephone Mr. Edison discovered some peculiar phenomena which at first puzzled him; but on connecting the binding posts of the telephone with a galvanometer, he found to his surprise that the chalk and platinum rubber of the telephone formed a generator of electricity of no mean order, as it equalled in electromotive force a half of a Daniell cell. He therefore arranged four of the chalk cylinders upon a non-conducting shelf, and connected the platinum rubber of each cylinder with the one beside it, the box of the next, the terminals being a rubber on one end, and a spring touching the rubber on the box of the chalk cylinder at the other end. A series of four chalk cylinders thus mounted and connected (see Fig. 1) is equivalent to two Daniell cells, but

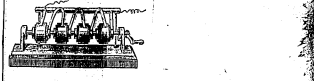

FIG 1

the power varies somewhat with the speed at which it is rotated. Mr. Edison is investigating the action of this peculiar battery. He states that its resistance is 1,200 ohms when at rest, and only 50 ohms when in motion; that for 10c. metallic surface on its rubber. When this surface is increased to 15in. the resistance will be reduced to 1 ohm. Whether the current is due to the decomposition of the solution with which the chalk is moistened, or whether it is due to capillarity or some other cause, has not been definitely determined.

As to Mr. Edison's dynamo all sorts of statements are made, and we are asked to believe that 95 per cent. of the power applied to the machine is converted into electric current, and 82 per cent. of the power is made available outside the machine. This, it is said, is about double the effective exterior current realized by other machines.

In endeavoring to measure the power required to drive the generator Mr. Edison has tried every dynamometer within reach, and condemned them all. At last, after considerable experiment, he hit upon the simple contrivance shown in Fig. 2. He claims that with the apparatus he can measure the 1-100th of a horse-power. The weighted box rests on the platform scale, and is provided with a pulley for receiving the driving belt, which passes over the driving pulley A, under the tightener C, and over the driven pulley B. The number of foot-pounds of power used will be indicated by

Engineer July 1879

Out of the most interesting novelties in the Berlin Exhibition is the construction of an electrical railway by Siemens and Halske. The electrical power is, says *Nature*, supplied by a dynamo-electric machine, which is worked by a stationary dynamo-electric machine, which works the wheels of an electric locomotive. The length of the way is 300 metres, the velocity three metres per second; the number of wagons three, and passengers twenty. The same experiment will be tried at the Scientific Institute at the Falais de l'Industrie, with Nyssel Dupuy's motor, which is very promising. A new model has been constructed, weighing seven kilogrammes, and, with twelve Bunsen elements, can give a one-power.

Engineer July 1879

4205. Apparatus for Generating Electric Currents, &c. C. F. Brush.—Dated 19th November, 1878. 10d.

Upon a revolving shaft are placed as many discs-magnets in the circumference of which are embedded soft iron cores. Coils of wire are so arranged that the one pole of one of the electro-magnets faces always the reverse pole of the next electro-magnet in the length of the shaft; but in the intervening spaces between the same poles. The coils are so so electrically connected as to the manufacture and application of circular or spiral carbon pencils.

Edison's Dynamometer.—An Improvement

To the Editor of the Scientific American:

Noticing in your last issue the dynamometer invented by Mr. Edison, it occurred to me as rather odd for him to adopt such coarse devices for measuring power, however effective they may be. Why did he not apply the principle of the taximeter to this purpose? It seems feasible enough to a layman. Suppose the driving and driven shaft to be placed suitably in line, but not connected; provide each with an arm, allow the arms to overlap each other at the ends, and place between the ends of the arms a carbon button having electrical connections as in the taximeter. The button would be pressed more or less, according to the power consumed by the driven shaft, and its electrical conductivity would be changed with every variation of pressure.

To insure accuracy in the indications of the galvanometer, another taximeter arranged to receive a variable amount of pressure should be connected with a switch, so that it could at any moment be thrown into the electrical circuit in place of the button carried by the arms.

If the taximeter is so sensitive and so accurate for exceedingly small pressures, why should it not be more accurate in indicating heavy pressure?

X.

The Edison Dynamometer.

To the Editor of the Scientific American:

In your issue of July 26th, you remark that Mr. Edison's new dynamometer is "in principle something like other dynamometers." Are you aware how much it is like one devised by Mr. Horatio Allen and used in the government experiments on steam expansion in 1863?

As described by Prof. Fairman Rogers, at a meeting of the Franklin Institute, March 16th, 1864, and published in my report as secretary, it appears as follows (see *Journal of the Franklin Institute*, vol. 48, page 281):

"The shaft being cut between the engine and the first fan, a grooved pulley is keyed upon the engine shaft and one exactly similar upon the fan shaft. An endless rope is laid over these two pulleys in such a way that the light of the rope hangs down before and behind. In these lights are hung two grooved pulleys of a diameter equal to the distance of the large pulleys apart, and to these smaller pulleys equal weights, so that the rope is held tightly in the grooves of the large pulleys. The engine pulley being turned by the engine, sufficient extra weight is added to the hanging pulley on the driving side of the rope to equal the strain on the rope, which represents the resistance of the fans, when the whole system will be in equilibrium, and the amount of power to drive the fans will be measured by the tension of the rope, and consequently by half the extra weight which has been added.

"If the resistance of the fans increases by any means, the weight rises; if the resistance diminishes, the weight falls, and a spring balance is fastened to the weight and to the floor to take up these irregularities.

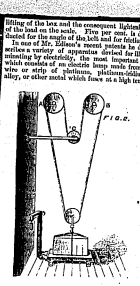
"A rod attached to the weight and carrying a pencil, now lag over the surface of a cylinder running from the shaft, serves to register the power required to run the fans.

"By the appearing the friction of the fan shaft can be measured and any change in the resistance from varying density of the air is immediately indicated."

HENRY MORTON,
Stevens Institute of Technology,
Hoboken, N. J., July 16, 1879.

fitting of the box and the consequent lightening of the load on the neck. Five per cent. is allowed for the angle of the bolt and for friction.

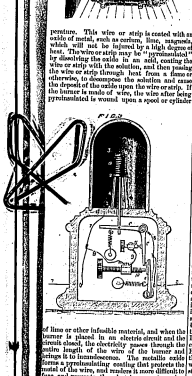
In one of Mr. Edison's recent patents he describes a variety of apparatus devised for illuminating by electricity, and one important of which consists of an electric lamp made from a wire or strip of platinum, platinum-iridium alloy, or other metal which fuses at a high temperature. This wire or strip is coated with an oxide of metal, such as magnesia, lime, zirconia, which will not be injured by a high degree of heat. The wire or strip may be "pyrolaminated" by dissolving the oxide in an acid, coating the wire or strip with the solution, and then passing the wire or strip through heat from a flame or otherwise, to decompose the solution and leave on the surface of the cable upon the wire or strip. When the burner is made of wire, the wire after being pyrolaminated is wound upon a spool or cylinder into a spiral. The strip of metal should be thin, so as to obtain considerable length in a short spiral. The spiral or helix thus made is compressed, and then compressed into a compact cylindrical form. Sometimes the pyrolaminating material is placed on a layer between the coils of the spiral or helix. When the expansion and contraction of the burner c is made to regulate the amount of current to the burner, the helix or spiral is placed between leads 2, 3, as shown in Fig. 2, and the rod b is connected to the burner c at one end and to the lever e. The burner c is supported by the legs 4, 4. The spiral helix may be continuous as a whole, and given exactly by the rod b to the best lever e, which latter opens and closes the circuit at f. When the burner is of platinum entire by wire 7 and passes to the burner c, by rod b, lever e, and wire 8, to the line. If the current becomes excessive the heat expands the burner c and rod b, and moves the lever e into contact with the short circuiting or shunting the current so that it passes by the contact-lug the most resistance, going by 7, 9, 6, e, and 8 to line. A resistance coil equal to the resistance of the burner may be placed in this short circuit. The lever e is a safety device which closes the short circuit through the screw 10, in case c and b should fail to make electrical contact.



This pyro-insulating coating allows of very fine wire being used for the burner, hence several feet of the wire may be wound upon the spool. Platinum is preferable material, and the burner will have a inclination of several hundred ohms which permits the use of a few burners or lamps being connected in multiple arc, as they are, without requiring bulky resistance.

Mr. Edison has devised a modification of pyro-insulating the wire, consisting of a spool or cylinder filled in more layers each forth under the described wire, and carrying a sponge moistened with the pyro-insulating solution, and a lamp for drying the coating applied to the wire. The sponge is moistened with a soluble salt of a pyro-insulating such as the nitrate, carabic, or acetate of lime, magnesium, or cerium, and the sponge of metals, whose oxides are infusible after being heated. The sponge is placed in a chamber, with the moistened sponge leaves a very thin film upon the wire, and the heat from the flame which is behind the sponge severely decomposes the salt and leaves the oxide of the metal as an adherent coating on the wire. This operation may be repeated many times, and thus the deposit becomes thicker, infusible oxides resolved a thickness of about one-third that of the wire, itself. The wire should be wound upon a spool having a large circumference before being wound upon the spool of the burner, to prevent the cracking of the oxide.

In some instances Mr. Edison makes the burner or candle of finely divided iridium or other metal that is not easily fused, mixed with an oxide of thorium, iron, or other metal which acts as a conductor when highly heated: this is to be moulded into the desired form, and by gradually proportioning the entrance the current to the burner is regulated by the heat of burner, the resistance falling lower in proportion to the heat.



Another feature of this invention relates to the arrangement of the main conducting wires so as to obtain a complete metallic circuit, and at the same time allow advantage of the conductivity of the earth, so that the mass of metal in one of the conductors may be reduced; the earth and metallic conductor serve at the same time as a protection for the underground conductors. The magneto-electric machines may be of any suitable character and driven by power. They may be arranged between the two main conductors, A, B, in multiple arc or series, or four, five, four, or more in each, and the connections should be for intermediate machines to each conveyor the current, but at every fifth, or such other interval as may be desired, the reverse end of the machine is only or one strand. Each machine is constructed, as single strand will connect the wires in the circuit, as shown in Fig. 3. Each lamp is to be provided with a switch, so that it may be disconnected from the conducting wires. The electric generators at the central station are provided with constant field of force magnets, the helices of which are in the electric circuit: hence if all the lamps feeding from the main conductors are disconnected by their switches the circuit will be broken and no current passes through the conductors leading from the station to the lights, hence the steam-engine driving the magneto machines will exhibit no

of line or other infusible material, and when the lamps are placed in an electric circuit and the circuit closed, the electricity passes through the entire length of the wire of the burner and brings it to incandescence. The metallic oxide forms a protoplasticizing coating that protects the metal of the wire, and renders it more difficult to fuse, and prevents the electric current passing from one coil to the next, thereby compelling the electricity to travel the entire length of the wire. If the burner is made from a strip of metal, the strip will be thicker at one edge than the other, so that it may be rolled to a uniform thickness at the same time that it is coiled

with the expenditure of a very small amount of force. If now the article of a single lamp is turned, the lamp is connected to the branch wires from the main conductors, the circuit is closed, and only sufficient current passes from the central station to supply that lamp, because the resistance of the conductors determines the amount of current. In this way the current will be proportioned to the number of lamps in the circuit. Each lamp contains a resistance, when incandescent, of 1,000 ohms. In case one consisting of one or more lamps ceases, from any cause, to receive a sufficient amount of current to keep it incandescent, the central station is to keep the same incandescent; it follows that if the machines at the station are arranged expressly for tension and quantity many hundreds of lamps may be placed in circuit between the main conductors, the reduction of resistance upon placing each lamp in circuit lowering the proper quantity of current from the station, hence the greatest economy possible is obtained by reading all the resistance outside of the main conductors to be light-giving resistance.

Another feature of the invention relates to means for storing the electric current, or energy so that the same may be used as required. This is done by the use of secondary batteries, and there are devices for shifting the current from the secondary battery to another periodically so that one may be in use while the other is being charged from the main circuit. The secondary batteries are of any desired construction. Mr. Edison prefers two sheets of lead wound together into a square or cylindrical form and immersed in acidulated water in a closed case. The main line is connected with any magneto-electric machine or other source of electric energy, and by wires to the secondary batteries, and the return wires pass through a switch to the earth connection.

MACHINE MAGNÉTO-ÉLECTRIQUE

Jeudi 15 — DE M. BENOIST

Nous recevons de M. l'envoyeur la communication suivante; elle constitue un document intéressant pour l'histoire des machines génératrices d'électricité, nous nous faisons un devoir de lui donner place.

Le Comité de rédaction.

Depuis que M. Gramme a inventé sa machine dynamo-électrique, les machines magnéto-électriques semblent délaissées par les inventeurs, bien que, théoriquement, le rendement de ces appareils dut être supérieur.

Les machines dynamo-électriques doivent créer en même temps l'action et la réaction; or personne n'ignore que rien ne vient de rien, et qu'une force produite, qui est ici l'aimantation de l'électro-aimant, doit se traduire par un excédent de charbon brûlé sous la chaudière de la machine à vapeur.

C'est pourquoi nous sommes convaincu que les machines magnéto-électriques doivent conserver leur supériorité de rendement, au moins dans certaines applications spéciales et surtout dans les machines à courants alternatifs et à division de foyers lumineux.

Du reste, rien encore dans la pratique n'est venu contredire ces prévisions.

Mais dans les machines magnéto-électriques créées jusqu'à ce jour, a-t-on placé les deux éléments de l'appareil, les aimants et les bobines, dans les conditions voulues pour obtenir le maximum de rendement? Nous ne le pensons pas.

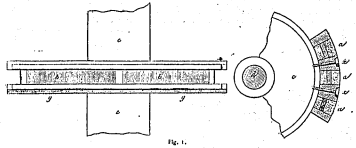


Fig. 1.

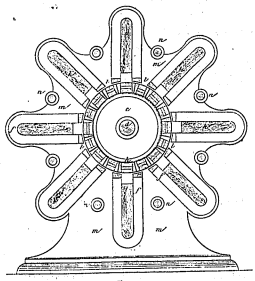

Fig. 2.

Ainsi, d'après les nombreuses expériences théoriques que nous avons faites en 1870, 1871, 1872, nous avons reconnu que, pour obtenir ce maximum de rendement :

1° Les aimants ne doivent pas être employés en fuseaux, afin d'éviter les actions réciproques des pôles de mêmes noms.

2° Les bobines doivent présenter de grandes surfaces polaires magnétiques.

1° Le fil induit doit être aussi rapproché que possible du noyau de fer doux.

2° Il est plus avantageux d'employer plusieurs fils enroulés parallèlement, au lieu d'un seul fil d'égale section.

3° La nature du noyau, acier trempé ou non trempé, fer doux au bois, ou fer au cobe, fonte grise ou blanche, n'influait pas autant qu'on le suppose généralement sur l'intensité de l'onde magnétique, mais que cependant il y a avantage à employer du fer doux.

4° Il y a également avantage à diviser le noyau magnétique pour faciliter la désaimantation.

5° L'un doit employer des bobines longues et étroites à pôles magnétiques rapprochés, afin de pouvoir en placer un plus grand nombre surune circonférence restreinte, ce qui procure le double avantage d'augmenter le nombre des ondes électriques pour chaque tour, sans exagérer la résistance angulaire du mouvement de rotation.

6° Il faut disposer un nombre suffisant de bobines, pour ne pas employer des vitesses exagérées de plus de 200 tours par minute, qui doivent fournir 6 à 7,000 ondes électriques.

7° Enfin, on doit donner la préférence aux aimants permanents, qui agissent mieux à distance que les électro-aimants.

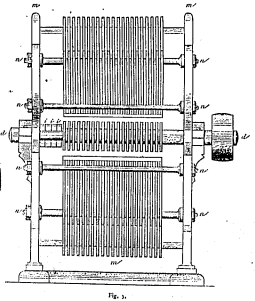

Fig. 3.

Dans le but de satisfaire autant que possible à ces conditions multiples indiquées par la théorie, nous avons réalisé en 1872 une première machine qui nous a donné des résultats remarquables; mais, depuis, en présence du succès toujours croissant des machines dynamo-électriques, nous avons dû renoncer à la suite de nos recherches, après avoir cependant assuré notre priorité par un pli cacheté déposé à l'Académie des sciences dans sa séance du 20 janvier 1873, sous le n° 2718.

Voici la description de notre machine :

Les bobines sont en fer doux (fig. 1 et 2) et ont une longueur de 0m,20, leur coupe transversale a la forme d'un fer double T, le voile latéral entre les ailettes est de 0m,03. L'âme I est formée de morceaux de tôle douce juxtaposés et encastrés dans une rainure longitudinale.

Le fil en fer fils s'enroulent dans le sens de la longueur et sont isolés comme dans toutes les machines analogues.

Les bobines sont juxtaposées au nombre de seize, au pourtour d'un cylindre en bronze, c, monté sur un arbre *dd* auquel on peut imprimer un mouvement de rotation.

Le cylindre en bronze est occupé que 1/3 de la longueur des bobines qui y sont fixées au moyen de deux fortes vis *ee*. Les deux extrémités libres des bobines se trouvent à droite et à gauche un cylindre creux, dans lequel on introduira plus tard un cylindre en tôle douce *h* d'un diamètre un peu plus petit, fixé sur le bâti de la machine, qui fermera l'armature magnétique intérieure par influence, et concourra à augmenter sensiblement le rendement.

Si l'appareil doit fournir des courants redressés, les fils des bobines aboutissent à des commutateurs ordinaires; si, au contraire, les courants sont alternatifs, l'un des pôles sera relié en communication directe avec l'arbre, tandis que l'autre sera relié à une ou plusieurs rondelles isolées *ll*, également centrées sur l'arbre, sur lesquelles les courants seront recueillis au moyen de frotteurs.

Par cette disposition du cylindre aimant induit, rien n'est plus facile que de diviser le courant, soit en couvrant plusieurs fils parallèlement sur chaque bobine, soit en divisant les bobines par groupes de 2, 3, 4, etc., et en recueillant les courants sur des bagues séparées et isolées.

Le cylindre aimant induit décrit ci-dessus tourne au centre de seize armatures en fer doux *ll*, convenablement espacées et sur lesquelles reposent les pôles alternés des aimants *fff*.

Les aimants permanents, au lieu d'être disposés en faisceaux, sont espacés le long des armatures au nombre de 21 de manière à en occuper toute la longueur, en sorte qu'il reste entre deux aimants consécutifs un espace vide occupé par une triangle en bois fixée sur la barre transversale *kk* qui est également en bois, et règle ainsi l'écartement entre les aimants.

Les barres en bois *kk* qui supportent les aimants, reposent par leurs extrémités sur le bâti en fonte non de la machine, dont les deux parties sont reliées entre elles par le socle en bois et par les boulons en bronze.

Aujourd'hui que les machines magnéto et dynamo-électriques sont entrées dans la pratique journalière de l'éclairage par l'électricité, par suite des nombreux perfectionnements apportés dans la disposition des lampes et des charbons, on peut dire que la période des tâtonnements est passée, et que d'après ces données exactes de rendement que le mérite de chacune d'elles sera établi. Dans ces conditions, nous croyons que les machines magnéto-électriques doivent reprendre leur rang.

On reproche à ces dernières d'être d'un prix plus élevé, d'un poids plus grand que les machines dynamo-électriques et d'occuper plus de place. Nous ferons remarquer que, pour une machine fixe, quelques kilogrammes en plus ou en moins et quelques décimètres sur toutes les dimensions importent assez peu, il d'autre part un rendement supérieur couvre en quelques mois la légère différence du prix.

Enfin, pour terminer, nous dirons que si les machines magnéto-électriques ne sont pas appelées à remplacer entièrement les machines dynamo-électriques, du moins dans certaines conditions spéciales, elles l'emporteront sur ces dernières sous le rapport économique, puisqu'elles exigent moins de force motrice.

A. DEMONT.

41940. DYNAMO-ELECTRIC MACHINE FOR PRODUCING ELECTRIC CURRENTS, C. J. Pilsworth.—dated 18th December, 1891. 6d.

Covered cylinders or rings are formed of soft iron capable of receiving one in the other concentrically, and insulated from each other. Each cylinder is wound with insulated wire leaving the spaces clear at one or more places to allow without producing injurious friction. In the grooves are lodged insulated conducting wires, either by single convolutions or a zig-zag manner, or the ring is surrounded with the wire wound on in the ordinary manner. Between the rings are placed permanent magnets lodged in the grooves, and are fixed with the projections. The rotary rings are brought under the influence of either permanent, temporary, or stationary magnetism, which rotating, [illegible]

THE SIEMENS DYNAMO-ELECTRIC MACHINE.

[From the Journal of the Society of Telegraph Engineers.]

Read at a meeting of the Society, held on March 11th, 1875.

At the meeting held on May 6, 1874, Dr. John Hopkinson, F.R.S., Mem. Inst. C.E., which gives some very interesting results of tests on a Siemens machine. By these tests the machine appears to have given, at 1,000 revolutions per minute, 27 per cent. of the energy delivered to it through the belt, which is very low. The following methods were used: The power absorbed was measured by a dynamometer, and the energy of the current was calculated either by measuring the electro-motive force in volts at the terminals, with a Daniell's cell and calculating the results in the usual manner, or measuring directly the heat given off from a part of the circuit, the total resistance in a calorimeter.

I would call attention to the fact that the electro-motive force of the gravity form of a Daniell's cell is assumed as nine-eighths of a volt, or 1.125 volts, though this form of cell is constantly employed as giving less than the standard cell with concentrated acid, and is accordingly the source of a serious error. The value taken by Messrs. Latimer Clark and Chrisperson, in their tests for the Practical Institute was 1.079 volts for the electro-motive force of a Daniell's. This value is the one given by Mr. Latimer Clark and is generally received as the normal one. As the energy given off is very directly as the square of the electro-motive force, in comparing the figures given by Dr. Hopkinson with those in his Practical Institute report, one must multiply his results by $\left(\frac{1.079}{1.125}\right)^2 = 0.92$. If this correction is made the Siemens machine would give back 32 per cent. instead of 30 per cent. of the power applied in the shape of electricity.

Though Weber's measurements, as cited by Winderman, in his work, vol. ii. 1110, give a high electro-motive force to the Siemens cells, yet since his results are questioned, there is no sufficient reason why the standard adopted by the British Association should be abandoned. In order that values obtained by various experimenters may be readily compared, even if the standards are slightly incorrect, it would be well to retain the original values until the question is fully settled. If nine-eighths of a volt be taken as the value of the electro-motive force of a Daniell's, a further correction must be made, that is, new machine tests by Mr. Latimer Clark gives their power in the current that it receives through the belt, unless some very careful ample tests are at fault.

It may mentioned that this machine, while transforming

five-hours power of energy, allows seven-eighths of the total amount to be recovered suitable, and that with less than one-tenth of a horse power consumed in the magnets the electro-motive force of 725 volts has been obtained from the armature, which is a remarkable result indeed.

In Dr. Hopkinson's last experiment of the kind, by means of the calorimeter, the resistance of the wire used was given as 0.2 of an ohm. As a very slight difference in this would be largely multiplied in the complete circuit, it seems always to me that the resistance was about one-fifth of an ohm, and that the conducting wire was sufficiently large to prevent undue heating. No allowance is made for the heat lost by the calorimeter during the passage of the current through it.

In experiment Number 12, a horse power is given off from a surface of 14.5 in., or, in other words, the total heat from a large-sized gas jet was concentrated on this surface. It seems impossible that the resistance of the wire could not have increased materially by this, and, consequently, the power absorbed by the machine must have seem to say slightly when a powerful current is passed through it, thus allowing economies from heating, and consequently increase of resistance.

The percentages obtained by comparing the power utilised, measured by the calorimeter, to the power applied were the following:

					Per cent.
Experiment	4	—	—	—	101
"	6	—	—	—	102
"	8	—	—	—	104
"	10	—	—	—	92
"	12	—	—	—	92

These results would lead one to distrust the accuracy of the methods used, as in two cases impossible values are obtained, and there is so great a difference between the extremes.

Before I am entitled to discuss the paper so fully in itself high praise of the care which was successfully taken to give full data regarding the experiments. Such a paper is on many accounts better than experimenting personally, for besides having another's experience, one often sees scores of error more easily in another's work than in his own.

Yours truly,

FRANCIS B. UPTON.

centre of gravity of a body is upon the other, the leaning of the one beyond which it would cease to stand upright. The wider the base, and the lower the centre of gravity, the greater the angle of leaning which can be given without overthrow. For each body to which the law could apply, there would be a certain angle of leaning at which the weight would be just on the point of overthrow. Now, if we take a body of the above general description, and lean it over to the extent of, say, 45°, we shall find that the weight would be just on the point of overthrow, and the line of gravity would fall on the edge of the base. Let us call this a body of unit weight. Now, if we take a body of the same general description, and lean it over to the extent of

Die Dynamo-elektrische Maschine, eine deutsche Erfindung.

Wenn man in den technischen Blättern von den Fortschritten des elektrischen Lichtes und den stromerzeugenden Maschinen liest, so ist fast nur von Frankreich oder von England die Rede; von Deutschen wird nur selten Erwähnung gemacht, obgleich sie sich in dem interessanten Wettstreite erfindender Geister ganz gut sich betheiligen. Die Gramme'sche Maschine aber spielt hierbei die Hauptrolle. Und doch ist die dynamo-elektrische Maschine erwiesenermassen *eine deutsche Erfindung* und existirt eine *deutsche* dynamo-elektrische Maschine, die vor der Gramme'schen dagewesen ist, und sich weit ökonomischer und besser bewährt hat, als diese und *alle* anderen ihresgleichen.

Gleich nach der Entdeckung der Magnetinduction durch Faraday wurden Maschinen zur Erzeugung von Inductionsströmen construirt, welche zweierlei Art waren; nämlich *magneto-elektrische*, bei denen *durch vorhandenen Magnetismus* vermittelst verwandter Arbeitskraft der elektrische Strom erzeugt wurde, und *elektro-magnetische*, bei welchen *durch vorhandenen elektrischen Strom* mit Hülfe des durch ihn erzeugten Elektromagnetismus Arbeitskraft hervorgebracht ward. Die ersteren Art dieser Maschinen litt an dem Uebelstande, dass die Wirkung der Maschine nicht im Verhältniss zu ihrer Grösse zunimmt, da die Stahlmagnete sich gegenseitig schwächen. Auch konnten sie eine weitere Verbreitung deshalb nicht finden, weilzu grosse Massen von Stahl, Eisen und Kupferdraht erforderlich waren, um eine kräftige Wirkung hervorzubringen; wodurch sie zu schwer und theuer wurden. Endlich kam Dr. Werner Siemens darauf, diesen Uebelstand durch die *Construction des rotirenden Cylinder-Ankers*, welcher in der elektrischen Technik seitdem allgemeinen Eingang gefunden hat, einigermassen zu vermindern und mit seiner Hülfe kräftige magneto-elektrische Maschinen von weit geringeren Dimensionen herzustellen. Zwei Jahre darauf hatten die Engländer Wilde und Ladd *nach diesem* Systeme verbesserte magneto-elektrische Maschinen. Dr. Siemens gelang es aber, im Jahr 1866 die Anwendung der Stahlmagnete gänzlich zu beseitigen. Nur mit der einem solch' ausgezeichneten Erfinder eigenen Beobachtungsgabe und Schlussfolgerungen kam er damit zu Stande, die *erste* sogenannte *dynamo-elektrische* Maschine herzustellen, mit welcher die Arbeitskraft direkt in elektrischen Strom umgewandelt wird und in welcher Magnetismus gleichsam nur als Zwischenprodukt, nicht aber mehr als eigentliche Quelle des erzeugten Stromes auftritt.

Einige Wochen, nachdem Dr. Siemens am 17. Januar 1867 der königl. Akademie der Wissenschaften die Begründung des Princips der dynamo-elektrischen Maschine mitgetheilt hatte, publicirte auch Prof. Wheatstone in England, ohne seine Arbeiten zu kennen, dieselbe Idee. Da aber Dr. Siemens die erste Veröffentlichung dieser Erfindung gemacht, und schon im Dezember 1866 vielen Gelehrten und Technikern *Berlins* eine in Thätigkeit befindliche elektro-dynamische Maschine gezeigt hatte, so gebührt ihm auch vollkommen und unbestreitbar *das Recht der Priorität*, und demgemäss ist auch *das System der dynamo-elektrischen Maschinen unbedingt und ausschliesslich eine* DEUTSCHE ERFINDUNG.

Auf der Pariser Weltausstellung von 1867 hatte der Engländer Ladd bereits eine ziemlich genaue Copie der vorerwähnten dynamo-elektrischen Maschine mit Cylindermagneten ausgestellt, ohne den Ursprung derselben zu nennen.

In ähnlicher Weise verfuhr später Herr Gramme

SMALL DYNAMO-MACHINES.

[1885.]—Mr statements with regard to small dynamo-machines in recent numbers of ENGLISH MECHANIC have called forth several communications, which I feel in duty bound to notice more directly into a subject which it has been above my province to enter into in these pages. The five communications, referring to the letter that appeared in last week's issue, would indicate that I must first of all draw a clear and distinction between dynamo-machines and electro-magnetic engines.

A magneto-machine is an apparatus in which a system of coils or armatures is made to pass alternately before the two or more poles of a system of permanent magnets, in such a manner that by means of magnetic induction from the poles of the permanent magnets currents are induced in the armatures, and that in the whole circuit in which the system of armatures may form a portion. The armatures generally consist of a number of steel, and sometimes of soft iron wires wound upon them. Good machines of that kind are made by Messrs Elliott, and by Mr Apps, of Hatton Garden, to refer to such machines which I beg to be understood.

Dynamo-machines differ from the former in so far as the inducing systems consist in temporary or electro-magnets, and that there are no coils of wire and consequently no currents are made or broken. There can on be magnetized insulated copper wire, according to the strength of which a weak greatly less under the influence of electric currents than soft iron. Hence it is impossible to excite a machine of that description by means of a battery of a few cells only. On the other hand, the power of permanently magnetized iron to retain its magnetism is well known, and after being completely magnetized, will manifest a very considerable power for a long time or remanent magnetism for a great length of time.

Cast iron contains a considerable amount of carbon, and the amount of that admixture of carbon stands in a ratio almost to the residual magnetism, but indirectly with the extent to which it can be magnetized. In other words, cast iron can be magnetized as highly as well annealed wrought iron, but the former will retain a greater portion of its magnetism.

We all know, from experience that magneto-machines which consist of, put in a spare No. 20, or No. 22, work well.

The most perfect of all dynamo-machines, the Gramme ring, has cores of annealed soft iron, and in order to obtain the very highest possible amount of magnetism it has been found necessary to make the bars and uprights large. [illegible]

[illegible] Gramme ring [illegible] this cause. In corroboration of this I need only refer each of our readers who may not access to the machines to look at the drawings in Tunzini's book.—[See pages 81, 85, 91, and 101.]

In the large Varley-Wallace machines also, the cores, uprights, and bases are all made of unusually heavy castings. Special reference has been made to the "light-house" contrary light in the small cores in Weston machine, each core only weighing 5 lbs. Another point which I would ask my reader to look at is Weston machine, and observe what extreme care has been taken in the proportions for securing a great amount of residual magnetism. The cores are all fixed in a heavy circular cast-iron frame, and the latter again is fixed on a heavy cast-iron frame. Now, "Anglo-Dane," no doubt, has experimented with the machines for electro-magnets, whether they were to be wound on the extreme pole-ends only, or to be wound on the centre of the legs, provided there are three complete of turns. It is clear then, and "Anglo-Dane" will agree, that we have to call to mind, in the Weston machine, are only the extreme poles, and the heavy cast-iron frame, and base form part of the magnets, and serve to retain residual magnetism, both by their shape and mass.

In the face of these facts it would be idle to dwell and useless, to dispute the importance of the residual magnetism, or what comes to the same, a constant supply of magnetic energy, and I think that in the following lines I may prove the truth of my own statements against those of Mr. Holme, out of the mouth of his own witness, my esteemed opponent.

Mr. Holme says—"We do not seem to know that the current from a large machine is distributed through the whole of the magnetic circuits, and consequently them varyingly power as he supposes, small magnets would do, with very expensive current sent round them from the armature." I have carefully tested this statement by various machines and by means of telephones, and found that the contrary is true of the latter, that the current is distributed. Mr. Holme has [illegible] Gramme machine, which is a very perfect contact-breaker, and found the current to be more continuous, he simply proves my own assertion that a perfection of action of a dynamo-machine depends largely on the accuracy of the current which is employed to excite the system of field magnets; and this is the very point I urged in the first argument supplied by Mr. Edison. I beg to state that the most powerful machines, as well as the permanent electro-magnets in them, are those periods of magnetization are altogether independent of the contact-breaker and the coils of the field-work armatures. Such machines are Wilde's and Siemens's, the improved machine, in each of these machines Fontaine, pp. 68 and 70) the current produced by the machine is not employed for exciting the powerful magnets of the large machine, which produces its actual work. In all these machines all the currents are against an intensified permanent magnetism of the large magnets attached to the machine, and the field-magnets with these in the armatures of the machine. In all these machines such machines as there were no magnets of wrought iron. But let us never forget that the second of either of these machines are powerful permanently permanent magnets, and that it would not work at all without them. Siemens and Wilde, in fact, of the dynamo-machine pure and simple. From the fact that the latter machine is very readily excited that he increased the winding of a dynamo-machine in it is of the very greatest importance to have field-magnets or inductor magnets of which the energy does not vary, or, if it varies, that the greatest attainable, and therefore with the greatest current strength in the armatures.

Now, the question arises as to whether, with the present knowledge of electricity and magnetism, we are able to produce small magnets, the energy of which we can predict with certainty, or at any approximate in any reasonable proportion to the work expended in producing these currents.

I have had occasion to experiment on large and small magnets, and have come to the conclusion, and others, and the result of my experience was expressed in my last letter, that the magnetic force can be found to depend on the [illegible] construction of such small machines as "Anglo-Dane" is making, which, as I believe, are less expensive than "No more tyre could make such a machine." Mr. "Anglo-Dane's" statement is near the actual truth. Such machines as "Anglo-Dane" has constructed, and I have tested several of them, and sent them ten to work them, and found that they carried out as fairly as intended by the [illegible] proportion whatever with the work expended. Experiments have also been contributed in an exceedingly [illegible] full of contradictions and unintelligible assertions. Written by "Orange," the gentleman who so far fails in fact as to altogether neglect to observe that accurate measurements on an exceedingly softer core to a corresponding value always freely signs his name with his commercial [illegible] He advises me of soldering machines [illegible]

SOME RECENT ELECTRICAL "NOVELTIES."

Electrician Aug 14/1880

It is always curious and sometimes surprising to find how fairly the idea of a recent invention has been mooted or its principle propounded by some other mind which lived before the time was ripe for the realisation of its schemes. "Nothing new under the sun" is a proverb to which these inventive times is ever giving proof. Edison's "Ore Separator" is a contrivance which has been again and again shown to be no novelty, but few are aware how old it really is—at least, in idea. It actually belongs to the last century; and, for aught that we know, may have entered into the idle dreams of Tubal Cain. In an English patent of date June 16, 1762, No. 1,891, William Fullarton, of Ayr, in Scotland, describes a new process for "separating iron from iron stones and other ores of that metal, of smelting it into the state of pig or cast iron, and of reducing or refining it into the state of malleable or forged iron." The patent was granted in the old style by King George III. for "His Kingdom of Great Britain, called England, His Dominion of Wales, and Town of Berwick-upon-Tweed, and also His Plantations abroad." There is a long time ago, but not before "telegraphs were thought about," for Charles Marshall, writing from the same district in Scotland, had long before (in 1753) suggested the principle of the electric telegraph; and Lesage, in 1774 had actually operated a frictional telegraph of the kind planned by Marshall.

Fullarton's patent goes on to describe the method of ore separation adopted by him. This consisted in crushing the iron ore by grinders, stamps, or mills worked by hand, horse, steam, water, wind, or other power, and, in the next place, of separating all "earthly (sic) impure, and extraneous matters from the metallic particles by all or any of the following apparatuses, namely, by washing, levigating, lotturing, winnowing, and by the application of magnetic attraction, according to the nature and qualities of the different stones and ores." The materials thus purified are put into the furnace and smelted.

The electrical railway of Dr. Werner Siemens finds a forerunner in the "Pneumatic Traveller" of Thomas Pain, patented on March 1, 1834, No. 6,510, for the propulsion of vessels, carriages, &c., on canals, railways, or common roads. This invention relates to a pneumatic railway in which magnetic attraction may be employed, and which may either form a "complete system of railway in itself," or be applied to common railways or canals.

An extended tunnel, tube, pipe, or conduit is laid down, which contains a piston. On one side of the piston the air is exhausted from the tube by suitable stationary engines placed at suitable distances along the line. To the piston is attached "a vehicle or machine," called "the dynamic traveller" which is in connection with a car on the outside of the tube, called "the governor," to which the wagons to be propelled are attached. In the pneumatic railway itself the rails are cast on the sides of the tube; but in its application to common railways the canals the tube is laid down between the rails, or at the margin of the canal. The connection between the dynamic traveller and the governor is made either by means of a longitudinal "pneumatic valve," through which a spiritual wire runs, or by magnetic attraction. To apply magnetic attraction effectively, the dynamic traveller carries a frame of horseshoe magnets, set transversely, with their poles placed as near to the under surfaces of the tube as possible. A similar combination of similar magnets inverted is attached or suspended under the body of the governor, and in order to enable the space between the poles of the magnets in the two frames to be as small as possible, the upper part of the tube has a copper plate fitted air-tight into the upper instead of a valve. In the dynamic traveller soft iron may be used instead of magnets, and electro-magnets may be used.

As regards the production of motive power by electricity, we have the patent of Miles Berry, a communication from Edwin Williams on behalf of Terence Davenport, dated June 8, 1857, No. 7,286. This invention describes a means of obtaining rotary power by "galvanic" magnetism alone, or "galvanic" force in combination with "permanent" magnets. The device in question consists of a number of electro-magnets fixed radially on a rotating shaft, and segmental permanent magnets, or electro-magnets, fixed to the frame supporting the rotating shaft. The motion of the rotating magnets is made to take place by the attraction of their poles towards the poles of the fixed magnets of opposite name. To effect this the rotating electro-magnets are made to change their polarity at proper times by the motion of plates (connected to the circuit of the electro-magnets) against segmental plates, corresponding in number and position to the number and position of fixed segmental magnets; which segmental plates are connected in a suitable manner with the poles of a galvanic battery.

EDISON'S ORE SEPARATOR.

Electrician July 17/1880

In our "Report" for last week we elected an American statement to the effect that an apparatus identical with Edison's vaunted ore separator had been in use in that country for some years. It is satisfactory to find that the Americans have themselves found out the ancient character of that latest bantling from Menlo Park. But the same device has been before the world in France for the last twenty years at least in Froment's machine for separating magnetic oxide from copper ore. Froment is the well-known mechanical electrician of Paris, and his apparatus consists of a hopper, through which the ore was poured, and a powerful electro-magnet, which was placed underneath so as to attract the magnetic particles of sand aside from the rest of the nonmagnetic copper ore. The contrivance is in fact, essentially the same as Edison's. No doubt there are several English patents describing the same arrangement; but Froment's is, as far as we are aware, the first instrument of its kind.

A similar device has been used for some years in America for extracting the bits of wire left in grain from the wire bands of the binding machines so commonly employed by American farmers. In fact, magnetism has been applied in the same way to a great variety of purposes.

The ore separator which was to cover Mr. Edison with the wealth of Ribonds, and transform him into a rival of Mr. Mackay, the owner of the "Big Bonanza" mine, is an old affair refurbished up, and though it may make the New York interviewers gape, and tickle the sensation palate of unobservant Yankees, it will, we imagine, hardly pay for its own manipulation in gold extracting. The proportion of "black sand" or magnetic oxide in gold "tailings" is, we are assured by an experienced gold miner, so very small, that its separation from the rest of the ore will make hardly any appreciable difference in the expense of extracting the small percentage of gold from the residue by washing over mercury. Had the black sand formed a considerable proportion of the whole "tailings" there might have been some value in the magnetic separator. As it is the game is not worth the candle.

BIBLIOTECA NACIONAL

différent sensiblement que lorsqu'on fait abstraction de la résistance. En désignant par E la force électromotrice de la pile employée, par r celle du fournant tellurique, par R la résistance de la pile, par r la résistance connue, par r la résistance inconnue du sol, par i la résistance totale du circuit complété par le sol, par r et r' les résistances développées sur le rhéostat dans les expériences faites avec les deux sens du courant, l'intensité électrique dans les deux circuits du galvanomètre pourrait être représentée par deux expressions de forme différente qui, au moment où la déviation deviendrait nulle, devraient avoir la même valeur et qui conduiraient aux deux équations :

$$\frac{Ei}{R(i-i')+i'r} = \frac{i'(ei+r)}{R(i-i')+ir} \quad \text{ou} \quad Ei=i(i'-e)\,r.$$

$$\frac{Ei}{R(i-i')+ir} = \frac{i(ei'+r')}{R(i-i')+i'r} \quad \text{ou} \quad Ei=i(i'+e)\,r$$

d'où

$$i = \frac{2ir'}{r-r'} \qquad \text{et} \qquad r = \frac{2ir'}{i-2i'} - 1$$

ment d'un plateau de fonte monté sur un axe horizontal, et supportant un système de ressorts destinés à recevoir l'effort transmis par une machine motrice. Cette transmission a lieu par le moyen d'une courroie sans fin et d'une poulie folle sur l'axe de l'instrument, mais qui entraîne le plateau par l'intermédiaire d'un ruban d'acier. Dès que la machine est mise en mouvement, la tension de la courroie se transmet d'abord à ce ruban qui agit sur le système des ressorts; le plateau est, entraîné, et une poulie montée à l'autre extrémité de l'arbre entraîne à son tour le récepteur dont on veut mesurer le travail résistant.

La figure ci-après montre les organes principaux du dynamomètre.

A est le bâti de l'appareil.

B la poulie (ponctuée sur la figure) qui reçoit le mouvement de la machine motrice.

C la poulie transmettant le mouvement au récepteur.

D la poulie folle qui permet d'arrêter le dynamomètre sans arrêter le moteur.

E le plateau de fonte supportant le ruban d'acier G et le système F des ressorts.

H le compteur de tours.

I l'enregistreur ou le totalisateur.

Il s'agit maintenant de faire comprendre de quelle manière on observe l'effort transmis par le moteur. Une plaque d'acier qui comprime les ressorts et à laquelle est fixé le ruban, est liée à une crémaillère parallèle au plan du plateau, engrénant avec un pignon fixé à l'intérieur de l'arbre qui est creusé à la fois transversalement et dans le sens de l'axe. Avec le même pignon engrène une seconde crémaillère, à angle droit de la première, prolongée par une tige qui vient servir à l'extrémité de l'arbre en marque sur une règle divisée le déplacement des ressorts.

La moyenne de ces déplacements mesure, dans un cas donné, l'effort qui s'exerce au point de tangence du ruban d'acier et du plateau. Le compteur de tours donnant d'ailleurs le chemin parcouru, on a les deux facteurs du travail, et une table des plus simples donne immédiatement ce travail exprimé, soit en kilogrammètres, soit en chevaux-vapeur.

Dans certains cas, on peut avoir quelque intérêt à connaître le trace et, pour ainsi dire, le procès-verbal des mesures effectuées. A cet effet, M. Morin remplace le compteur de tours par un enregistreur qui trace sur une bande de papier le diagramme du travail produit ou consommé.

Il y a d'autres circonstances où l'on a besoin de connaître après une durée quelconque de marche, plusieurs jours ou même plusieurs semaines, le travail total fourni ou absorbé; c'est, par exemple, le cas des Industriels qui louent de la force motrice. L'emploi d'un compteur à roulette résout le problème. Combinant enfin les mouvements de la roulette avec ceux d'un indicateur de régime, M. Morin parvient, de la manière la plus simple, à donner, *à chaque instant*, l'indication du travail en kilogrammètres.

On voit, par ce rapide exposé, qu'aucun des points de vue sous lesquels on peut envisager les mesures dynamométriques n'a été laissé de côté par l'habile et persévérant électricien auquel est dû l'appareil dont nous nous occupons.

Il est bien évident que si l'on veut obtenir des résultats suffisamment exacts avec un appareil de ce genre, il faut tenir compte du travail absorbé par le dynamomètre lui-même. Dans ce but, nous avons établi la théorie rigoureuse de son fonctionnement, et cherché ensuite les simplifications dont il sera permis, nécessaire même, d'user dans la pratique.

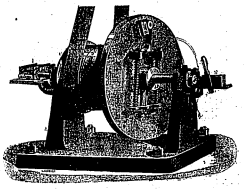
Si l'on désigne par F l'effort en kilogrammes indiqué par l'instrument dans une expérience faite sur un récepteur; par F' l'indication correspondante au cas où l'appareil fonctionne à vide, c'est-à-dire sans entraînement du récepteur, on a pour l'expression du travail absorbé :

$$z = N\,r\,(F - k\,F')$$

Formule où N est le nombre de tours du plateau par minute, r son rayon, et où k est un coefficient dépendant des réactions qui s'exercent sur les coussinets. — Pour faciliter les applications, j'ai calculé la table suivante, qui donne les valeurs du facteur k dans des limites suffisamment étendues :

F	k	F	k
0	1,00	60	1,09
10	1,01	70	1,1
20	1,1	80	1,11
30	1,1	90	1,1
40	1,1	100	1,0
50	1,1	110	1,0

Il y aurait aussi à tenir compte de la force centrifuge due au déplacement du système qui comprime les ressorts; mais une analyse très-simple montre qu'entre les limites de vitesse, où l'on se tient ordinairement, l'effet de la force centrifuge



ou compensé par les frottements inévitables de l'instrument.

En résumé, deux grands avantages paraissent attachés à ce nouveau dynamomètre. Le premier est de mesurer le travail pendant toute la durée de la marche, ce qui permet d'apprécier et de découvrir toutes les variations de travail produites par diverses causes accidentelles ou systématiques; le second c'est d'éviter, pour chaque mesure, l'arrêt des machines en fonctionnement dans un atelier. Ces deux points sont d'une importance capitale en toute circonstance, mais particulièrement en ce qui touche aux applications de l'électricité.

Nous devons dire, en terminant, que nous n'avons en aucune façon le dessein d'opposer l'appareil dont il est ici question à celui qui a été si ingénieusement réalisé par M. le général Morin et si habilement appliqué par M. Tresca. La similitude de nom des deux auteurs nous impressait, à elle seule, le devoir de faire cette déclaration; mais en dehors de cette raison, qui est toute de convenance, il y a une autre considération, c'est que le dynamomètre du Conservatoire des arts et métiers est et restera l'appareil scientifique auquel on a recours dans les circonstances où la plus haute précision est de rigueur. Mais comme son prix élevé, et la difficulté de son emploi ne permettent guère de l'introduire dans la pratique courante, nous pensons que l'auteur du nouveau dynamomètre a rendu un véritable service aux industriels, aux ingénieurs, aux électriciens, à tous ceux enfin qui ont besoin au monde d'établir, dans l'ordre physique ou mécanique, un rapport suffisamment exact entre la dépense et le produit.

Ch. Tellier.

DYNAMOMÈTRE DE ROTATION DE M. MORIN

Journal 15 1879

L'appareil dynamométrique qui fait l'objet du présent article ne renferme rien qui s'applique exclusivement à l'électricité, mais il est d'un emploi si simple et si sûr, qu'il paraît devoir jouer un rôle important dans l'étude du rendement des diverses machines qui servent à transformer le travail mécanique en chaleur ou en lumière. A ce titre, il y a peut-être quelque intérêt à représenter aux lecteurs, particulièrement compétents, d'un journal consacré à la théorie et aux applications de la lumière électrique.

Le dynamomètre de M. J. Morin se compose essentielle-

(1) Pour obtenir le chiffre exact de la résistance de la terre dans ces conditions, il n'a fallu faire un calcul du moyen duquel les effets du courant tellurique étaient éliminés, et pour cela, j'ai eu recours aux formules d'Ohm appliquées aux deux circuits du galva-

MACHINE DYNAMO-ÉLECTRIQUE

DE M. BURGIN

La Lumière Électrique 1879

Professeur comme M. de Méritens de la pensée du résultat, dans l'armature Gramme, de l'échappement du groupe de fer des pôles inducteurs, M. Bürgin a cherché à en opérer le rapprochement, en le faisant exagérer des lieues d'intervalles plus ou moins rapprochés. Pour y parvenir, il compose cet anneau de six anneaux distincts montés parallèlement les uns à côté des autres sur le même arbre, et ayant chacun pour noyau magnétique un cadre carré de fils de fer sur les côtés duquel sont enroulées les bobines induites. Ces bobines sont enroulées en faisceau sur les côtés de ce cadre de manière à ce que les quatre parties anguleuses des noyaux se trouvent à peu près au niveau des spires extérieures de ces différentes bobines, et présentent par conséquent passer à très-petite distance des pôles inducteurs. De plus, ces cadres sont disposés entre eux de telle façon que les parties unies et anguleuses des noyaux se trouvent en retrait les unes par rapport aux autres, de manière à se présenter selon une spire d'hélice. Il en résulte que les actions alternantes s'effectuent successivement, et que les courants dus à cette action aussi bien qu'à celle échangée sur les fils des bobines, sont toujours de même intensité dans les différentes phases de chaque révolution de l'anneau. L'enroulement des bobines induites en cadres d'ailleurs effectué en sens inverse pour les bobines consécutives, afin d'obtenir des courants de même sens dans chaque moitié de l'anneau. Enfin ces bobines sont réunies à un collecteur exactement de la même manière que dans les machines Gramme et Siemens, ce qui permet d'obtenir, comme dans ces machines, des courants continus.

L'inducteur a d'ailleurs la même disposition que celui des machines Siemens, et le courant induit le traverse en totalité comme cela a lieu dans ces machines.

Les expériences faites devant nous à Genève dans les ateliers de M. Turettini, qui est le constructeur de ces machines, ont montré qu'elles ont à peu près le même pouvoir lumineux, pour une vitesse donnée, que les machines Gramme du modèle ordinaire; mais elles ont l'avantage de s'échauffer infiniment moins. En fait, on peut dire qu'elles ne s'échauffent pas du tout. Sous le rapport de la construction, elles présentent également quelques avantages. Ainsi, grâce aux parties nues des noyaux magnétiques, on peut fixer avec précision les tensions sur l'axe de rotation, ce qui est difficile avec l'anneau Gramme.

En somme, cette machine est très-intéressante et promet beaucoup.

TH. DU MONCEL.

MR. EDISON'S EXPERIMENTS.

From Nature Sept 4 1879

AMERICAN MASTER INVENTOR'S NEW DEVELOPMENTS.

THE Professors of Electricity Hunted Heroes in Various Quarters—Results of the Experiments Made in his Laboratory—The Power Used by his Instruments Estimated.

RAHATAN, Sept. 2.—Nine new inventions were voted in at the opening of the Association for the Advancement of Science to-day.

The following is the paper presented by Mr. Edison:

In the course of my experiments on electric lighting I have developed some striking phenomena which I think may be of interest to men of science and to the electric current, especially wires of platinum and platinum alloyed with iridium. These experiments are in progress.

The first fact observed was that platinum lost weight when heated in a flame of hydrogen, that the metal colored the flame green, and that these two results continued until the whole of the platinum in contact with the flame had disappeared. A platinum wire four-thousandths of an inch in diameter and weighing 306 milligrammes was heated together and successively in a hydrogen flame. On last weight of the rest of a fraction less than one milligramme per hour, as long as it was exposed in the flame. When a platinum wire is stretched between electrical clamping-rods and screwed up past its breaking strain, and it is raised to a light red heat when the temperature of the wire is raised above that of the flame by passing a current through it, the platinum is not lost by evaporation, but by combining with the flame and becoming a volatile oxide. A platinum wire twice-thousandths of an inch in diameter and weighing 306 milligrammes was heated in the blast of the Bunsen burner, and in ten minutes was broken in two in the middle. The two ends of the spiral were found to weigh 306 milligrammes, and the loss of platinum was 306 milligrammes exactly, showing no diminution and three inches thick. Upon subjecting the ends to the same treatment it became apparent that part of the globe in this case was not lost by evaporation, but by combination with the flame. Experiments repeated between the globe and the incandescent spiral would not be sufficient to account for the loss of the globe in the least period, calculated at 1 milligramme per hour. I am inclined to think that large globes of platinum might be raised successively by passing them at a high rate of speed through a flame, and, thus, kept from melting, would lose weight rapidly. Platinum in vacuum, together with the deposit upon the glass, presented a very curious character to the eye. Under the microscope the deposit appeared in a beautiful, regular, and very permanent crystal. As the cause was ascertained, I carried this view of the subject no further. I found that platinum alloyed with iridium would not lose by evaporation or combustion; under such circumstances I venture many, although I have not yet had the opportunity of making the experiment. I have mentioned the fact merely to show that the crystal from incandescent platinum was effect that may be produced with no clue to the weight of the carbon in the material, etc. After the experiments with platinum I made a number of experiments in order to ascertain the resistance of platinum under varying circumstances of temperature, and was surprised to find that the resistance of two equal pieces of platinum wire, one heated to incandescence in the air and the other to incandescence in a vacuum, was not the same, but that the resistance of the wire heated in the vacuum was greater than that of the wire heated in the air. The difference was found to be very considerable, and a higher exhaustion is required for some before the difference ceases. A platinum wire heated to incandescence in a vacuum of an inch three times per hour, and the resistance of the wire was increased about 10 per cent. Platinum wire heated to incandescence in a vacuum of one-millionth of an atmosphere showed a resistance of 20 per cent. greater than the resistance of the same wire heated to incandescence in the air. The wire was then heated to incandescence in a vacuum of one-millionth of an atmosphere for twenty minutes, and the resistance was found to be

[illegible] un journal on un abonnement de [illegible]
Les [illegible] à l'électricité et à la dynamite

L'Électricité fait connaître une [illegible] d'un genre nouveau.

Le [illegible] de guerre anglais, le *Vengeur*, a été envoyé sur les côtes d'Irlande par un autre navire l'*Iron Duke*. Désapprouvé de la relever, le gouvernement, après la résolution de faire sauter l'épave avec de la dynamite. Cette mission difficile, confiée au *Volontaire*, a parfaitement réussi à l'aide de torpilles explosionnées par l'étincelle électrique.

Les effets ont été extrêmement énergiques, comme on s'y attendait ; mais ce que l'on ne prévoyait point, c'est l'énorme quantité de poissons de toute nature qui avaient été foudroyés et qui furent trouvés flottants à la surface de la mer. Les marins de l'équipage du *Volontaire* auraient pu faire une pêche si abondante que le pont en aurait été encombré s'ils avaient ramassé tous les cadavres flottants dans le voisinage du navire.

On peut conclure de la richesse de cette pêche miraculeuse, que les torpilles pourraient être parfaitement mutilées, lors du passage d'un banc de harengs ou de morues sur un haut-fond. L'essai n'a point encore été tenté ; mais il mériterait d'autant plus de l'être que les pêcheurs pourraient être prévenus télégraphiquement ou par pigeons de l'arrivée prochaine des poissons dans les parages qu'ils fréquentent.

C'est là l'incompressibilité presque absolue de l'eau qu'est due l'énergie de cette action destructive, car les poissons reçoivent ainsi un choc équivalent à un coup de marteau, dont l'énergie décroît en raison inverse du carré de la distance au centre d'ébranlement.

S'il l'on voulait employer pratiquement cette méthode, on devrait répartir sur un espace plus ou moins grand un certain nombre de foyers.

L'expérience seule indiquerait la masse de dynamite qu'il faudrait employer à chaque centre d'explosion, masse qui serait plus ou moins grande elle-même suivant la profondeur de l'eau.

La condition la plus essentielle à remplir, pour arriver au maximum d'utilisation, serait la simultanéité absolue de l'explosion.

A new machine of Mr. Edison's invention, designed to turn power into electricity? is said to give back 92 per cent. of the power expended in the form of electricity. All these results point to a speedy solution of the problem of electric lighting, if it can be solved.

Chic Journal Oct 1879

THE SIEMENS-ALTENECK ALTERNATING CURRENT DYNAMO-MACHINE.

THE general construction of this machine is shown by figs. 1 and 2, fig 1 being a longitudinal section, and fig. 2 a front view. On the brass A are fixed the two iron frames B, carrying each a number of electro-magnets C, C (of which 16 are shown in the drawings), and bearings for the shaft E. On this shaft is fixed a disc D, carrying a number of coils c, of elongated shape, as shown by the dotted lines in fig. 2. These coils are wound in the plane of the disc or cores D of elongated shape. The electro-magnets C have their facing polar ends extended by fixing on them tangential iron plates F, and these plates and the coils c are so proportioned, that each coil has advanced over about half the width of the plate from which it is retreating. The coils of the magnets C are so connected that the two polar-fields facing one another are always of opposite polarity, also the polar-fields contiguous to one another are of opposite polarity, and thus the coils c, in passing through the successive fields, have alternating currents induced in them.

The collection of the currents induced in the coils c, by the passage of the latter through the magnetic fields of alternate polarity and the combination and commutation of these currents, and of such portions of them as may be employed for exciting the electro-magnets C, C, is effected in the usual way by contact rings H and the commutator G, provided with tangential contact brushes K, K. Such commutation of the currents through the coils C would be required if the apparatus were used as a direct current machine.

In using the apparatus as an *alternate* current machine, the electro-magnets C, C are excited by a separate dynamo-machine of the ordinary Siemens construction. The general view of this dynamo-machine, and also of the machine just described, which are together capable of burning 16 Jablochkoff candles, are shown by figs. 3 and 4 respectively.

The dynamo-machine, if used separately, will produce a light equal to 1,400 standard candles.

LIGHTING BY ELECTRICITY.—*Continued.*

DYNAMO-ELECTRIC MACHINES.—*Continued.*

We have in former articles described the duty magneto-electric machines of Holmes and of the Société l'Alliance* and the single torrent machines of Gramme† and Siemens.‡ Each of these machines is typical of a class, the last named forming a class by itself. We now come to speak of an order of machines to which the same multiple circuit has been applied, and to which order belong the machines of Lontin, Wallace-Farmer, and Wilde, as well as the multiple circuit machines of Gramme and Siemens.

In the Lontin machine, which we illustrate on the next page, the revolving armature is in the form of a six-shaped wheel consisting of a central boss P, Fig. 1, into which are fixed ten or more radial bars of soft iron, circular in section but slightly conical in form, marked in the drawing D D D. Each of these radial spokes is covered with a coil of insulated copper wire, the ends of which are connected together in series, and to a cylindrical commutator. The armature wheel is fixed on a shaft and revolves in the magnetic field of two powerful electro-magnets A A fixed vertically into a base-plate of iron by which they become the two limbs of a "horseshoe" electro-magnet. The cores of the radial magnetic inductors as they revolve approach very close to and recede from the poles of the inducing magnets A A, being at their point of closest proximity when their axes pass the line X X, Fig. 1. By Lenz's law, a coil approaching the north pole of a magnet has a current of electricity induced in it in one direction, and when receding from the same pole the induced current is in the opposite direction, and a coil receding from a north pole has a current induced in it in the same direction as a similar coil approaching a south pole, and *vice versâ*. Bearing these laws in mind, and referring to Fig. 1, it will be seen that when the machine is revolving in the direction of the arrows, all the radial bobbins above the horizontal line X X are receding from the left hand or south pole of magnet A A and approaching the right hand or north pole, while those below the line X X are doing just the very reverse, that is to say, they are receding from the north pole and approaching the south pole; the currents induced, therefore, in all the bobbins above the line X X are similar in direction to one another, but inverse to those below the line X X. The coils in the arrangement shown in the figure are coupled together in series as in the Gramme machine, and each pair of contiguous coils is connected to a sector P of the cylindrical commutator, there being as many sectors as there are bobbins, and insulated from one another by thin strips of ebonite B B C, against the surface of this commutator collectors *a a a a* are pressed by means of springs, the one taking

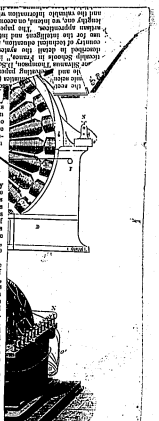

Fig. 1.

off the current from the sectors which are in contact with it, and conducting it to the binding screw 1, whence it passes through the electro-magnets A A, and returns by the binding screw 2 to the lower collector *a*, and so on round the machine. The current induced in the coils of the armature is thus caused to traverse the electro-magnets A A in such a direction as to increase the magnetism of the iron cores of the latter, and thus to increase the power of the machine. The electro-magnets A A are wound with a coil of insulated copper wire, the ends of which are connected to the binding screws 1 and 2, and the current induced in the armature coils is

NEW YORK, SEPTEMBER 20, 1879.

MORIN'S ROTARY DYNAMOMETER.

THE apparatus ordinarily used for measuring the work performed by a motor is Prony's brake, and the results obtained by this are very accurate. For measuring the work of machines actuated by a motor, dynamometer friction or tension plates are employed, but they are open to the objection of complication. M. Morin, then, has just produced a genuine service to all manufacturers by contriving a simple and practical apparatus for the purpose of measuring the work of machines used either in small workshops or large manufactories.

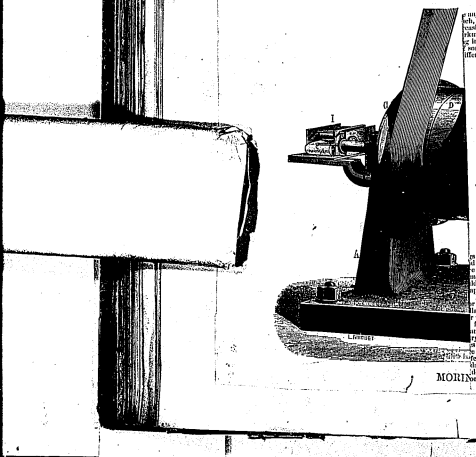
This new dynamometer (the illustration and description of which we borrow from the *Revue Industrielle*) consists of a flat cast iron disk mounted on an independent axle, and carrying a system of springs designed for receiving the effort transmitted by a motor machine. The power is transmitted by means of an endless belt and a shifting pulley on the shaft of the instrument, but which moves the flat disk through the intervention of a steel ribbon. When the machine is set in motion, the tension of the belt is transmitted to the extremity of the axle, and marks the movements of the spring upon a divided scale.

We thus know the effort, expressed in kilogrammes, that is exerted at the tangential point of the steel ribbon and the flat disk.

The whole have just seen, an apparatus for marking the number of revolutions is placed at one of the extremities of the axis of the apparatus, and an automatic register, placed at the other extremity of the same axis, traces upon an unrolling paper ribbon a diagram of the work produced and employed.

One of these two apparellees may be replaced by a totalizer, to make known, after any length of movement whatever, the power furnished by the motor, or the resistance offered by the machine actuated by it.

Morin's dynamometer resolves, as simply as it does correctly, every question relating to the force developed by all motor machines, as well as the work absorbed by the machines which are actuated by them. Two great advantages connected with this new apparatus deserve to be particularly noticed. The first is, that it measures the work, not



only at any given moment while the machine is in movement, but it continues to do so during the whole time the machine is in operation—two collateral causes to be ascertained. The second is, that of avoiding the stoppage of all the machines in operation (as required by the use of all other known dynamometers) when it is desired to observe the dynamometric effects.

The apparatus will occupy a place, then, that has never as yet been filled in experimental mechanics, and there will be no doubt as to its success. Its very low price places it within the reach of all classes of buyers, and its solidity as well as its simplicity permits of its being placed in any hands, even in those of employes who have had little mechanical experience.

MORIN

THE SIEMENS DYNAMO-ELECTRIC MACHINE.

TO THE EDITOR OF ENGINEERING.

SIR,—I have to thank Mr. Upton for the courteous tone of his criticism of the paper which I read before the Institution of Mechanical Engineers. In reply I would remark:

1. That the value of a Daniell's element was taken as nine-eighths of a volt as a rough mean of published results.

2. My paper does not pretend to minute accuracy, but rather to give rough easily obtained results of *the right order*, and that I would more accurate results may be obtained by those who will arrange apparatus with a single aim to the greatest accuracy, and who will not purposely gave in the Table results, in which it was apparent that the estimated power of the current was in excess of the estimated power applied. It may be well to mention some of the causes of irregularity, they are:

3. The varying temperature of the coils of the machine itself.

4. The uncertainty of the correction for temperature in the brass coils introduced in the main circuit. In a permanent laboratory there would be no fear or few fears as large a scale, but they would be on the same principle, that is, many comparatively thin wires would be used in order to obtain a large cooling surface.

5. The resistance of the lead line rose rapidly, and the consequent heating of the wire, when the current was of any intensity from this cause. The leading of the wire, which was German silver, introduces a much smaller error.

6. The main object of my paper was to show what ought to be ascertained concerning any machine, in order that our knowledge of it might be complete in kind, and sufficiently to insure the use of the electro-motive force should be known for the use of all constructors, and that the most contented capabilities of a dynamo-electric machine should at least include the resistance of the parts of the machine, the electro-motive force for a given speed, when the current is very powerful, and the total resistance which overpowers the machine, by the maximum current, this last was a little more than four-tenths.

7. I trust that the practical interest to the publication of the mass of valuable results which have been accumulating in Mr. Elliott's laboratory, and trust they will not be long delayed.

J. HOPKINSON.

IMPROVEMENTS IN DYNAMO-ELECTRIC MACHINES.*

By Mr. W. Lahn.

My object in this communication is to describe in a few words the peculiarities and improvements in the construction of Weston's Dynamo-Electric Machine. The general appearance and arrangement of the Field Magnets may be seen in the annexed engravings, where fig. 1 is a perspective view of the machine, and fig. 2 a similar view of

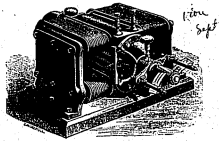

Fig. 1.

the armature. The pole pieces are composed of iron plates placed side by side in a mould, but separated a uniform distance from each other. The iron magnets on which the wire is to be wound are cast on to legs or projections on the ends of the plates. The two cast-iron ends and uniting plates form one magnet, the upper and lower magnets are alike, and when joined together by some perforated vertical supports, the inner curved edges of the field plates embrace about two-thirds of the circle in which the armature is made to revolve. The armature, which is seen at fig. 2, is built up of plates which are somewhat like a cogged wheel in shape. These plates are stamped out of sheet iron, and when mounted on the shaft are separated from each other at uniform distances. The radial projections are then arranged in lines, so that the whole forms a very broad cogged wheel, or cylindrical structure having longitudinal grooves with transverse spaces at regular distances. The longitudinal grooves are for carrying the wire, and

Fig 2.

it will be observed from the nature of the structure that the wire lies in channels three sides of which are iron; so that the mutual effect upon each other is increased as much as possible. The ends of the wires are connected to the field magnets and commutator in much the usual way, the currents travelling in one direction only. The commutator is fitted on a portion of the shaft, which projects beyond the bearings. This admits of its easy removal, and a new one being replaced in three minutes.

Another important feature in the construction is the arrangement for ventilation. The separation between the pole plates of the field magnets, the perforation in the vertical supports of the magnets, and the light framework of the armature, are all for this purpose. The air enters the centre of the armature, and is driven out between the layers of wire through the spaces formed by the separated plates of the armature and the field magnets, and thus prevents any part from becoming unduly heated. Machines of this description are made of various sizes and strengths, and give from one to sixteen lights in single circuit.

THE WESTON DYNAMO-ELECTRIC MACHINE.*

By Mr. Lahn.

My object in this communication is to describe in a few words the peculiarities and improvements in the construction of Weston's Dynamo-Electric Machine.

The Field Magnets.—The general appearance and arrangement of these may be seen in the diagram,

FIG. 1

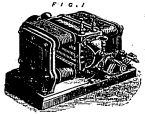

Fig. 1. The pole pieces are composed of iron plates placed side by side in a mould, but separated a uniform distance from each other. The iron magnets on which the wire is to be wound are cast on to legs or projections on the ends of the plates. The two cast-iron ends and uniting plates form one magnet; the upper and lower magnets are alike, and when joined together by the perforated vertical supports the inner curved edges of the field-plates embrace about two-thirds of the circle in which the armature is made to revolve.

FIG. 2.

The armature, Fig. 2, is built up of plates which are somewhat like a cogged-wheel in shape, see Fig. 2. These plates are stamped out of sheet-iron, and when mounted on the shaft are separated from each other at a uniform distance; the radial projections are then arranged in lines, so that the whole forms a very broad cogged wheel, or cylindrical structure, having longitudinal grooves with transverse spaces at regular distances. The longitudinal grooves are for carrying the wire, and it will be observed from the nature of the structure that the wire lies in channels, three sides of which are iron; so that the mutual effect upon each other is increased as much as possible. The ends of the wires are connected to the field magnets and commutator in much the usual way, the currents travelling in one direction only. The commutator is fitted on a portion of the shaft, which projects beyond the bearings; this admits of its easy removal, and a new one being replaced in three minutes.

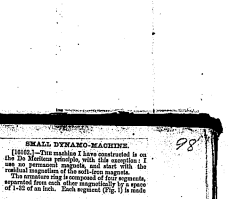
Another important feature in the construction is the arrangement for ventilation; the separation between the pole-plates of the field magnets, the perforation in the vertical supports of the magnets, and the light framework of the armature, are all for this purpose. The air enters the centre of the armature, and is driven out between the layers of wire through the spaces formed by the separated plates of the armature and the field magnets, and thus prevents any part from becoming unduly heated. Machines of this description are made of various sizes and strengths, and give from one to sixteen lights in single circuit.

98

SMALL DYNAMO-MACHINE.

[1868.]—The machine I have constructed is on the De Meritens principle, and is intended for use as permanent magnets, and short with internal inequities of the soft-iron magnets.

The armature ring is composed of four segments, separated from each other magnetically by a space of 1-32 of an inch. Each segment (Fig. 1) is made



of eight plates of steel-tape 2.32in. thick, placed on one another and riveted together, and wound with five layers of silk-covered copper wire No. 16, then screwed to the face of a brass disc and made to revolve between the horns of the two iron-ring magnets, by which means we get the currents reversed by the magnetisation and demagnetisation of the iron-rings as well as the inductive effect on the magnetism of the steel magnets, and thus you can do as a regular Gramme machine. The armature ring is only 4in. in diameter outside, and 3in. inside. The electro-magnets are very small, the cores being only 3in. long and 2in. diameter, and wound with four layers of No. 16 cotton-covered wire. They are arranged so that the poles are alternately N and S, and the armature ring, which revolves between the soft-iron horns (Fig. 2 side view, Fig. 3 front), they being screwed on to the end of each pole. One end of each segment will then be at the same time opposite the end of a pole, and the other between the horns of a magnet, with an air-space about 1in. of No. 20 Gramme copper wire on it to it is, but with larger magnets it would do much better. The segments all being wrapped the same way, the currents generated in each of the same lines are opposite, and have to be made to run in the same direction round the armature before going to the electro-magnets. I get the best effect by coupling the wire of the segments, so as to get the electromotive force of two and the quantity of two, the same as you would a battery of four cells. The residual magnetism of the poles is so small, that neither pole will affect a small pocket-compass at the distance of 1in. from it, and the machine will run at about 600 revolutions a minute the wires are changed instantly on closing the circuit. If any further particulars are wished for, I shall be happy to give them through these columns.

Hatfield, Mass. Chas. Cutteris.

99

DE MERITENS'S NEW MAGNETO-ELECTRIC

Jan. 8 1878 NE 043 23/679

Jumored by the number of little lamps that this machine is capable of lighting, it might be thought that it formed the most powerful magneto-electric generator for a given motive force. It might, in fact, with a motive force not exceeding one horse power, suffice to keep three Jablochkoff candles lighted indefinitely, without requiring of the motor a velocity of over 700 revolutions per minute, and without the production of any appreciable heat. But the light furnished by these candles does not seem to be so strong as that from candles fed by the Gramme machine; and until we have more accurate measurements we cannot definitely judge of the relative power of this generator. The machine is magneto-electric, and furnishes, like the Alliance, reversed currents; but to produce the same effect it requires only eight Alvarez magnets instead of forty-eight, and only a fourth of the motive force; at least this is what M. de Meritens asserts.

The advantages derived from the use of this kind of a machine are due as the fact that to the induction currents set up in the ring of the Gramme machine are added those which are produced in the ordinary magneto-electric machines.

That we may understand this, let us imagine a Gramme ring (Fig. 1) divided for example into four sections, magnetically insulated from each other, and consequently forming four arched electro-magnets placed end to end. Let us imagine that the iron core of each of these sections terminates at each of its extremities in a plate of iron, A B, forming as it were an outspreading of its poles; and let us suppose that all the coils are fed by a proper source, C D, form a solid ring around which are arranged permanent magnets, N, S, N, S, whose poles alternate with each other. Now let us see what will happen when this ring shall have made a movement of rotation; and let us first see what will be the result, for example, of the approximation when the outspread pole, B, moving from left to right, nears N. At this moment an induced magnetic current will be developed

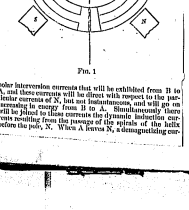


FIG. 1

in the electro-magnetic helix, A B, as in the Clarke machine. This current will be instantaneous and in an inverse direction to the Ampère currents of the inducing magnet; and it will be very powerful because of the proximity of B to the pole N. But the ring in moving forward will set up a series of magnetic displacements between the pole, N, and the core, A B, and which will give rise to a series of

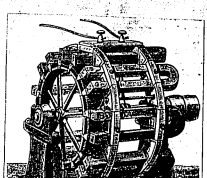

FIG. 2.

rent will be set up, equal in energy to and in the same direction as the inducting current read[illegible] from the approximation of the outspread pole, B, to the pole, N. The effect is then produced, in fact, at a different extremity of the magnetic core, and the helix is submitted to the action of induction in an inverse manner. We have, then, inverse induced currents of the inductor caused by the approaching

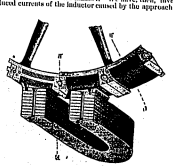

FIG. 3.

and receding of the appendages, B and A; direct induced currents during the passage lengthwise of the core, A B, before the inductor; and direct induced currents resulting from the passage of the spirals before A in other words, we find in this combination all the causes of induction united.

It will be observed that the action that we have just studied with regard to a single section may likewise take place at the same time in all the others, and that to this are also added the currents resulting from the lateral reaction of

polar intervention currents that will be exhibited from B to A, and these currents will be direct with respect to the particular currents of N, but not instantaneous, and will go on borrowing in energy from B to A. Simultaneously there will be joined to these currents the dynamic induction currents resulting from the passage of the spirals of the helix before the pole, N. When A leaves N, a demagnetizing current

the poles, A and B, on the neighboring cores. In order to still further increase the effects of induction, M. De Meritens forms the core, A B, and the appendages, A and B, of plates punched out of thin iron, as seen in the figure, and juxtaposed to the number of fifty in bundles, each plate being one millimeter (0·04 of an inch) thick. The wires of the helices, moreover, are so wound that they can be submitted to tension, in quantity, or in series, according to the conditions under which they are to be applied. In the theoretical figure which we have considered, we have given only four sections; but in point of fact there are a larger number, and in the model of which we have spoken there are sixteen of them, and these may be readily distinguished in the figure (Fig. 2). They are mounted on a bronze wheel fitted to the shaft of the motor. Above this wheel are found the inducing magnets placed horizontally, and firmly fitted into two bronze skeleton frames (Fig. 3). A very slight inspection of the way in which the induced ring is placed will at once show that it could not possibly have been constructed in a better manner. Indeed, as each section is separate, it can be taken out by itself, and in wire consequently wound upon it without any trouble. Those who know the difficulties attending the winding of the Gramme ring will see the precedent advantage. The second point, viz. the fact of the magnetic insulation of juxtaposed plates, which may be cut out at a single blow of the punch, also presents an immense advantage; for this system dispenses with the precision that is necessary in constructing thole-rings, which are always so difficult to keep perfectly round. Finally, there is neither a commutator nor collector in this machine, and consequently no loss of current.

We have seen that the currents furnished by this machine could light three to four Jablochkoff candles; but it has been found equally possible to light regulators, and in the latter case it has been found possible, too, to separate the carbons as far as 5 centimetres (2 inches) apart without extinguishing the light. These results are certainly very important.—*Ch. de Mosnel, in La Nature.*

SMALL DYNAMO-MACHINES.

To the Editor of the Electrical Review.

SIR,—I see the editor of *Engineering* has made bulls of 70 Gorman silver wire." I was mistaken as to the size, and having got a little time to spare, I have tried it more exactly, and find the wire is 0·0135 inch in diameter. I have also found it will be best to bind. I think one great cause of failure in these small dynamo machines is that the resistances of the armature and the magnets are not in proper proportion to one another. In my machine, firstly, when the two magnets are joined up in one circuit, the end of one set of coils to the terminal, and the end of the other magnet coils to the frame, and the 4 armature coils joined up in the same way give 1·42 Ohm; the result is that the machine will not work. Secondly, joining up the armature coils, two for quantity and two for E.M.F., their resistance becomes 0·71 Ohm, and the machine works splendidly. Thirdly, joining the electro-magnetic coils in multiple arc, their resistance becomes 0·71 Ohm, and the machine will not work till (fourthly) I have connected up all the armature coils for quantity, reducing their resistance to ·19 Ohm, and then not so well as in second case. Therefore, I think it safe to say that there must be a certain proportion between the two, and the nearer we get to 1 to 1 the better. Also, I believe one reason the armature should have the least resistance, and that a current of great quantity rather than E.M.F. is necessary. "Ohm's" difficulty (No. 1682) may be greatly owing to this, and although his machine will run very well as an electro-motor, and give a powerful current (at high E.M.F.) when the armature coils are changed by battery, it will still not be able to work as a dynamo.

I am afraid that [illegible] so far away my letters may arrive after someone else has been over the same ground, and, therefore, not be worth the setting up.

In conclusion, I would say, Do not give up any machine you may have on hand, as the theory is right, and with patience they can be made to work. Especially those where the currents resulting from the magnetization and demagnetization of the armature, as well as the Gramme effect on the wire can be utilized, viz., the Brush (American) Wilde, De Meritens, and Lontin machines.

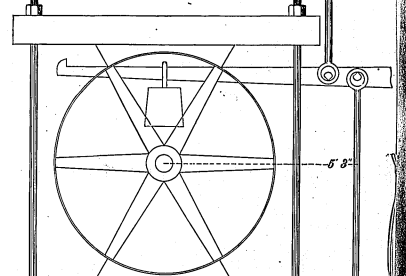
Some Engine Tests.

(*Letter Received March 2nd, 1878.*)

I enclose you the results of the tests on Engine Tests made at the St. Louis Exposition last fall, with a sketch of the dynamometer that was used. I have also made an attempt to draw isothermal lines on two of the cards given in the report, and to locate the terminal pressure as nearly as possible on the third. The outside lines on the cards *A* and *B* are mine, and the inside lines are as they appear in the report. The short line projecting from the right of card *D* was also on addition.

Three entries have been made for this test, which was made Thursday, September 12th, 1878. The three engines tested will be designated as *A*, *B* and *C*.

A was a horizontal frame, iron jacketed, slide crank, steam chest on the side of the cylinder, with variable expansion, balanced slide working on the back of the main slide on what is known as Hyde's system, the change in cutting-off being made by a right and left hand screw, changing the lap of the



Dynamometer used in the St. Louis Engine Tests.

expansion slide. The cylinder is lagged and covered, but not steam jacketed, governor acting on throttle.

B was a cylinder 10"×20" lagged and covered, but not steam jacketed, with strong horizontal frame; the main feature of the engine being an automatic or governor cut-off, consisting of an expansion slide on the back of the main slide, worked from an auxiliary center connected with the main shaft by spur gears. The change in cut-off is effected by changing the load of the expansion slide, which is done by the governor acting through a bevel sector, steam chest on the side. The remainder of the engine is of ordinary proportions. Slide crank.

C was a cylinder 13"×24", horizontal trough frame, common slide valve, steam chest on top, bent rock shaft. Cylinder covered, governor on throttle, disk crank.

The percentage numbers given by the compilers are the average of the individual tests on the different points. The testing apparatus consisted of a dynamometer shown herewith, designed by the Scientific which proved a very reliable piece of apparatus, an engine counter, a standard steam gauge, a Fahrenheit scale, a tank for weighing the feed water, and, as a small scale and three

meter for testing the dryness of the steam. A Hickard's Indicator had been provided by the committee, but upon agreement with the exhibitors a Thompson Indicator was used. The test was made three hours in duration.

Referring to the *A* card we find an average effective pressure of 23.4 lbs., a terminal of 23 lbs. corresponding to a value of 1063.3 according to Zeuner, and figuring it out according to Engineering Papers I we have a water consumption of 15.3 lbs. per I. H. P. per hour. The point of cut-off due to the terminal pressure is very nearly $\frac{1}{4}$ stroke. The clearance is assumed to be about 3 per cent., in both *A* and *B* cards, in *C* perhaps 8 or 10 would not be far off. The actual water consumption of the *A* engine, per report, was 15.5 lbs. per I. H. P. per hour. The *B* card shows a water consumption of 28 lbs., and the point of cut-off due to the terminal pressure is about $\frac{1}{3}$ stroke.

The *C* card shows 30·05 lbs. average effective pressure, 32 lbs. terminal corresponding to nearly 37 lbs. water per I. H. P. per hour. The actual consumption of this card, per re-

space of the brake, it being held in a horizontal position by the scales. The distance from the center of engine shaft to the center of scale attachment was 5′ 5″, or rather a radius corresponding to a circumference of 31 ft. The engine was started with the brake loose; and after it got up to its speed the desired load was applied by tightening the break blocks on the pulley. The resistance occasioned by the friction could thus be weighed with considerable accuracy. The question was asked a member of the committee how the power was calculated with this instrument, but the information was politely withheld. The calculation is simple and reveals itself on a second thought—the base of the calculation being that force, time and velocity equal the power, the weight shown by the scale to be considered the force and the velocity, the speed which it would travel if fixed to revolve with the shaft. For example, take an engine making 100 turns per minute and balancing 200 lbs. on the scales, which is virtually a force of 200 lbs. traveling 33 ft. every revolution of the engine, or 3,300 ft. per minute, which equals

$$\frac{33 \times 100 \times 200}{33{,}000} = 20 \text{ H. P.}$$

The object in attaching the scales 5′ 5″ from center of shaft was to facilitate the calculation in case the engine ran 90, 100, 150, etc., as in this case it is only necessary to add 1,000 by the revolutions per minute to the weight by this quotient, in the above sample it would be

$$\frac{1000}{100} + 10, \frac{200}{10} = 20 \text{ H.P.},$$

which is easily calculated without the aid of paper and pencil.

J. H. Dubbs.

Sept. 18, Cleveland, O.

---

duce current in the coils of the field magnets, and these currents are all in such a direction as to increase the already existing magnetism."

If this action is exact (and, it will be found to be strictly a corollary from the law of Lenz, and this principle may be applied to De Meritens', Alliance, Lontin's, Gramme's machines, and also to the Siemens-Hefner drum and the Siemens with the connection of the field magnets with a magnetizing armature, and still retain the increasing action and reaction which takes place in three machines as presently constructed.

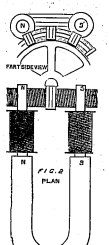


Fig. 2 shows how I apply this principle to the De Meritens machine, by attaching coils and soft iron pole-pieces to the permanent magnets; only one magnet is shown. Current will be induced in these coils by the motion of the segments on the shaft, and will be increased by the reaction upon the current from the segments. By attaching pole-pieces and coils to the permanent magnets of the Alliance machine, you can more than double its power in the same way.

I have modified the Gramme ring, and field-magnets, so that this principle may be applied to it also.

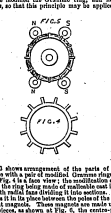

Fig. 3 shows arrangement of the parts of the machine with a pair of modified Gramme rings, of which Fig. 4 is a section. The magnets are on each side of the ring being made of malleable cast iron, and with radial fans dividing it into sections. Fig. 3 shows it in its place between the poles of the four straight magnets. These magnets are made up of three pieces, as shown at Fig. 5, the centre-piece being hard steel, the ends of soft iron. This construction is not, perhaps, indispensable, but secures a large amount of residual magnetism: the

commutator is of the same construction as the Gramme.

The action of this machine is very similar to the action of the Gramme, with this difference: the coils on the magnets are not connected to any ring or armature for magnetizing them.

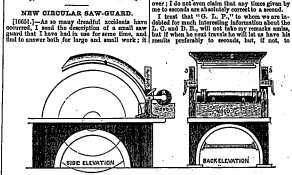
The field magnets are magnetized by the current induced in their coils by the inductive effect of the coils on the rings, as they revolve in the magnetic field of the magnets, and by the reaction on each ring and core through the coils on the magnets; and the same increasing action and reaction takes place-as in all other machines, although in the same position and not made in any machine for this purpose.

Orkney, Dec. 1. Hamlin Kennedy.

NEW CIRCULAR SAW-GUARD.

[16553.]—As so many dreadful accidents have occurred, I send the description of a small saw guard that I have had in use for some time, and find to answer both for large and small work; it

consists of a protecting frame of sheet-iron, G, hinged upon two standards SS, so as to work freely for almost any size of wood; there is a roller at bottom, R, which presses against the wood to be cut, and keeps the guard down; the guard can be safely raised up by attendant, as it is supported by cut themselves (unless removing guard); two elevations are shown in plan made smaller than working, as it would take up too much room if shown in your copy; the saw is shown in large circle than in work, for clearness; the dark-shaded parts represent cast iron. D. Tervin.



SPEED OF TRAINS.

[16552.]—In J. A.'s letter on p. 695 he has answered my letter, November 1st, p. 325, but I cannot find that I have stated in any of my letters that speeds not worked out in seconds are not trustworthy," as stated by "T. P." With the latter's views on p. 313 I am more in agreement, but in these days of competition with the speeds of two of the principal railways, it would be unwise to trust to figures alone. In writing letter on p. 291, Vol. XXVIII., supposing my doubts as to the trustworthiness of speeds *for short distances*, when the times have not been taken to seconds, I had then in my mind "if L. P.'s" timing of a train, which I had seen, was correct, as in the letter signed "G. D. P." on p. 147 of this volume he has to repeat these remarks esp. 147, but if I have wrongly ascribed to "T. P." the authorship of that letter I willingly acknowledge my error.

Now, "G. D. P." in his last letter states "that in any case it was impossible to miss more than two 'posts' in a second." In his letter on p. 291, Vol. XXVIII., he gives 2 miles run in 72 min. = 55·45 miles per hour; 2 miles run in 71 min. = 56·33 miles per hour; 2 miles run in 70 min. = 57·14 miles per hour. Between 55·45 and 57·14 miles per hour, or between 2 miles run in 72 min. and 2 miles run in 70 min., a difference of 2 minutes, or 120 seconds, might give 2 miles in 2m. 35sec., or in 2m. 55sec., or 20 seconds. Now, supposing the 2 miles were actual, and not assumed, figures, 2m. 35s. = 155 seconds, that we have 1 mile from Bromley to Shortlands run in 1 minute, a speed of 88; in this case it must be twelfth of a minute, when the possible error is not more than 1 seconds, he will become a reliable authority on the question of speeds.

My difficulty lies in not knowing the exact position of the engine when "G. D. P." and "T. P." observed that, and, consequently the ascertainment of relative the posts and of being unable to record some exceptionally fast runs. V.

G. W. R. LOCOMOTIVES.

[16553.]—I was pleased to see the letter of "T. P." on G. W. R. engines. This list, on account of its two gauges and its extensive absorption of other lines, presents a type of engine not found in any other railway on the kingdom, and although the principle of improvement has taken place in them, yet I think at present it is much behind several other companies in that respect.

The long, comparatively broad-gauge engines which run the "Flying Dutchman" belong to a past era in locomotive construction, and although they have in their favour that they working almost entirely loads—the latter a most important consideration—are locked out, they will be found greatly inferior to G. N. or Midland engines.

The only suitable cylindrical engine I know is No. 230, a six-coupled narrow-gauge goods, but I have not had an opportunity of seeing it, although arrangements can be made to which the cylindrical are placed.

Several new narrow-gauge single engines, and 70, drivers, have just been built at Swindon. These engines have not any frame, and are made entirely from 1/2.

"T. P." will find some information as to measurements of driving-wheels, &c., of G. W.

LOUTIN'S DYNAMO-ELECTRIC MACHINES.

The dynamo-electric machine recently invented by M. Louis Antoine Loutin, of Paris, is just now acquiring considerable notice in France, and chiefly because of a series of experiments lately carried out with it at the Lyons Railway station, Paris. Loutin has made some important improvements in dynamo-electric machines. In 1875, he patented in England a plan for turning the whole of the electricity produced in the revolving armature, or bobbin, of a machine into the existing electro-magnets, instead of only a portion, as had hitherto been done. This of course renders the exciting magnets very powerful in a short time, and the magnetic resistance to the rotation of the bobbin increases in a few moments to such a degree that it is almost impossible to overcome it. The circuit is then broken by an ordinary commutator, and the special circuit in which useful work is required to be done, such as the apparatus for producing arc-light, electro-plating, etc., is inserted so as to form part of the circuit. The action of the machine then becomes normal and continues so, the superabundant energy of the current being utilized in chemical decomposition. M. Loutin proposed to himself all the applications which might result from this new mode of employing the current from any sort of dynamo-electric machine, whether in the production of chemical, magnetic, heating, or lighting effects. He also proposed to use this class of machine, in which all the current is centred into the inducing electro-magnets, or, in other words, which have a single circuit, such as powerful breaks. When the

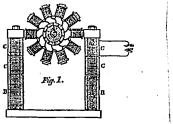


Fig. 1.

circuit is open the bobbin turns without any difficulty, but as soon as the circuit is closed by the slightest contact it exercises considerable resistance to rotation. A machine exciting 100 lamps, for example, requires but the weight of a child to turn it; when the circuit is open, but six or eight horse power will be insufficient to overcome the resistance to turning when the circuit is closed. All this effect is brought about by the simple act of making a contact. The machine itself immediately generates the magnetism necessary to produce this magnetic break-power, which may be applied in various ways.

In 1876 (Patent Nos. 386 and 3584) Loutin patented in England further improvements of magneto electric machines. One defect in machines is the great heat developed in the bobbin or bobbins, which is due to overfrequency of the induction in them. To overcome this objection Loutin multiplies the number of bobbins or parts of the revolving armature. He constructs the armature in the form of a wheel provided with a central boss and spokes of soft iron, and mounted on a shaft in which rotary motion can be imparted. This wheel is represented in Fig. 1 at A. Each soft iron spoke of the wheel has a coil or bobbin of insulated wire on it, and is, in fact, an electro-magnet, which becomes a source of induced electricity when the wheel is revolved between the poles of a fixed electro-magnet, B B, as shown in the figure. The residual magnetism of the cores of B B is sufficient at first to generate a feeble current in the bobbins when the wheel is revolved, and a portion of this current sent in one direction by a commutator is diverted in the usual manner into the electro-magnets B B, in order to intensify them so that they may in turn induce more powerful currents in the bobbins. Loutin reserves the right of employing one or several of these induction wheels on the same shaft, or coupling them opposite one or more series of electro or permanent magnets. When two wheels are fixed to the same shaft, one of them can supply currents exclusively for feeding the electro-magnets, and the currents from the other can be used for external work. When there is only one wheel on the shaft, as a portion only of the current generated is employed to feed the magnets, the remainder can be turned to other purposes. If these currents are required to be invariable in direction, a commutator or collector is used, otherwise the electricity may be collected by friction or contact clups. When commutators are used, one for each bobbin, or at most each pair of bobbins, is placed on the shaft, and to each are attached the two extremities of the wire of the bobbin or pair of bobbins corresponding. When collectors are used all the bobbins on the wheel are connected up in series so as to form a completely closed circuit. The result is that all the bobbins which are approaching a pole of the electro-magnet are inversely electrified to those entering from the same pole. A metal strip or rubber is placed opposite this pole of the electro-magnet to collect by contact the electricity generated in the bobbin at the instant that its polarity becomes reversed, a similar rubber being applied at the other pole of the electro magnet to form the second pole or electrode of the machine by which the induced current is led away. It will be seen that if the arms of the wheel are sufficiently numerous the induced current will be continuous and even in quality. Commutators are liable in powerful machines to rapid destruction by the oxidizing and volatilizing heat of the sparks emitted. M. Loutin avoids this satisfying effect a presence of air by inclosing the commutators in a bath of non-drying oil. This precaution is not necessary with small machines.

Various modifications of this machine are described by Loutin, who also points out that it can be efficiently utilized as an electric motor. Whether the wheel be placed between the poles of a permanent or an electro-magnet, if actuated by a battery or a dynamo-electric current it possesses considerable motive power

The most valuable of Loutin's improvements seems to be his plan of constructing dynamo-electric machines in such a manner that the inducing electro-magnets shall have a rotary motion, while the induced bobbins remain stationary, thus reversing the ordinary method of working. Fig. 2 is a representation of a machine of this kind. An induction wheel, A A, revolves in front of the poles of a series of electro-magnets, B B. The bobbins of the induction wheel are not fed with the currents they themselves produce in the electro-magnets by the current of a spare magneto-electric machine, but through them, and on rotation of the wheel they induce in the surrounding bobbins B B a series of currents which may be utilized without employing any collector or contact of any kind. For example, in a machine having fifty induced bobbins fixed round it could be fifty sources of electricity, which could be used either separately or combined. A special application of this plan is the production of any desired number of electric lights, and it is this form of

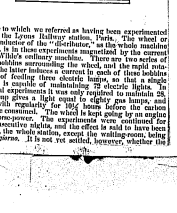

Fig. 2.

machine to which we referred as having been experimented with at the Lyons Railway station, Paris. The wheel or armature, inductor of the "distributor," as the whole machine is called, in these experiments magnetized by the current from a Wilde's ordinary machine. There are two series of twelve bobbins surrounding the wheel, and the rapid rotation of the latter induces a current in each of these bobbins capable of feeding three electric lamps, so that a single machine is capable of maintaining 72 electric lights. In the actual experiments it was only required to maintain 28. Each lamp gave a light equal to eighty gas lamps, and works with regularity for 1000 hours before the carbon wicks are consumed. The wheel is kept going by an engine of 40 horse-power. The experiments were continued for forty consecutive nights, and the effect is said to have been splendid, the whole station, except the waiting-room, being lit up *a giorno*. It is not yet settled, however, whether the Railway company will agree to the increased expenditure of this method over gas in order to secure the better light.

Another modification of this plan, similar to that described, patented in England in 1876, consists in prolonging the core of the inducing electro-magnets B B of the machine shown in Fig. 1, so that one or more additional coils of insulated wire, or bobbins, C C, can be placed upon them. These will be fed with A in this machine is turned into an inductor, by means of the currents already induced in it by the electro-magnets B B. It will be by rotation induce currents in the additional bobbins, C C, which can be led away, and utilized for the production of separate electric lights as shown, or combined together. These bobbins yield rapidly alternating currents, because the induction in them is due to the successive recession of each bobbin of the inducing wheel. This machine is, therefore, handy as yielding alternating currents from the fixed bobbins, and unvarying currents from the movable ones.

By the use of the distributor and the method last described, either separately or conjointly, currents can be taken off with either for tension or quantity, either wholly or partially, alternating or uniform, and without employing any collector for the alternating currents.—*Engineering.*

GRANDES

EXPÉRIENCES DE LUMIÈRE ÉLECTRIQUE

Faites au Mont-Valérien

La première idée de l'application de la lumière électrique à l'art militaire remonte à la guerre d'Italie en 1859.

Une Société fut formée à cette époque pour exploiter, en vue de cette application, la pile de Grenet, et l'on put voir circuler dans les rues de Paris une voiture portant une pile et une lumière électriques.

La paix de Solférino mit fin à ces expériences dont, avec les moyens alors connus de produire l'électricité, on aurait pu attendre des résultats pratiques sérieux.

En 1867, à l'Exposition universelle de Paris, l'Autriche avait envoyé une parabole métallique de grande dimension, ayant une lampe électrique à son foyer; à côté étaient exposés plusieurs dessins, montrant diverses applications qui pouvaient être faites de cet appareil à l'attaque ou à la défense des places ou à d'autres opérations militaires.

Les premières applications pratiques que nous connaissons datent de la guerre franco-allemande, du siége de Paris. On n'obtint, à cette époque, aucun résultat saillant. Cela tient, d'une part, à ce que, pendant cette opération militaire, les attaques par l'artillerie n'eurent lieu qu'à de grandes distances et à ce que les tentatives d'attaque de vive force furent extrêmement rares; d'autre part, à ce que les moyens dont on disposait pour produire la lumière et la projeter à distance étaient hors de proportion avec la portée des engins d'artillerie. Les producteurs d'électricité étaient des plus et la machine de l'Alliance (la machine de Gramme était à peine inventée); les appareils : des projecteurs, des réflecteurs paraboliques ou sphériques de petits diamètres; quelques combinaisons plus ou moins ingénieuses de lentilles, et un projecteur lenticulaire « L. Sautter, Lemonnier et Cie ».

Malheureusement, les machines du l'*Alliance*, à cause de leur poids considérable, ne se prêtent point à accompagner l'armée dans des mouvements stratégiques, et l'immobilité de leur stationnement diminua dans une proportion considérable les résultats qu'elles étaient appelées à rendre.

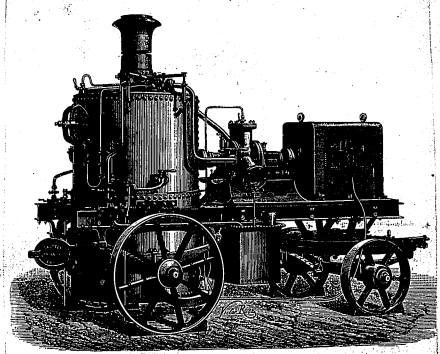
Le principal résultat de ces patriotiques efforts fut donc de démontrer qu'il était nécessaire d'avoir des appareils mobiles pouvant opérer hors de l'enceinte et la place et susceptibles d'accompagner certaines opérations. A cet effet, on étudia des piles portatives très-ingénieuses d'ailleurs, mais dont les dimensions encore encombrantes ne permettaient pas un emploi courant.

Si la lumière électrique employée dans ces conditions ne paraît pas aux assiégés d'une grande utilité, les assiégeants n'en jugèrent point ainsi, car, dès cette époque, les Allemands s'en occupèrent. En 1873, nos ennemis envoyaient à l'exposition de Vienne, dans leur section, un appareil de projection de lumière électrique approprié aux usages de la fortification ou de la côte que l'on veut éclairer.

Cet appareil, décrit en détail dans le *Mémorial de l'officier du génie*, se compose d'un miroir en verre concave-convexe, à surfaces sphériques de rayons différents. La face convexe est recouverte d'argent et est réfléchissante.

Entre le miroir et le foyer est interposée une lentille concave-convexe dont la concavité est tournée vers le foyer lumineux. Son rôle est de recueillir au profit du miroir une plus grande quantité de rayons de la source lumineuse et d'augmenter ainsi l'amplitude du champ éclairé.

Le faisceau qui sort de cet appareil, quand la lampe est au foyer de la lentille, est parfaitement limité par une circonférence presque sans pénombre.



Machine de Gramme portative, système Sautter-Lemonnier et Cie

Il n'a de divergence que celle due à la dimension de la source lumineuse, c'est-à-dire 2 degrés 1/2 environ.

Les expériences ont eu pour but d'essayer à quelle distance l'on peut éclairer soit un espace étendu, soit un espace restreint; enfin, de constater qu'on peut déterminer à l'avance pendant le jour, avec un chercheur, les points dangereux dont l'exploration nocturne offrira de l'intérêt pendant la nuit.

On est parvenu à rendre visible à 3,400 mètres le clocher de Saint-Cloud avec le plus petit des types adoptés. Avec le plus grand, on a éclairé les tours du Trocadéro dont la distance, n'est pas moindre de 7,800 mètres et les moindres détails se trouvaient visibles à merveille.

Le champ éclairé à 3,300 mètres de distance avait une largeur de 300 mètres sur laquelle on pouvait compter les fantassins envoyés à dessein dans la zone éclairée.

Tous les officiers d'artillerie présents ont hautement manifesté leur satisfaction et déclaré que la lumière électrique avait désormais sa place marquée dans les grandes opérations stratégiques de la guerre offensive aussi bien que défensive.

Cette belle et grandiose expérience aura certainement un retentissement considérable dans les armées de toutes les nations

HALLEZ D'ARROS

109

about 205 degrees, the special feature of this heater with the fact that exhaust steam is not mixed with the being that the exhaust steam is not mixed with the feed-water; that the water is heated after passing through the pump, thereby getting rid of the difficulty of pumping very hot water; and that the entire whole of the heating surface over which the feed water passes can be exposed for cleaning in less than five minutes by the removal of two small covers.

The heating wires from the machines to the lights in the Reading-room are brought over the roof of the buildings to the lantern on the top of the dome, being a distance of about 200 yards, whereas the leads for the other lights are laid partly in the basement and partly in pipes underground.

EDISON'S ELECTRIC GENERATOR.

When Mr. Edison said he was about to produce a practical economical electric light for general use, the entire business world took it for granted that it was forthcoming. Gas stocks tumbled both in this country and in Europe, and the people waited for the coming light. Scientists having had experience in this direction shook their heads, but for the most part suspended judgment.

Delay on the part of Mr. Edison comforted the holders of gas stocks, and confirmed the scientists in their belief that he had undertaken not only a task of great magnitude and difficulty, but one that would require more time and means than could be controlled by most experimenters. But Mr. Edison, flushed by his scientific victories, was undaunted and determined to yield to no obstacles.

Unfortunately, however, the daily papers from time to time printed reports of progress in electric lighting, which, from their extravagance and inaccuracy, placed Mr. Edison, to say the least, in an extremely embarrassing position as regards his alleged promises and the expected fulfilment of them, besides misleading the public as to the true nature of the problem to be dealt with, resulting in a reaction of feeling prejudicial to Mr. Edison's just fame.

At present little is said by Mr. Edison concerning his electric light, excepting that he considers it an assured success, and that he is perfecting the details of his electric lighting system as rapidly as possible.

It is not our purpose just now to enter into a description of Mr. Edison's electric lighting system as a whole, but to describe his new electric generator—one of the most important factors of the system—and also to describe his new electrical motor used in driving light machinery for domestic and industrial purposes.

The new generator resembles in some respects other well known forms, but it differs from them all in several very important particulars; for instance, the field-magnets are immense, being about 54 inches high, and weighing about 1,700 lbs. The magnet cores—of wrought iron—are 6 inches in diameter, and 36 inches long; they are mounted upon heavy cast iron blocks, 10½ inches high and 9 inches wide, and are connected at the top by a wrought iron yoke, 6 inches high and 7 inches wide. The cores are wound with 3 layers of No. 10 cotton covered wire, the ends of which are connected with binding posts on the base of the machine. The two blocks upon which the cores rest, as well as the bearings of the armature, are supported by a cross-shaped brass casting.

The armature which revolves in the cylindrical space between the poles of the field-magnet is shown in section in Fig. 1. It consists of a wooden cylinder, A, mounted on a 1½-inch shaft, and having attached to its ends soft iron plates, B, between which there are several layers, 10, of No. 20 soft iron wire wound circumferentially. Outside of the iron discs, B, there are vulcanized fibre discs, C, having their peripheries notched to receive the several coils, E, of insulated wire wound lengthwise on the cylinder and connected with copper bars, F, of the commutator cylinder, G. There are 48 coils inch wires in each strand, and each strand passes lengthwise around the cylinder on diametrically opposite sides, the opposite ends of all of the wires in each strand being soldered to commutator bars on opposite sides of the commutator cylinder. There are 40 strands surrounding the armature, and the commutator cylinder is pressed on opposite sides by copper wire brushes which take off the current. The armature shaft has a 10-inch pulley with a 3-inch face, and the speed of the machine is about 700 turns per minute. Although the current from the armature may be used to excite the field-magnet, Mr. Edison finds it more economical to charge the field-magnet by means of a separate machine. In fact, he intends to charge a battery of such generators with a single Parsell engine of this form.

An important fact has been developed in the course of Mr. Edison's experiments with this generator. He finds that by connecting the ends of the field-magnet by a copper wire for a moment when the machine is at rest, the field-magnet retains almost its maximum charge, which it retains so long as the generator is in continuous operation. It requires a minute or more to fully charge the immense magnets, and when charged their influence is far reaching and powerful. The internal resistance of the armature is only ¼ ohm, and Mr. Edison claims that he realizes 90 per cent. of the power applied to this machine in effective external current. It requires but 3 horse-power to drive it, and the current generated is sufficient to make 40 lights of 16 candles each. The economy of this machine is shown by the fact that one man may turn it with sufficient rapidity to maintain the electric arc of a Jablochkoff candle.

While this generator in general principle is the same as in the best of the well-known forms, still there is an all-important difference, which is that it will convert and deliver for useful work nearly double the foot-pounds of energy that any other machine will under like conditions. It has been shown by Hopkinson that the Siemens machine, which is generally recognized as the best form yet devised, converts from the belt to the circuit 92 per cent. of the energy, but later corrections reduce this to 83 per cent.; from these results many scientists have inferred and stated that there was little margin for improvement in the generating machine. Now the energy converted is the product over the whole resistance; hence if the resistance of the machine be represented by 1, and the exterior

elements face seen saturate, et qu'alors le courant excitateur est déjà trop puissant. On pourra le réduire avec avantage en employant un plus petit nombre de bobines dans le circuit des excitatrices.

Nous voici arrivés à un résultat important qui, je l'espère, est clair pour vous tous et dont vous voudrez bien vous souvenir, à savoir que :

Une machine dynamo-électrique, avec un excitateur séparé, marchant à grande vitesse par l'action d'un moteur à vapeur ou d'un moteur à eau, à haute ou basse pression, et envoyant un faible courant par un conducteur, même assez fin, à un électro-moteur placé à distance, tournant aussi à une grande vitesse, et magnétisé par un excitateur séparé, constitue une disposition économique pour la transmission de la force à distance.

Cette phrase résume le problème de la force motrice à distance par l'électricité. M. Ayrton, passant alors à l'application, a examiné la question au point de vue d'une installation spéciale, comme à Sheffield, par exemple.

Il a montré, chiffres en main, que le profit augmenterait en proportion du nombre et de la puissance des machines.

Les autres applications de l'électricité n'ont pas été non plus oubliées par le savant professeur.

Les applications de l'électricité à l'éclairage et au chauffage ont été rapidement passées en revue. L'expérience que nous allons faire sera intéressante, et qu'elle ait ou non pleine réussite, elle aura le mérite d'être inédite.

Par exemple, avec le courant électrique qui nous est envoyé par les ateliers de MM. Walker et Hall, le pain chauffe cette fonte boîte de fer à vous, de manière qu'en le plaçant dans un vase d'eau, cette eau, comme vous pouvez le voir, est amenée très-rapidement à l'ébullition. De même, le chauffeur a mis du charbon dans le feu, rue Howard, et l'eau bout ici à Albert Hall.

La conférence de M. Ayrton s'est terminée par quelques explications sur les expériences de laboratoire électrique faites à Seemalac. Relativement à la distribution du courant électrique, l'orateur a exposé le principe des régulateurs de courants dont le but est de maintenir l'intensité constante dans un circuit donné lorsque l'on établit plusieurs dérivations sur une même source électrique.

Dans les villes où la force motrice produisant l'électricité serait fournie par des chutes d'eau, M. Ayrton veut utiliser les grandes crues pour emmagasiner le travail. Pour cela des machines dynamo-électriques seraient mises en mouvement par les eaux en excès qu'on devrait laisser perdre sans produire de travail en toute autre circonstance. Le courant de ces machines traverserait un voltamètre décomposerait de l'eau, et les gaz dégagés seraient emmagasinés à *haute pression* pour être utilisés plus tard comme force motrice ou source de chaleur, en opérant à nouveau leur combinaison.

M. Ayrton a calculé que la quantité de travail que représente un pied cube d'hydrogène à la pression de 20 atmosphères, se combinant avec un demi-pied cube d'hydrogène à la même pression, représente environ 110,000,000 de foot-pounds, soit le travail de soixante chevaux, pendant une heure, ou le travail d'un cheval pendant soixante heures.

Démontrer l'une solution aux grandes questions par le courant électrique, dit M. Ayrton, nous pouvons donc non-seulement de nous approvisionner d'énergie, mais encore de faire cet approvisionnement sous sa valeur économique.

Nous retrouvons ici, sous une forme plus scientifique et plus pratique, l'idée qui avait fait entrer la société des machines de l'Athénée, idée dont les résultats, sous leur forme primitive, furent absolument nuls.

Dans l'hypothèse de M. Ayrton, on veut seulement *emmagasiner* une force que les circonstances obligent à laisser *perdre*. A ce point de vue, la question mérite d'être étudiée.

Nous avons cherché, dans cet exposé incomplet de la remarquable lecture du savant professeur, à bien marquer les points essentiels de la grande question qu'il a agitée. Nous nous réservons d'y revenir plus tard pour en marquer les détails et en signaler les progrès.

M. Ayrton croit qu'il faut attendre au siècle prochain pour que l'idée de la distribution de la force motrice par l'électricité se réalise. Est-ce que les vingt années qui nous en séparent ne suffisent pas pour résoudre la question?... Après avoir constitué la lumière et la chaleur par le gaz, le pensée par les fils télégraphiques et les tubes pneumatiques, la parole par les conducteurs téléphoniques, ne pourrons-nous pas achever l'œuvre en distribuant l'électricité qui animera chez nous la *force motrice*, cet élément indispensable du travail. M. Ayrton a été trop observé. Le progrès marche à pas de géant et les découvertes qui se succèdent si rapidement depuis quelques années nous montrent qu'*une c'est possible*. Qui osera le premier?

E. HOSPITALIER.

MACHINE DYNAMO-ÉLECTRIQUE
D'EDISON

Nous donnons ci-dessous, d'après le *Scientific American* du 28 octobre, d'intéressantes informations sur la machine électrique à laquelle s'est arrêté le célèbre Edison, après avoir, comme on le sait, expérimenté longtemps les meilleurs types de Siemens, Gramme, Brush, Wallace, etc.

En réalité, comme système de machine, il nous paraît incontestable, que l'inventeur du phonographe a tout simplement réalisé un composé éclectique des systèmes de Siemens et de Gramme.

La brièveté est, commeil dit d'ordinaire, des fils, identiquement celle de Siemens, mais, recelant avec raison, croyons-nous devant la difficulté mécanique du type Siemens dans le noyau magnétique un fer, il a été conduit à adopter l'excellente disposition du noyau magnétique de Gramme en fil de fer cerclé. Enfin, il a emprunté encore, aux dernières

circuit by ½ than of the total energy converted; ½ will be useful, as it is outside of the machine, and ½ lost in the resistance of the machine.

"The Siemens machine, and nearly all other machines in use, make the external resistance equal to that of the machine; hence one-half of the energy only is useful, and any attempt by these inventors to increase the exterior resistance, so as to change the distribution of energy to obtain more exterior work, results in reducing the power of the machine to convert energy. Therefore, efforts toward economy in one direction are met in the other direction by loss in the interior. Hence the so-called necessity of using a greater number of machines to convert a given amount of power.

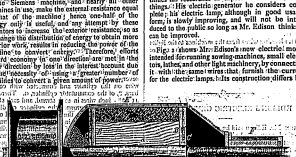

FIG. 1.

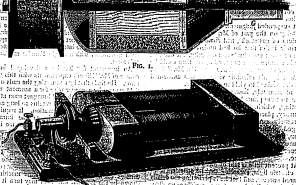

FIG. 2.

Mr. Edison's generator stores power in the form of electricity of high tension, and then converts it into that of low tension, thus delivering it to the consumer upon a circuit exterior to the machine; thus nearly the maximum economy is gained when other machinery under like conditions will scarcely give any current at all.

In dealing with the electric light problem, Mr. Edison has very properly devoted a large share of time and attention to the production of an economical generator, as it is the very foundation of the system. It bears the same relation to electric lighting that the cheap production of gas does to gas-lighting. It is as important to produce electricity cheaply as to use it economically. Mr. Edison seems equally both ends of the question, and is carrying on his experiments on a gigantic scale, encouraged by new developments, his continuous researches in expectation of still better things. His electric generator he considers complete; his electric lamp, although in good usable form, is slowly improving, and will not be introduced to the public so long as Mr. Edison thinks it can be improved.

Fig. 2 shows Mr. Edison's new electric motor intended for running sewing-machines, small elevators, lathes, and other light machinery, by connecting it with the same wires that furnish the current for the electric lamps. Its construction differs but slightly from the electric generator. The armature is arranged parallel with the magnet instead of transversely, and the magnet is formed of a single casting. In other respects it is like the generator, having the same form of armature, also commutator, cylinder, and brushes. The engraving represents the motor about one-fourth of its real size.

Whatever may be said or thought in regard to Mr. Edison's progress in electric lighting, it cannot be denied that he has made important discoveries which must tend to cheapen the electric light generally, and when he shall have completed his electric-lighting system we hope he will reap the reward merited by his untiring perseverance.

Edison (3) a suggéré rendu le courant d'excitation de la polarité inductrice indépendant du courant de ses lampes, ce qui, toutes choses égales d'ailleurs, a le grand avantage de rendre la force électro-motrice beaucoup plus facilement constante et d'exiger une moins grande perfection du nombre de tours de la machine.

Il y a lieu de signaler un point fort intéressant sur lequel

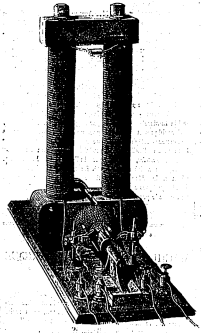

Fig. 1.

nous insisterons un peu : M. Edison a mis judicieusement en pratique le désidératum théorique que nous mettions en avant dans notre article du 15 août 1879, n° 5 de ce journal (quatre derniers paragraphes de la page 94).

Nous nous exprimons ainsi :

« ... Il n'y aura donc pas d'empêchement théorique à réaliser un fonctionnement de machine magnéto-électrique permettant de recueillir extérieurement, en chaleur régénérée, la majeure partie du travail dépensé, *le nerf électrique, par exemple*, du résultat de la transformation du travail moteur en courant.

« Sans doute, si l'on voulait appliquer une organisation de cette sorte, je suppose, à la production de la lumière avec arc voltaïque (je prends l'arc comme type des dispositifs, reconnaissant la chaleur régénérée, exposés à intliger des variations accidentelles considérables de la résistance extérieure, contact des charbons par exemple), la chose pourrait être dangereuse en ce sens que, lors d'une grande diminution de la résistance extérieure, le fil constituant la résistance intérieure de la machine serait aussitôt échauffé, pourrait même être brûlé, et cela d'autant plus sûrement que, dans la construction de la machine, on aurait mieux réuni à la rendre apte à supporter juste la circulation électrique du régime prévu, avec un minimum de poids de métal conducteur.

« *Cependant, dans les cas où la résistance extérieure totale peut être maintenue sûrement entre des limites rapprochées, il n'y aura pas lieutité à poursuivre simultanément toutes ces possibilité de maxima relatifs et spécifiques, et il est permis de supposer que ce pourra être précisément le cas pour les systèmes de production de lumière basés sur l'incandescence réalisée dans des conditions de constance suffisante des résistances exploitées.* » ...

Cette affirmation nous avait attiré quelques animadversions; or, s'il faut en croire les informations du *Scientific American*, on va voir que M. Edison vient d'atteindre en partie cet objectif, et tout le monde admettra que la réalisation matérielle est le meilleur des arguments en faveur des croyances théoriques.

Tout en rendant justice à M. Edison, le lecteur pensera sans doute, avec nous, qu'il n'y a d'ailleurs pas de raison pour que l'emploi des mêmes principes, avec les systèmes des autres bonnes machines, avec ceux des machines Gramme, par exemple, ne permette pas d'atteindre les mêmes valeurs de ce que nous avons appelé le rendement relatif thermique.

Gaud.

Lorsque M. Edison annonça qu'il allait produire une lumière électrique économique, pratique et d'un usage général, tout le monde des affaires, sans exception, accueillit cette nouvelle comme une chose certaine. Les actions du gaz baissèrent considérablement tant en Amérique qu'en Europe, et chacun attendit l'apparition de la nouvelle lumière. Les hommes de sciences, qui avaient pu apprendre par expérience ce qu'il fallait penser de cette découverte, reconnurent la vérité, mais la plupart observèrent leur jugement.

Les lecteurs de M. Edison rendirent le courage aux détenteurs de fonds de gaz en confirmant les savants dans leur croyance qu'il avait entrepris non-seulement une tâche très-grande et très-difficile mais encore une tâche qui réclamerait plus de temps et de moyens que ceux dont pouvaient disposer la plupart des expérimentateurs. Mais M. Edison, entouré par ses visiteurs scientifiques, était infatigable et résolu à ne reculer devant aucun obstacle.

Malheureusement, cependant, les journaux quotidiens imprimaient de temps à autre des détails sur les progrès de l'éclairage par l'électricité, qui, par leur extravagance et leur inexactitude, plaçaient, pour ne pas dire plus, M. Edison dans une position extrêmement embarrassante en ce qui touchait ses promesses et leur accomplissement, sans compter qu'elle égarlaient le public quant à la véritable nature du problème à résoudre; il en résultait une réaction de sentiment qui portait préjudice à la juste renommée de M. Edison.

(3) Revenant ainsi sur-disant en arrière par rapport à l'idée de la réunion des deux courants, comme Wilde, Wheatstone, Ladd, etc.

A présent, M. Edison dit : peu de chose concernant sa lumière électrique, sauf qu'il la considère comme un succès assuré, et qu'il perfectionne les détails de son système d'éclairage électrique aussi rapidement que possible.

Ce n'est pas notre intention, pour l'instant, d'entrer dans une description détaillée du système d'éclairage électrique de M. Edison, mais seulement de décrire son nouveau générateur électrique, un des facteurs les plus importants du système, ainsi que son nouveau moteur électrique qui sert à mettre en mouvement de petites machines pour les usages domestiques et industriels.

Le nouveau générateur (fig. 2) rappelle, sous quelques rapports, d'autres machines bien connues, mais il diffère de celles-ci sous plusieurs rapports très-importants; par exemple les aimants de champ sont immenses; ils ont environ 3½ pouces de hauteur et pèsent environ 1,100 livres. Les noyaux d'aimant ont 6 pouces de diamètre et 36 pouces de longueur; ils sont munis sur de bonnes bases en fer fondu, de 10 3/4 pouces de hauteur sur 9 pouces de largeur, et sont reliés au sommet par une culasse en fer de 6 pouces de hauteur sur 7 de largeur. Les noyaux sont entourés de trois couches d'un fil métallique n° 10 couvert de coton; dont les bouts sont mis en communication avec des barres d'attache sur la base de la machine.

Les deux blocs polaires ainsi que les supports de la bobine reposent sur une plaque en laiton en forme de croix.

La bobine-armature qui tourne dans l'espace cylindrique compris

Fig. 2.

entre les pôles de l'inducteur est représentée dans la figure 2. Elle consiste en un cylindre creux A, monté sur un axe de 1 1/2 pouce, et ayant, attachées à son extrémité, des plaques de fer doux B, entre lesquelles se trouvent plusieurs couches D, d'un enroulement de fil métallique de fer doux n° 20. A l'extérieur des disques en fer B, il y a des disques volcanisés C, qui ont leurs périphéries entaillées afin de recevoir les diverses bobines E, de fil métallique isolé enroulé dans le sens de la longueur sur le cylindre et reliées à des barres de cuivre F de système commutateur G.

Il y a 42 fils de $\frac{22}{100}$ de pouce dans chaque tours de spires, et chaque tours fait longitudinalement et diamétralement le tour du cylindre. Les bouts opposés de tous les fils métalliques des tournes sont soudés à des barres métalliques aussi nombreuses aux sections opposées du cylindre commutateur; ces sections sont au nombre de 40, et des brunes, opposées, en fil de cuivre, y recueillent le courant. L'axe de la bobine porte une poulie de 20 pouces de diamètre et de 3 pouces de largeur, la vitesse de la machine est d'environ 800 tours par minute. Bien que le courant provenant de la bobine puisse être employé pour exciter l'aimant, M. Edison trouve plus économique de charger l'aimant à l'aide d'une machine séparée; en fait, il se propose de charger une batterie de ces générateurs avec une seule machine.

Un fait important à dit occuper dans le cours des expériences de M. Edison avec ce générateur. Il a trouvé qu'en reliant les bouts de l'aimant à l'aide d'un fil en cuivre, pendant un moment, lorsque la machine est mise en mouvement, l'aimant atteint bientôt sa charge maxima, qu'il conserve aussi longtemps que le générateur est en fonction. Il faut une minute ou davantage pour charger complétement les immenses aimants, et lorsqu'ils sont chargés leur influence d'aimantation est puissante. La résistance intérieure de la bobine n'est que de $\frac{1}{100}$ ohm, et M. Edison prétend qu'il réalise 90 pour 100 de puissance, soit en appliquant à cette machine, un courant extérieur efficoll. Il ne faut qu'une force de 5 chevaux pour la mettre en mouvement, et le courant produit est suffisant pour produire 40 lumières de 160 candles chacune. On jugera de l'économie de cette machine par ce fait qu'on sait fournir pour la tourner avec une rapidité suffisante pour maintenir l'arc électrique d'une bougie Jablochkoff.

Bien que ce générateur, en principe général, soit analogue aux meilleures connus, il présente cependant une différence très-importante : c'est qu'il peut convertir et livrer, pour un travail utile, près du double des livres-pieds d'énergie que fournirait toute autre machine dans des conditions semblables. Ilquilconque a montré que la machine Siemens, qui est généralement reconnue comme étant la meilleure que l'on ait encore imaginée, convertit, en tout, déjà la bobine jusqu'aux circuit extérieur, 92 p. 100 de l'énergie, mais les dernières corrections réduisent ce chiffre à 85 p. 100. D'après ces résultats, plusieurs savants ont déclaré qu'il n'y avait guère de différence entre les pôles de l'inducteur est représentée dans la figure 2. Elle consiste en un cylindre creux A, monté sur un axe de 1 1/2 pouce, et ayant, attachées à son extrémité, des plaques de fer doux B, entre lesquelles se trouvent plusieurs couches D, d'un enroulement de fil métallique de fer doux n° 20. Edison trouve plus économique de charger l'aimant à l'aide d'une machine séparée; en fait, il se propose de charger une batterie de ces générateurs avec une seule machine.

Un fait important à dit occuper dans le cours des expériences de M. Edison avec ce générateur. Il a trouvé qu'en reliant les bouts

de l'aimant à l'aide d'un fil en cuivre, pendant un moment, lorsque la machine est mise en mouvement, l'aimant atteint bientôt sa charge maxima, qu'il conserve aussi longtemps que le générateur est en fonction. Il faut une minute ou davantage pour charger complétement les immenses aimants, et lorsqu'ils sont chargés leur influence d'aimantation est puissante. La résistance intérieure de la bobine n'est que de $\frac{1}{100}$ ohm, et M. Edison prétend qu'il réalise 90 pour 100 de puissance, soit en appliquant à cette machine, un courant extérieur efficoll. Il ne faut qu'une force de 5 chevaux pour la mettre en mouvement, et le courant produit est suffisant pour produire 40 lumières de 160 candles chacune. On jugera de l'économie de cette machine par ce fait qu'on sait fournir pour la tourner avec une rapidité suffisante pour maintenir l'arc électrique d'une bougie Jablochkoff.

Bien que ce générateur, en principe général, soit analogue aux meilleures connus, il présente cependant une différence très-importante : c'est qu'il peut convertir et livrer, pour un travail utile, près du double des livres-pieds d'énergie que fournirait toute autre machine dans des conditions semblables. Ilquilconque a montré que la machine Siemens, qui est généralement reconnue comme étant la meilleure que l'on ait encore imaginée, convertit, en tout, déjà la bobine jusqu'aux circuit extérieur, 92 p. 100 de l'énergie, mais les dernières corrections réduisent ce chiffre à 85 p. 100. D'après ces résultats, plusieurs savants ont déclaré qu'il n'y avait guère de différence entre l'énergie convertie est distribuée sur toute la résistance; il s'ensuit que si la résistance de la machine est représentée par 1 et celle du circuit extérieur par 9, $\frac{9}{10}$ de l'énergie totale convertie seront utilisés, puisque cette portion du travail a lieu en dehors de la machine, et $\frac{1}{10}$ sera perdu dans la résistance de la machine.

La machine Siemens, et presque toutes les machines en usage, rendent la résistance extérieure égale à celle de la machine; il est clair qu'une moitié seulement, $\frac{1}{2}$, de l'énergie est utile, et que toute tentative faite par ces inventeurs pour augmenter la résistance extérieure, de manière à changer la répartition d'énergie pour obtenir plus de travail extérieur, ne fait que réduire la puissance totale de transmission d'énergie que possède la machine; les efforts qui tendent à l'économie sont ainsi directement contrebalancés par ceux qui tendent à l'économie sont contrebalancés par ceux qui tendent à l'économie pour faire diriger par suite de la nécessité qui élimine perte dans l'autre direction par suite de la nécessité qui élimine perte dans l'emploi un plus grand nombre de machines pour produire plus d'énergie au plus grand nombre de machines pour produire plus d'énergie au même prix de puissance donnée.

Dans le générateur Edison, la résistance est une puissance de 5 chevaux est employée sur une résistance de 5 ohms, dont 1/2 ohm est dans la machine, livrant ainsi $\frac{10}{11}$ du courant total sur un circuit exté-

Dans le générateur Edison, la résistance est une puissance de 5 chevaux est employée sur une résistance de 5 ohms, dont 1/2 ohm est dans la machine, livrant ainsi $\frac{10}{11}$ du courant total sur un circuit extérieur à la machine; l'économie la plus grande maxima est ainsi atteinte par rapport d'autres machines, dans des conditions semblables, donnerait à peine quelque courant.

Un correspant du problème de la lumière électrique, M. Edison a consacré une grande partie de son temps et de son attention à la production d'un générateur économique, attendu qu'il y voit la base même du système. C'est, pour l'éclairage électrique, ce que représente dans l'éclairage au gaz, la production à bon marché du gaz. Il est aussi important d'engendrer l'électricité à bon marché qu'il l'est de l'employer économiquement. M. Edison aborde carrément les deux termes de la question; il poursuit ses expériences sur une échelle gigantesque, et, encouragé par de nouveaux progrès, il continue ses recherches dans l'attente de résultats encore meilleurs.

Il considère son générateur électrique comme étant complet; la lampe électrique, bien qu'elle soit déjà propre à un bon usage est perfectionnée lentement et ce sera peu présentée au public tant que M. Edison croira qu'elle peut être perfectionnée davantage.

A l'atelier de Menlo Park, la puissance motrice est prise sur une machine à vapeur de 80 chevaux, et l'on mesure dynamométriquement le travail mécanique consommé par les machines électriques en essai.

Le dynamomètre employé pour la mesure du courant est une invention du professeur J. W. Trowbridge. M. Edison l'a cependant perfectionné et adapté à ses propres usages. Comme il n'y a ni fer ni aimants dans l'appareil, on peut s'en servir dans le voisinage du générateur sans qu'il soit influencé par ses aimants.

Le courant électrique traverse deux grandes spirales de ruban de cuivre, et aussi une plus petite spirale intermédiaire dont la suspension bifilaire le maintient à angle droit des grandes spirales lorsqu'aucun courant ne passe. La petite spirale porte un miroir, et les lecteurs sont faites sur une échelle éloignée par l'observation d'un point lumineux.

Le circuit est complété à travers la plus petite spirale au moyen de coupes de mercure maintenues fraîches à l'aide d'eau qui coule à travers leurs parois creuses.

Les essais galvanométriques se font dans un bâtiment spécial à cabri de toutes les influences qui pourraient affecter l'exactitude des lectures. Le galvanomètre réflecteur de Thomson est placé sur une table qui repose sur des fondations en brique, et est renfermé dans une chambre obscure qui a des ouvertures pour que l'on puisse voir l'échelle.

Le perfectionnement de ce nouveau générateur électrique a exigé des mois d'attentive investigation au moyen de ces deux instruments, et ce n'est qu'après avoir fait des centaines de changements et d'expériences que le type de l'appareil a été arrêté.

M. Edison a aussi établi un nouveau moteur électrique destiné à faire marcher des machines à coudre, de petits élévateurs, des tours et autres légers mécanismes, en le reliant avec le même fil conducteur qui fournit le courant pour les lampes électriques. Sa construction ne diffère guère de celle du générateur électrique. L'armature est disposée parallèlement à l'aimant au lieu de l'être transversalement.

Quoi que l'on puisse dire ou penser au sujet des progrès de M. Edison dans la question de l'éclairage électrique, on ne saurait nier qu'il ait fait d'importantes découvertes qui tendront à rendre la lumière électrique meilleur marché d'une manière générale; et, lorsqu'il aura complété son système d'éclairage par l'électricité, nous espérons qu'il recueillera la récompense due à sa persévérance (1).

(D'après le *Scientific American.*)

(1) Il est bien entendu que nous laissons toute responsabilité, comme il convient, au journal américain, pour ses informations qui nous reproduisons.

MACHINE DYNAMO-ÉLECTRIQU

DE M. WESTON

Ceux qui ont visité avec soin l'exposition de 1878 o
évidemment remarqué la petite machine dynamo-électriq
de M. Weston qui, dans la section américaine, était appliqu
à la galvanoplastie et semblait fournir des effets considérable
eu égard à ses petites dimensions. Cette machine, tourné
en raison de sa fermeture hermétique, n'avait pu être ex
prise du public intelligent, et je dois même dire que je n
pu obtenir aucun renseignement sur sa disposition intérieu
Ceux qui la faisaient fonctionner n'étaient sans doute p
plus au courant que ceux qui la voyaient, car on avait be
leur demander sur quel principe elle était fondée, on ne

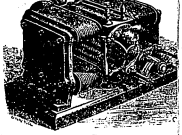

Fig. 1.

pendait qu'en montrant l'étincelle qu'elle pouvait produire
une lame de cuivre; en un mot on n'en savait pas plus
ceux qui regardent la figure qui accompagne à la huitième p
de nos annonces. Heureusement le journal *l'Iron*, du 27 s
tembre dernier, nous a enfin donné quelques détails sur c
machine, qui ne paraît être qu'une dérivation de celle de Lon
et dont nous donnons ci-dessous la représentation.

Effectivement, dans cette machine, l'organe d'induction
les Anglais appellent l'*armature*, est un véritable pignon d'
grenage en fer doux (voir fig. 2) dont les dents sont entour
des hélices isolées et sont assez éloignées les unes des au
pour laisser passer à un courant d'air qui, venant du centre
pignon, se répand dans les diverses parties de la machine p

THE SIEMENS DYNAMO-ELECTRIC MACHINE.

TO THE EDITOR OF THE SCIENTIFIC AMERICAN:

SIR,—Referring to your article on my brother, Siemens' dynamo-electric machine, and also to the method of winding the armature, the principle of winding is the same as the ring armature as a modification of the Gramme ring. The principle is best explained by the

diagrams. Fig. 1 is a transverse section of the Gramme ring. Now, instead of winding the wire through the ring wise, it seems the ring. Fig. 2, and make the commutator connections in the same way as they are made in the Siemens armature. In the Siemens armature

JOHN HENRY KNIGHT.

Wychcourt House, Farnham, Feb. 19, 1859.

DEPREZ'S ELECTRO-MAGNETIC ENGINE.

BY THE COMTE DE MONTGOMERY.

ACCORDING to Comte de Moncel (writing in *Le Lumière Electrique*), M. Marcel Deprez has succeeded in solving the problem of making an electro-magnetic motor capable of doing useful work in many industrial applications. We venture to say that the machine in question can compete with even a water-motor of 3 horse-power, and that without calling of gas and steam-engines into requisition. In Dr. Marcel Deprez's apparatus is hardly 6lb. long, by less than 6in. in breadth; it weighs about 25lb., and can supply a power of nearly 3 foot-pounds per second with five Bunsen elements. The cost of working it would be an extraordinary item, and has hitherto scarcely have been anticipated a few years ago. The electro-magnetic lines serving may be with perfect ease be worked by electricity without any cumbrous apparatus. The ingenious system contained a horseshoe magnet of eight plates 60in. in length, between the poles of which revolves the Siemens armature, a ring of soft iron with magnet over a length of 70in., fifty to the inch, and of 0·7 millimetre in thickness. The rotating magnets or electro-magnets are not alike; wise than by their polar extremities; and all the engine circles (circles) have been arranged on this principle; but M. Marcel Deprez thinking that the maximum machines the whole of the magnetism that the maximum magnet was not utilised, reasoned to extend the magnetic field, and consequently the effect performed by the magnetic power, by adding multiple-system to be fashioned; that is to say, in his present case, the armature of the magnet acted up to the neutral line. The electro-magnetic armature, instead of being placed transversely to

THE EDISON ELECTRICAL GENERATOR.

To the Editor of the Scientific American:

Your issue of November 15 contains a letter from Mr. Edison accompanied by a reply to the strictures contained in mine the 1st December.

I feel confident that so far as the opinion of thoughtful electricians is concerned, I might leave the matter as it is, and stands without detriment to my reputation; but I am not willing the general public should suppose I acquiesce in the statements made by Mr. Upton, or that my views are, in any great degree, modified by anything he advances.

Mr. Upton says I have "confounded the obtaining of a maximum current with the obtaining of a maximum of economical efficiency." Now I submit I have done no such thing. In my letter I have assumed that in dynamo-electric machines the electromotive force is a function of the external resistance, and decreases as the external resistance increases.

The article on page 240 says nothing about the electromotive force being constant. Mr. Upton, it is true, does say that this is the case with Mr. Edison's machine; but this is a mere assertion, the truth of which I do not only not concede, but positively deny.

I do not lose sight of the statements on page 242, that "although at most times the armature may be used to excite the field magnet, Mr. Edison finds it more economical to charge the field magnet by means of a separate machine." Then follows an intimation that such is his intention in the future.

Mr. Upton says, "according to the reasoning in the letter in question," it would be "mathematically absurd to connect a battery with a resistance often times greater than itself," and it undoubtedly would be if, as was beyond all question claimed on page 242, that *simply by so doing it necessarily rendered that battery four times as efficient as any other battery*, or if the electromotive force of the battery was a function of the external resistance, and decreased as the external resistance increased.

I now propose to re-examine some of the statements on page 242. I quote first: "The internal resistance of the armature is only ½ ohm, and Mr. Edison claims that he realizes 80 per cent of the power applied to this machine in effective external current." Second: "Now the energy converted is distributed over the whole resistance; hence, if the resistance of the machine be represented by 1, and the exterior circuit by 5, then of the total energy converted, 0·9 will be useful, as it is outside of the machine, and 0·1 lost in the resistance of the machine." Now, Mr. Upton, claiming for Mr. Edison's machine constant electromotive force, fully indorses both of the above statements, which I again pronounce mathematically absurd, and again assert that the statement, if true, proves beyond all doubt that Mr. Edison has discovered perpetual motion. For Mr. Edison and Mr. Upton both distinctly communicate the assertion that 0·9 of the power applied is available in effective external current, and concede that 0·1 is lost in the resistance of the machine. Consequently there is no escape from the conclusion that no power is required to overcome the inertia of the mass of metal comprising the armature, nor the friction of the journals, none is lost in the production of counts which are not available in the working circuit, and none in the production of spark and heat at the commutator, etc. etc. In other words, you have only to start the machine and it will continue to revolve for ever, and perpetual motion is accomplished fact.

Now if, as Mr. Upton leaves us to infer, the electromotive force is constant and independent of the resistance of the external circuit; there is no exception the conclusion that power has to be applied to move the field magnet, and in the absence of any information other than is afforded by Mr. Edison and Mr. Upton, we are obliged to assume that this power is supplied by a machine which furnishes the current for this purposes and *runs itself*. Perpetual motion is more than possible.

The question to be considered is: Is it true that a machine, in which the resistance of the armature circuit is only ½ ohm and the external resistance 5 ohms, *necessarily* more efficient than a machine in which the resistance of the internal and external circuit must be equal in order to obtain the maximum efficiency? I answer, no; Mr. Upton says yes, and introduces the expression $E^2(r+1)^{-2}$ R to prove his assertion and the efficiency of Mr. Edison's machine. It proves nothing.

It is true that Mr. Upton's statement differs materially from anything first stated, in that it takes into consideration the electromotive force as an element of efficiency. But what does it prove? Nothing more than was proven years ago by Jacobi and Favre, and the reference to a recent number of *La Lumière Electrique* is not the best that can be made.

There have been numerous machines built in which the resistance of the armature of the working circuit was only a fraction of that of Mr. Edison's machine, and the difference between the internal and external circuit much greater. One instance out of many may suffice.

Professor Trowbridge, of Harvard University, made tests of three well known machines, the results of which are published in the Philosophical Magazine for March, 1870. The results obtained are given in the following table:

Wilde Machine (Large Size).						
Resistance Of Circuit in ohms.	Current, per sec.	Speed of Engine per min.	Metre-grammes exerted per sec.	Equiv. of Current in grain's per sec	Eff. Resist.	Efficiency.
0·081	69·33	548	356,056	893,486	42·7	
0·181	57·35	548	294,512	739,000	52·7	
0·281	49·00	548	251,657	631,500	62·7	
0·607	30·25	539	155,125	389,366	71·1	
1·107	20·00	539	102,640	257,600	79·1	
1·607	14·50	539	74,420	186,800	86·1	
1·911	30·43	531	142,992	359,017	90·5	
2·411	24·00	531	112,811	283,200	93·5	
3·589	17·31	536	83,796	210,333	97·9	
4·589	13·64	536	65,975	165,600	98·9	
Gramme Machine (Large Size).						
0·675	96·0	472	580,745	809,416	40·3	
0·769	73·0	468	554,356	416,911	42·7	
0·781	71·0	466	544,387	409,377	54·9	
Siemens Machine (Large Size).						
0·273	72·4	364	281,326	670,264	19·0	
1·023	69·0	292·5	257,852	625,000	59·5	
1·273	60·0	292·5	223,452	542,000	69·5	

The resistance of the Gramme armature is 0·129 ohm; the resistance of the magnet, 0·213 ohm. The total resistance is therefore 0·341 ohm.

The total resistance of the Siemens machine is 0·281 ohm.

The Wilde machine differs essentially from the other two, the magnets not being included in the working circuit. The armature has two circuits, the one for exciting the magnet, and the other for working circuit. The resistance of the armature coils of the working circuit is 0·074 ohm. The resistance of the coils of the armature for exciting the magnets is 0·451 ohm. The coils of the field magnet have a resistance of 2·85 ohms.

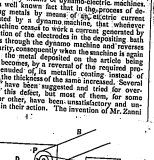
In this machine the resistance of the coils of armature of the working circuit was about one-fifth the internal resistance of the Gramme machine, and the ratio of the resistance of the internal to the external circuit, when the maximum efficiency was obtained, was not far from that given by Mr. Edison *for his generator* on page 242. Yet the efficiency was much less than the Gramme, in which the internal and external resistances were about equal when the maximum efficiency was obtained. It is therefore evident that there is something more than the matter of resistance to be considered in the building of dynamo-electric machines.

Mr. Upton also gives two examples of the performance of Mr. Edison's machine, but they neither prove the efficiency of the machine as a generator nor as compared with other machines.

The only proof of the efficiency of a machine is the ratio of the work done in the external circuit to the force power expended in driving the machine, and, other things being equal, it may

ZANNI'S PATENT MAGNETIC CUT OFF FOR DYNAMO-ELECTRIC MACHINES.

The object of this invention is to prevent a reversal of the polarity of the electricity employed in the process of the electro-deposition of metals, and it is a well known fact that in the process of depositing metals by means of the electric current generated by a dynamo machine, that whenever the machine ceases to work a current generated by the action of the electrodes in the depositing bath returns through the dynamo machine and reverses its polarity, consequently when the machine is again started the metal deposited on the article is being eaten, dissolved, or in a reversal of the requisite process, denuded of its metallic coating instead of having the thickness of the same increased. Several devices have been suggested and tried to overcome this defect, but most of them, for some cause or other, have been unsatisfactory, and uncertain in their action. The invention of Mr. Zanni



for effecting the object in view has been tested and proved to be thoroughly reliable in its action, and is therefore a very useful addition to the electroplater's plant.

The principle of the invention is shown by the fig.

B is the dynamo machine driven by the band *n*, which is connected with the source of power. On the same axle to which the driving pulley, *n*, of the machine is fixed, is also attached another pulley, *b*, which drives by means of a band, *b*, and pulley, *b'*, a small magneto machine, *c*; the circuit of this machine is closed through the electro-magnet, *m*. The armature, *i*, of the electro-magnet normally rests against the insulated stop, *i'*; but when the magnet is excited it is attracted against the stop, *i'*, thus completing the circuit of the wires, *m' m'*, which lead to the depositing bath through the wires, *n' n'*.

The action of the apparatus is almost self-evident: when the machine is at rest the circuit of *m' m'* is open, but when the dynamo machine, *b*, is rotated and with it the magneto machine, *c*, the current from the latter at once excites the electro-magnet, *m*, and attracts the tongue, *i*, against the stop, *i'*, thus closing the circuit of *m' m'*, the current then passing from the tongue, *i*, this back against the stop, *i'* thus opening the circuit and sending the current of the current from the depositing bath through the machine, *b*.

In the article on Zanni's in the *Journal* for December 15th, 1859, in a notice of Mr. Dingler's book on electric plating, we expressed our surprise that a simple form of chemical had not been adopted on electro-plating apparatus for the purpose of regulating the strength of the current. In the process of Mr. Zanni's we find that this has been suggested and patented by him together with the use of galvanometer in the circuit, by which the current strength could be seen.

Although fully recognising the efficiency of Mr. Zanni's "magnetic" cut off, we think the machine is not the same end could be effected in a simpler manner by working the electro-magnet, *m*, by a "direct" circuit from the machine *b*, the resistance of the electro-magnet being sufficiently high to avoid a drawing off more of the current than is actually required to excite the electro-magnet. The amount of current required to excite it, it is evident, would be but an infinitesimally small portion of the total current, and would therefore in no way diminish the efficiency of the machine.

Dynamo-Electric Machines in Telegraphy.

The Western Union Telegraph Company is announced to have lately taken their first steps to dispense with batteries in their telegraphic system, and extensive chemical factories which have hitherto been universally dependent on supply of them dynamo-electric machines driven by steam. And the facility in place of effecting this change is said to have been recognised, and have been found hardly at work upon it, no difficulty being anticipated, and have been indifferent success up to the present time. But, as it appears, with many

The importance of this innovation about being adopted by the Western Union Company will be seen from the following statistics. The profits of the following year cost of $6,923,055. In 1870, the company sent 14,450,823 messages, at a rates, to 24,079,106, and the cost had fallen to $6,160,250. By reason largely of improvements in the construction of batteries and of telegraphic apparatus, it cost $1,117, in 1870 the cost of battery per mile of wire had fallen to $0·36. By the introduction of the new style of wire and fallen to the batteries, and supplying the electric currents from dynamo-electric machines, it is confidently believed that the cost of working will be considerably surpassed by, from present indications, at least 50 per cent. We do not wish to be understood as implying that the public will be benefited in the least by any reduction of rate or of any of the improvements, past or present, by the adoption of that has hitherto been introduced by the Western Union Company, either the country; for the only thing that will bring this about will be the competition of a rival company strong enough to hold its own against the other; but the improvements are in a scientific and practical interest, that makes it out of the mouth of such considerations, inasmuch as it promises to work a thorough and speedy revolution in the economies of telegraphic the world over. On the account, a few words relative to the improvement itself will be of interest.

The efforts likewise made to supply electric current for telegraphic purposes, by using electric machines, were all alike in that they all sought to accomplish the object by using a single machine at high tension, and on this account they are believed to have failed of success. The new system, said to have been adopted by the Western Union Company, after a thorough test of its merits in San Francisco by Western Union Company, after the company in that city, consists of "a number of battery-rooms of connected in series, and having their field magnets excited by a current furnished by a single Siemens dynamo-electric machine, excited by a current

For the explanation of the details of the system in question, we must refer our readers to the columns of the technical journals. Three sets of these machines and engines are at present in use in the batteries of the Western Union Company, and have given much satisfaction; and a set of fifteen more are now constructing to entirely take the place of the batteries hereto in use in that company. What this means will appear from the statement that there are now on the top floor of the Western Union building, 14,000 gravity batteries, and 4000 bichromate elements, and in an adjoining building 4000 bichromate elements, all of which will, in a short time, be removed by steam, relieving the battery-rooms

THE GRAMME COMBINED EXCITING AND DIVIDING MACHINE FOR THE ELECTRIC LIGHT.

Engineering 7/5/13/1880

(For Description, see Page 136.)

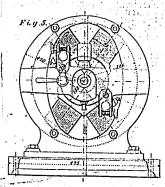

Fig. 4.

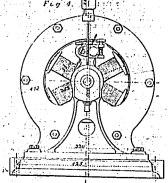

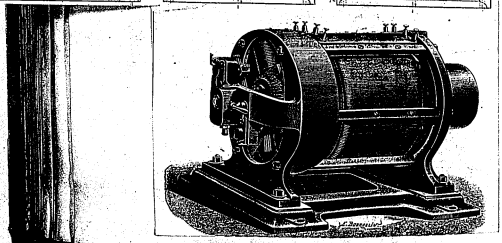

GRAMME'S COMBINED DYNAMO-ELECTRIC MACHINE.

...We reproduce, from our contemporary, *La Revue Industrielle*, illustrations of a new form of dynamo-electric machine which has been lately introduced by M. Gramme. The machine differs considerably from the Gramme machine brought out in 1878, both in the greater amount of light it is capable of producing per horse power and in its lower first cost.

By reference to the engravings it will be seen that the arrangement of the machine is as follows: On a cast-iron foundation are fixed two plates of the same metal almost circular connected together by six square bolts and provided with bearings for the main shaft. One of these plates is furnished on the inner side with a circular rib on which are mounted the distributing and the exciting apparatus. As in the earlier models the coil for the alternating currents rests on the square bolts connecting the end plates with packing pieces of lead wool. The six annular electro-magnets are fixed radially on a cast-iron hollow sleeve which is bolted to the shaft. The armatures are held by the same screw as the rings in the longitudinal section. The shaft carries on one side the annular exciting coil, and on the other the distributing coil. The bearings are wide, and the Gramme machines a system of automatic lubrication is employed.

In lieu carrying a wire brush shown in the section, Fig. 1, serves to place in communication the coils of the moving electro-magnets with the exciting circuit. The current is collected and transmitted by small brushes of silvered copper wire. The tension are moved by means of a small endless screw. For regulating the power of the machine a copper wire, the length of which can be varied at will, is introduced between the exciter and the electro-magnets. The method of coiling the wire differs slightly from that adopted in the other machines, as instead of winding one wire two are coiled, in order to obtain by this mode of coupling tension currents for small lights, or quantity currents for large ones. The exciter of this machine are now manufactured. The smaller weighs 660 lbs., and supplies 12 candles of from 19 to 20 Carcel burners, or 8 candles of from 40 to 50 burners. The larger machine weighs 990 lbs., and supplies power of 24 candles of 20 Carcel burners, or 16 of 40 to 50. The following Table contains the results of some recent experiments:

Number of Revolutions per Minute.	Horse Power Expended.	Number of Lamps.	Power of each Light in Carcel Burners.
1400	5	12	28.5
1415	6	8	43.0
1380	4	6	48.5
1000	25	16	31.5
1023	13	24	21.0
1291	11	24	31.0

With a machine especially arranged for small lights, there have been obtained with a speed of 1200 revolutions 14 lights of 20 Carcel burners each, with an expenditure of power of 4.66 horse power. The candles consisted of carbons 2 mm. (.07 in.) in diameter. In all played last carbons 2 mm. (.07 in.) in diameter. In all the experiments made a much steadier light was obtained than that given by the machines employing an independent exciter.

A recent application of this machine has been made on board the Cosmos, a ship recently built by Messrs. J. & J. Laird, Birkenhead, for the Messageries Nationales Company, Glasgow and Greenock, for the Messageries Fluviales à Vapeur in South America for running on the Rivers Plate and Uruguay. The machine employed is the Brush machine, producing 8 small or 12 large lights, and capable of developing 8 small or 12 large lights, and running at a speed of 1050 revolutions per minute maintained lights of 20 Carcel power each, with an expenditure of 5 horse power. The lights are distributed as follows: Three in the upper saloon, three in the lower saloon, one on the landing of the stairway leading from the upper to the lower saloon, and one over the pantry. The exciter, which is fixed on deck amidships and under the cabin, which is fixed on deck amidships and under the cabin, which is fixed on deck amidships and under the cabin

of the electro-magnet. When no current is passing, the influence of the steel renders these cores temporary magnets, and enables them to hold the moveable armature, A, against the force of an opposing spring. The current is in such a direction that tends to reverse the magnetism induced by the steel. It is not necessary, however, that it should be strong enough to produce an actual reversal, but merely that it should weaken the initial magnetism of the cores sufficiently to enable the opposing spring to overpower them. This is one of those cases in which a "balance" is apparent, and is a matter of interest and satisfaction.

The reciting-shaft consists of two portions, one of which (fig. 538), carries the fly-wheel, V, and turns uniformly under the action of the clock movement; the other which is next in front of the machine, remains at rest when no current is passing; but when the armature of the magnet rises, the two parts of the shaft become locked together by means of ratchet-wheel and click (not shown).

ENGLISH MECHANIC AND WORLD OF SCIENCE: No. 872.

Dec. 30, 1881.

NOTES ON THE PROPERTIES OF DYNAMO-ELECTRIC MACHINES.

By Prof. ELIHU THOMSON.

THE subject of the properties of dynamo-electric machines attracts, at present, considerable interest. Perhaps, therefore, the following observations may be of interest as exhibiting some unusual traits of their behaviour. The machines with which the experiments were made were of my own construction, and had an armature of spherical outline and two bipolar inductor magnet poles, constituting two nearly hemispherical cavities surrounding the armature. The field coils are two in number and surround the field cores and electro armature itself. The armature has three coils only wound upon it, and the commutator, three insulated segments of a ring, the slots between the segments subtending an angle of 60°. Each of the segment covers over 120° of the circle of the ring of the commutator. A full description of this machine and its performances is in preparation. The machine experimented with could sustain from four to six ten lights in series, at about 800 revolutions per minute.

The first experiments to be described illustrate the tendency of the machine to produce, as a motor, in reversing the current of the machine, and then suddenly stopped and immediately thereafter its circuit opened, when there appeared a small but distinct spark at the break. Other evidences of the circulation of current were obtained immediately after the complete stoppage of rotation. A smart shock could be felt by grasping the wires on each side of the break in the circuit at the time it was made.

The origin of this after-current or current after stoppage of the machine is, of course, the great, the gradual loss of magnetism of the field-magnet cores, which induces a current in the enclosing wire during the time that such magnetic change is taking place. The direction of the current induced is, therefore, the same as that which the machine would send if driven as a motor. The current, of course, endures only until the machine magnets have lost all current what is known as their residual or permanent magnetism.

A more curious effect, however, is produced by pulling the same machine, with its bearings perfectly free and well oiled, upon closed circuit and then reversing it as before at a moderate speed. The momentum acquired by the armature will be quickly thrown off its driving belt. The armature of the machine in this case rapidly comes to rest and then, singularly, takes about 1 of a turn in the opposite direction.

I have repeatedly verified this result, but cannot know whether it would be obtained with other dynamo-electric machines. The armature must be very light and free. Here, again, the contrary current not only stops the machine but reacts upon it so as to work it for a moment as a motor in the contrary direction—just as if a current had been applied from a source outside the machine. What, then, is the source of this current which is able to work the machine against friction? Clearly, it is the battery of current generated by and continued during the loss of magnetism of the field-magnets of the machine, and this current is, of course, in the same direction as when the machine was received by the applied power.

Another observation made with these machines was as follows:

A single machine driven by power was connected in two circuits in multiple arc, so as to drive them as motors; but these latter, although relatively nearly alike in properties, were of different sizes—the electromotive force of one being double that of the other, as in the experiments of Sprague. The smaller could maintain four, and the larger eight lights in series, the character of the arcs being alike. When joined up to the first machine as generator in parallel circuit as above indicated, both the other machines acted as motors and revolved. The speeds which they acquired, while not performing work, were nearly equal, and the speed at which they found is by approximately in the inverse *ratio of their electromotive forces in generators when driven at an equal speed.* This observation was repeated with other sizes, with results very nearly agreeing with the above statement. It would seem from the above that both machines, working as motors without load, adjusted their speeds of rotation so that the counter-electromotive forces developed by them are nearly equal and the current traversing each of them also nearly equal. The different electrical resistances of the two machines is no doubt a modifying influence; but it seems to have little effect and, in fact, appears to be in competition with the counter-electromotive forces developed under the conditions.

The effect of running the two machines in series as motors is very different. When so used, and with their shafts very free to turn, the larger, or one capable of producing the highest counter-electromotive force, runs at a comparatively slow rate, while the smaller runs at a high rate. If, however, the former or larger machine be made to perform mechanical work—that is, to furnish power—its running speed is, of course, retarded and the other machine turns with a speed depending on the amount of work abstracted from its companion.

Improvements in Electric Motors, Dynamo and Magneto-Electric Machines.

[1880. — I propose to confine myself to such of the warkards by me as are simple, cheap, and, when well made, efficient; specially for amateurs in possession of a handy lathe. I will first describe a machine of a simple form, on the double-acting principle. Fig. 1 shows plan; Fig. 2 a transverse section; Fig. 3 a perspective, without wire, of the making of the armature.—A A are two pieces of soft iron, fixed on a wooden, gun-metal, or brass bar as shown from the block, in the shape, B shows end view and plan. These are screwed on a shaft, being fixed by screw (fig. steel) to keep on shaft. C C, Fig. 6 shows slots of these spokes or shaft; Fig. 4 shows winding of wire and attachment to commutator, which is simply two segments, fig. commutator, which is simply two of gun-metal, the lower two ends go to one ring, the upper two to the other. The shaft is shown in section, fig. page. It must be centred as to be borne true; a fork or a drill for 1-16th hole; D D, fig. 6, to be turned up true as far as B, at one end, and No. at other end, to receive pieces, as then to be firmly bored in or screwed. The pieces are then to be put in places as true as possible, and secured with screws in the spokes. They should be bored with No. 10 cotton-covered wire, three layers, and wound in their places, and the wire commenced up to commutator. The whole is then to be mounted in rest between two steel centres, in a grooved head and or brass pulley for driving off.

The magnets (two composed of four each) are made of steel, tempered down to purple, each 4 inch thick, fig. 5, and 1 inch in length straight part of each, bent together after magnetising, as shown in sketch; pole pieces (fig. 5) of soft iron, 1 inch square, 2 inches long, 1/4 inch thick, to, as shown, so that the armature rotates freely, but as closely between the poles as may be without touching. The wire may then be wound on the magnets, three layers, No. 14 or 16; the bobbins of soft iron fitted on in place. Fig. 7 shows winding of two springs on magnets.

The springs are thicker, to make to press on the rings on the commutator, and from these springs

[1] The following is a copy of the Specification as it was left at the Patent Office:—

I, Wallenstein, Hoxton, in the County of Middlesex, Gentleman, do hereby declare that I am not at home at present but hope to be back in time to see you before dispatch.

Yours truly,

P.S.—I forgot to say what I have used by some post as to the Specification of the Improvements in Electric Motors, Dynamo and Magneto-Electric Machines.

Yours, JAMES EDMUND.

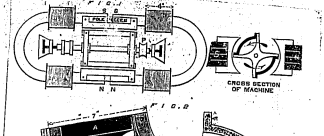
ELECTRICITY.—THE MICHIGAN PARALLELOID.

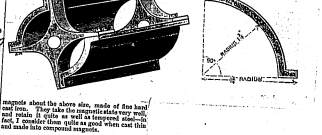
To the Editor of SCIENCE.

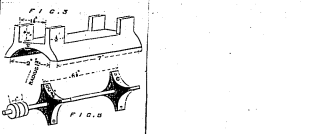
SIR,—The instructive pyrotechnical illustrations for the Centennial, as newly described in the recent notice of the Parallelograph, in connection with the Electric Light, suggest to me the propriety and practicability of a new device for the Michigan Parallelograph, to be called the Michigan Parallelograph, which I have constructed, and which will be exhibited at the Proceedings of the Royal Society for 1876. As I have published illustrations of the same described by Mr. Wallenstein, in the Scientific American, and in the Mechanics' Magazine, I have not thought it necessary to publish them in the Weekly Mirror. I hope to be present at the Centennial Exhibition, and shall be glad to see you there.

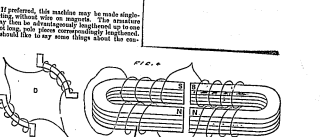
Yours truly,

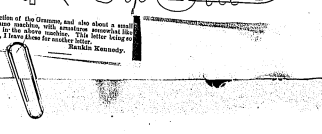
J. EDMUND.











wire may be led to the binding-screws; the wires from the magnets are also led to those screws, care being taken to join + spring and + end of magnet-wire together, and the same for the — spring and — end of wire to other, or magnet wires may be led to another two binding-screws. I have had magnets about the above size, made of fine hard iron wire. They take the magnetic state very well, and retain it quite as well as tempered steel—in fact I consider them quite as good when cast thin and made into compound magnets.

If preferred, this machine may be made single-acting, without wire on magnets. The armature may then be advantageously lengthened by one half long, pole pieces correspondingly lengthened. I should like to say some things about the construction of the Gramme, and also about a small dynamo machine, with armature somewhat like that in the above machine. This letter being so long, I have those for another letter.

Franklin Kennedy.

une série de conférences dans lesquelles serait résumé l'ensemble des notions relatives à la photographie.

Ces conférences, qui principalement pour but de faire connaître, par un enseignement oral et démontré, les méthodes photographiques que jusqu'à présent on ne pouvait étudier que dans les traités spéciaux.

Une large part y sera donnée aux notions élémentaires et aux différents procédés pratiques dont la connaissance est nécessaire pour les applications diverses de la photographie. M. Davanne, vice-président de la Société française de Photographie, a bien voulu se charger de cet enseignement.

Les conférences auront lieu les mardis à 8 heures 30 minutes du soir, à la Sorbonne, dans le grand amphithéâtre; elles commenceront le 2 décembre 1879 et continueront jusqu'au milieu du mois de janvier suivant; elles seront publiques.

CHRONIQUE D'HISTOIRE NATURELLE

Puissance germinative des graines.—M. C. de Candolle, de Genève, a expérimenté, de concert avec M. Raoul Pictet, l'action des températures très basses sur la faculté germinative des graines. Il a soumis, pendant deux heures, à une température inférieure à 80° centigrades, des graines des espèces suivantes : *Sinapis alba, Lepidium sativum, Artemisia annua, Mimosa pudica, Galactella dracunculoides, Silene pendula, Perilla Nankinensis, Hyoscyamus niger, Cobæa scandens, Ricinus communis, Fraxinus ajfinalis, Nicotiana acuminata*, et enfin le blé ordinaire.

Toutes ces graines, à l'exception de celles de *Perilla, Hyoscyamus* et *Nicotiana*, ont germé et poussé leurs premières feuilles aussi rapidement que d'autres graines des mêmes espèces, non soumises au froid, et semées en même temps.

Métamorphoses des batraciens urodèles. — Mlle de Chauvin a fait sur les Batraciens Urodèles un certain nombre d'expériences fort curieuses. La *Salamandra atra* est vivipare et met au monde des petits dépourvus de branchies, destinés à vivre immédiatement sur la terre; mais, avant leur naissance, ils ont passé par une phase pendant laquelle ils ont des branchies et une *queue natatoire*. Mlle de Chauvin a pris plusieurs de ces embryons dans le ventre de leur mère, et les a introduits dans l'eau pour voir s'ils continueraient à vivre sous cette forme larvaire. Les branchies embryonnaires tombèrent bientôt, mais, après une crise assez grave, il s'en reforma de nouvelles; la frange membraneuse délicate de la queue embryonnaire fut remplacée également par une autre plus ferme; le peau resta plus molle et moins noire que dans la *Salamandra atra* ordinaire. Toutefois, au bout de seize semaines de séjour dans l'eau, les branchies disparurent graduellement par résorption, comme cela a lieu dans le développement normal des autres Salamandres. Mlle de Chauvin parvint aussi à plier un jeune Protée à la vie terrestre, en le faisant séjourner pendant plusieurs mois dans de l'eau bouillie. Enfin, la métamorphose des Axolotls donna lieu à une observation curieuse. Un Axolotl, transformé presque complètement en Amblystome, fut remis dans l'eau ordinaire; ses branchies se développèrent de nouveau et la frange caudale se reforma, devenu ainsi à-la forme primitive, il fut replacé dans de l'eau bouillie, et il reprit, plus complètement encore que la première fois, la forme d'Amblystome.

R. Tuo.

L'ÉCLAIRAGE ÉLECTRIQUE

L'ensemble des appareils actuellement exposés par M. Lontin au Palais de l'Industrie comprend :

1° Une *machine excitatrice* ou *magnéto* à courants continus destinée à alimenter, à nourrir la machine à lumière.

2° Une *machine à lumière* à courants alternatifs dont la disposition permet de produire, à volonté, soit un petit nombre de foyers puissants, soit un grand nombre de petits foyers.

3° Un régulateur électrique à arc voltaïque qui permet d'établir plusieurs lampes dans un même circuit.

4° Un régulateur de courants pour l'incandescence à fil de platine, régulateur appliqué à une rampe à incandescence. Nous allons examiner rapidement ces divers appareils qui présentent un réel intérêt autant par leurs dispositions ingénieuses que par les applications dont ils sont susceptibles.

Machine excitatrice. Il est facile de comprendre le fonctionnement de cette machine en se reportant à la machine de Gramme dont nos lecteurs connaissent le principe. Sur une roue à laquelle M. Lontin donne le nom de *pignon magnétique* sont disposées quarante petites bobines B,B en dix rangées de quatre bobines chacune (fig. 1) ; dans chaque rangée les bobines sont disposées en hélice et sont garnies d'un noyau de fer à l'intérieur; elles constituent ainsi une série d'électro-aimants, qui, en tournant entre les pôles du grand électro-aimant ou inducteur A A, prennent des polarités dont le sens change à chaque demi-révolution. Les courants d'induction engendrés sont recueillis sur un *collecteur* analogue à celui de la machine Gramme par des balais formés de feuilles minces de cuivre qui frottent sur ce collecteur.

L'inducteur AA dont la cuisse forme le socle de la machine est excité par le courant même de la machine, c'est-à-dire que son fil est dans le circuit des bobines par l'intermédiaire des balais du collecteur. Le courant continu produit par cette machine est envoyé dans la machine à lumière.

Machine à lumière. La machine à lumière se compose d'une série d'électro-aimants 3ll (fig. 2) fixés, sur une couronne, les fils de chacun de ses électro-aimants aboutissent à un appareil nommé *manipulateur* dont nous allons examiner la fonction tout à l'heure. A l'intérieur de cette couronne d'électro-aimants tourne un pignon magnétique formé de 24 dents. Chaque dent est une lame de fer entourée de son hélice magnétisante.

Le courant de la machine excitatrice arrivant par F, vient par un fourteur sur une bague a reliée à l'une des extrémités du pignon magnétique.

Après avoir traversé les 24 bobines 3, il sort par une seconde bague et un second fourteur pour retourner à la machine excitatrice. L'enroulement du fil est tel que les pôles développés aux extrémités des

SUR LE RENDEMENT ÉLECTRIQUE

DES MACHINES GRAMME

Les machines dynamo-électriques considérées comme source d'électricité ne peuvent, à cause des conditions multiples de leur fonctionnement, être assimilées aux autres sources électriques, piles liquides ou piles thermo-électriques.

Nous avons entrepris à Silvertown, au mois de juillet dernier, grâce au bienveillant concours de M. Robert Gray, ingénieur de la C^e^ *India Rubber Works*, une série d'expériences pour établir, en dehors de toute considération théorique, les éléments électriques des machines dynamo-électriques placées dans certaines conditions de fonctionnement.

Nos expériences ont porté sur les machines Gramme du type A *dit type d'atelier*, modèles dont nous donnons ci-dessous une vue d'ensemble pour en rappeler le modèle à nos lecteurs.

Hâtons-nous de dire que des expériences semblables ont été déjà faites en France par MM. Mascart et Angot (*Journal de physique* 1878) et en Angleterre par le docteur Hopkinson (Institution of mechanical engineers). Les premières ont été faites surtout à un point de vue théorique, point de vue auquel nous ne pouvons nous placer ici; les secondes se rapportent à des machines Siemens, et c'est un travail analogue que nous avons voulu faire en France sur les machines qui, jusqu'ici, y sont le plus employées.

Les machines dynamo-électriques sont établies pour marcher à une vitesse donnée, vitesse qu'il convient de conserver pour faire produire à ces machines tout ce qu'elles peuvent donner sans nuire à la solidité et au bon entretien des organes qui les composent. Nous avons donc admis que la vitesse de rotation était constante et nous avons toujours ramené les éléments électriques à la vitesse normale (1,000 tours par minute) lorsque le compteur de tours indiquait une vitesse supérieure ou inférieure. Cette réduction est toujours facile, car on constate facilement par expérience que, toutes choses égales d'ailleurs, la force électro-motrice est proportionnelle au nombre de tours de la machine, même pour des variations de vitesse qui atteignent 500 tours par minute.

Nous nous sommes rendu compte par l'expérience des variations des éléments électriques des machines Gramme en faisant varier la résistance extérieure depuis 10 ohms jusqu'à une résistance extérieure nulle.

Dans une expérience, la machine tournant à une vitesse de 1,000 tours par minute, avec une résistance extérieure de 2,7 ohms, soit 1,8 fois la résistance intérieure, développait un courant de 25,5 webers d'intensité avec une force électro-motrice de 107 volts. Le travail total transformé en électricité était de 273 kilogrammètres, soit, 3,64 chevaux; le travail utilisable était de 179 kilogrammètres, soit 2,38 chevaux.

Dans ce cas, le rendement atteignait 65 p. 100. En tenant compte des frottements, des résistances passives etc., dont la [illegible] soit utilisable, n'est-ce pas [illegible] intermédiaires, mais les chiffres que nous venons de donner montrent entre quelles limites sont comprises les machines Gramme employées pour la lumière électrique.

E. HOSPITALIER.

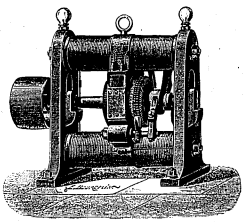
Résistance intérieure de la machine. — En mesurant par la méthode du pont de Wheatstone les résistances de la machine soumise à l'expérience, nous avons trouvé:

Résistance totale de la machine avant le fonctionnement	1,185
Résistance de la bobine *induit*, après avoir fonctionné quelque temps en court circuit	0,75
Résistance des électro-aimants dans les mêmes conditions	0,72
Résistance totale de la machine *chaude*	1,47

Ces résistances sont exprimées en *ohms*.

Ces chiffres montrent que la *résistance intérieure* de la machine varie dans de très-faibles limites, et que ces variations sont dues à l'échauffement du fil dont la résistance augmente avec la température.

Force électro-motrice. — La courbe I du diagramme montre la variation de la force électro-motrice lorsque la résistance extérieure augmente. Les résistances totales sont portées sur l'axe des abscisses à l'échelle de 1 centimètre par *ohm*, les forces électro-motrices sont portées en ordonnée à l'échelle de 1 millimètre par volt. Lorsque la résistance totale est supérieure à 2 fois la résistance intérieure, on voit que la force électro-motrice est à peu près constante et très-faible. Cela tient à ce que l'induction sur la bobine n'est produite que par le magnétisme rémanent des électro-aimants. Puis, cette force électro-motrice croît très-vite entre 6 ohms et 4 ohms de résistance totale, elle atteint une valeur de 107 volts et varie alors très-peu. Cela tient à ce que le courant qui traverse les électro-aimants les ayant aimantés à saturation, le champ magnétique reste constant et comme, d'autre part, la vitesse



de l'induit est elle-même constante, la force électro-motrice qui est proportionnelle à ces deux quantités ne peut plus varier que par l'échauffement du fil.

Intensité du courant. L'intensité du courant exprimée en webers est représentée par la courbe II du diagramme à l'échelle de 1 millimètre par weber.

On voit que cette intensité d'abord très-faible augmente ensuite d'une façon assez régulière pour des résistances totales variant entre deux fois et quatre fois la résistance totale de la machine.

Ces intensités ont été calculées par la formule :

$$Q = \frac{E}{R}$$

Q. Intensité en webers.
E. Force électro-motrice en volts.
R. Résistance totale en ohms.

Travail transformé en électricité. — Les chiffres que nous avons trouvés se rapportent à l'unité de temps, la seconde. La valeur du travail transformé en électricité est exprimée par la formule de Joule :

$$W = 10\ Q^2\ R.$$

Q et R ont les mêmes valeurs que ci-dessus.

W est le travail exprimé en *sup-ergs*. Pour réduire en unités françaises un kilogrammètre vaut 98,1 *sup-ergs*.

La courbe III du diagramme montre que le travail transformé en électricité qui en très-faible tant que la résistance totale dépasse 6 ohms augmente ensuite rapidement et régulièrement à mesure que la résistance diminue. L'échelle des courbes III et IV est de 1 millimètre pour 2 kilogrammètres.

elettrico di Edison; esso è stato fatto allo scopo di essere situato dappertutto, ove una forza poco importante sia necessaria, come quella per muovere una macchina da cucire, un tornio, un elevatore ecc. ecc.; basta per ciò di staccare il filo della lampada a di comunicare al piccolo motore: avete così la scelta sia d'illuminare, sia di far lavorare il vostro motore. Il disegno rappresenta la macchina a questo. Il diagramma rappresenta la macchina a motore. Il disegno rappresenta la macchina a 1/6 della grandezza reale.

La sua costruzione non differisce in niente per così dire dal generatore. L'armatura è situata in parallelamente all'elettro-calamita, invece d'essere trasversale, e l'elettro-calamita è fissa in un sol pezzo invece di essere in diverse sezioni, come nel generatore figura A. Tutto il resto è assolutamente simile al generatore avendo la stessa armatura e lo stesso commutatore con spazzolo di rame.

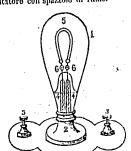

Figura B. Questo disegno rappresenta la nuova lampada d'Edison, la quale, come si vede, è molto semplice, ed è rappresentata mento 1/4 della grandezza reale.

(1) È il globo di vetro che ricovre tutto e nel quale si produce il vuoto.

(2) Base della lampa'a, per la quale base s' introducono i fili conduttori della corrente.

(3) Piccolo filamento di carta carbonizzata.

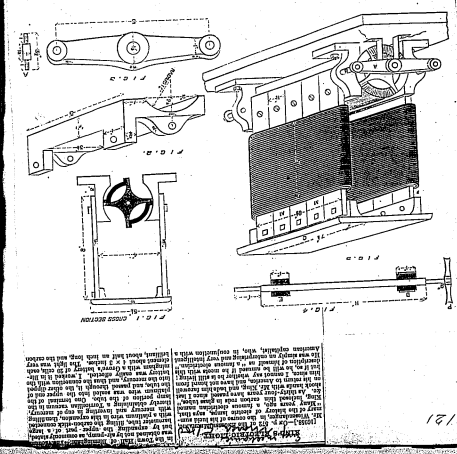
(5) (6) Fili di platino che conducono alle viti (4) (5) e di là al generatore.

Uno dei grandi vantaggi della luce elettrica è il non dare calore: e di più l'incandescenza nella nuo va lampada producendosi nel vuoto, l'aria non no è menomamente vitiata.

La qualità de' del conto comparato al gaz sarà di circa 60 a 70 per conto a miglior mercato per la nuova lamp.; ma: ciò che in gaz costerà 2,50 a 3 franchi vers. ubia al massimo a costare 1 franco, colla supe. verità incontestabile della qualità dell'illuminazio. ne.

La maniera della lampada d. Edison è delle più semplici; essa può essere reg. sta su Jasciato. La luce può essere a volonta. portata istantaneamente ad una grande intens. à ed essere ridotta ad una luce impercettibile.

E una fortuna che Edison abbia trovato il nuovo sistema di carbone fatto colla carta; stanza questo la quistione sarebbe ancora lungi dal essere risolta, perchè per farsi un'idea del c dero intenso che si produce colle due cor enti basterà dire che nel momento dell'accensione al punto luminoso il calore della corrente sensitiva è di 9800°.



MATTINO

Amministrazione o agli Uffici postali.

Gli annunci, le inserzioni di 3ª e 4ª pagina, le necrologie non si ricevono assolutamente nell'impresa di Pubblicità Deposito e Collocamento, Via Roma (Largo della Carità N. 79).

...sono di suscitare gravi discussioni. — Che ...abbia provveduto al maggior incremento dell'esercito, tutti sono d'accordo. Le discussioni sono circa ai mezzi. — Lon. Primerano, relatore della Commissione, vorrebbe che si provvedesse alle maggiori spese per l'esercito con un'operazione finanziaria, gl'interessi della quale soltanto sarebbero scritti sul bilancio della guerra. Ma i suoi colleghi della Commissione non sono tutti d'accordo coll'on. relatore, e anche su questo argomento finora non si conosce... — Vedremo se la Camera assenta a pronunciare il *Fiat Lux!*

Corriere della Sera

LA NUOVA SCOPERTA
di Thomas Aloa Edison

Edison, l'uomo illustre, che da tutti è considerato per non aver rivali, ha aggiunto testè, al suo genio e coi suoi lavoro incessante, al suo nome, nuovi, meravigliosi, la telegrafonia, difficoltà per quel che riguarda la scienza e incontestabile utilità per tutte le classi dell'umanità.

Or sono alcuni mesi allorchè si sparse la voce che Edison, il misterioso, avesse risoluto la questione della illuminazione elettrica, il unico prese gli azionisti del gas e le azioni ...addero in un momento a prezzi rovinosi per ...detentori. I freddi pensatori, che sono ...sommano, vegliono toccare prima di credere, ...on si allarmarono; aspettò ...ervano di nervi sensibili compra ...scrutivo quanto più conveniente per questo ultimo. Credendo ad una mistificazione e nella l'unanimità ...sione che la soluzione d'Edison fosse ...polta sotto le rovine dell'insuccesso, a poco ...poco la fiducia si ristabilì, gli uni si tolsero ...rono del loro speculativo ...rimento, gli altri ...lamentarono della loro momentanea debolezza; e non restò loro altro che giurare di ...la farsi più accalappiare.

Or sono alcuni mesi... quando avvennero i ...tti accennati lo persone interessate avrebbero dovuto accorgersi che le belle promesse ...on erano di quelle che ...chiare, concise, ...o senza fondamento emanavano sia dalla ...ampa lusingatrice, sia dalla cupidigia d'speculatori poco coscienziosi.

Ed dunque, naturale, che ora, quando il ...e inventore annunzia di aver compiuta l'opera ...a si abbia una certa ripugnanza a credervi, ...ppo essere stati da uno o da un altro più ...lo mistificati.

Quelli che vogliono vedere non aspettavano ...mai molto!

Il grido di vittoria che risuonò allora, lo riflettano, non venne da Edison; il quale ...progettare è molto serio per mettere fuori ...na falsa notizia. Egli, anzi, non avrebbe ...lon pubblicherebbe l'opera sua se non quando ...gli stesso non avrebbe più alcun dubbio sul ...efficacia di quella.

Oggi dopo lunghi e penosi lavori Edison fa la prima applicazione del suo sistema e solo dietro un maturo esperimento egli viene a farci di aver superate tutte le difficoltà, e questo collo prova alla mano; imperocchè la ...a luce è uscita dal suo laboratorio, è stata dotata a Menlo-Park; per conseguenza a ottoposta al giudizio del pubblico. E si noti ...ha i primi clamori che si giungono sono del ...ubblico e non di Edison; di più dunque fin ...ora registrare l'illuminazione elettrica come ...a'attualità all'ordine del giorno.

* * *

Due parole di Edison e del suo laboratorio.

Edison è figlio delle sue opere; ha esordito ...assai umilmente in questo mondo, e senza voler tornare molto indietro, lo troviamo impiegato in un ufficio telegrafico.

Là in pochi mesi la sua superiorità è talmente ammirata, egli fa invenzioni così preziose in telegrafia che ...ne trovano in Europa ...ispettore generale di tutta la Compagnia.

Edison è lontano ...a sua statura è al disopra della mezzana; quantunque non abbia che trentadue anni, i suoi capelli sono grigi; il suo sguardo penetrante fa ...avvedere le sue continue preoccupazioni; il suo pensiero è giorno e notte fisso ai suoi progetti; la sua osservazione si aggira pure e sempre su tali argomenti.

Egli non è veramente in casa sua che nel suo laboratorio, il quale è fornito del più completo ...rredo, della macchina a vapore di 80 cavalli ...sino all'utensile più delicato. Gabinetto di fisica, di chimica, ecc. ecc. tutto vi è: egli ha tutto l'occorrente per poter ...re i suoi lavori e studi progetti. Vi è un buon numero d'assistenti, i quali sono, di ...ordate, occupati in una quantità d'operazioni di natura assai diversa. L'apparecchio che è stato finito il giorno vien sperato provato la notte quando tutto è silenzio e quando non vi sono visitatori.

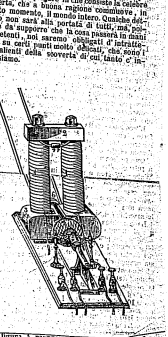
A malgrado queste grandi fatiche egli confessa la sua salute essere buona, le sue occupazioni essergli piacevoli e non soffrire del lavoro eccessivo a cui egli si dà.

La sua abitazione ed il suo laboratorio sono splendidamente siti sul fianco d'una collina, la quale sovrasta una vallata assai pittoresca; quella vista incantevole e quell'aria di montagna sono i migliori rimedii per gli spiriti senza riposo.

Edison può essere superbo della sua posizione nel mondo della scienza, perchè per la sua energia e la sua pertinacia egli si è assicurata una rendita che lo mette in grado di potere attuare sopra vasta scala gli esperimenti immaginati dalla sua prolifica intelligenza.

* * *

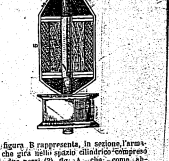
Ora che abbiamo detto più o meno chi è Edison andiamo con l'aiuto delle figure qui riprodotte a spiegare in che consiste la scoperta, che a buona ragione commuove, in questo momento, il mondo intero. Qualche dettaglio non sarà alla portata di tutti, ma poi competenti, noi saremo obbligati d'interessarci su certi punti molto ...ostici, che sono i più salienti della scoverta di cui tanto ci interessiamo.



La figura A rappresenta la nuova macchina dinamo-elettrica di Edison, quella cioè che produce il meglio, genera la corrente elettrica, che deve alimentare le lampade, i motori ecc. ecc.

(1) rappresenta le braccia dell'elettro-calamita; esso sono formate da un cilindro di ferro battuto di 0 metri e 15 c/o di diametro, sopra una lunghezza di 0 m. 20 c. ; questi cilindri sono montati sopra grossi ferro fuso (2) che formano i poli dell'elettro-calamita ; questi pezzi sono molto pesanti e le loro dimensioni sono 0 m. 27 di altezza per 0 m. 171 di larghezza ; i cilindri in ferro battuto (1) sono forati per aprire il passaggio ad un bottone, al quale rimbocca i pezzi di ferro (3) i cilindri, e la traversa (2) per non formare che un corpo solo : dei resti la madrevite che si veggono sulla traversa (2) indicano evidentemente come le differenti parti sono riunite.

I cilindri (1) di ferro sono ricoverti di tre strati di filo di cotone n. 10, isolati con cotone; le estremità di questi fili sono trattenute da viti che si osservano sulla base della macchina ; tutti i pezzi della macchina sono fissati sopra una placca d'ottone che ha forma di croce.



La figura B rappresenta, in sezione, l'armatura che gira nello spazio cilindrico compreso fra i due pezzi (3) *fig:* A. che ...come abbiam detto formano i poli dell'elettro-calamita; questa armatura consiste in un cilindro (3), largo (2) inondato sopra un'asse di ferro, (1) di 0 m. 038 di diametro. L'asse è fissato alle sue due estremità due dischi di ferro dolce, fra i dischi vengono disposti strati (4) di filo di ferro dolce n.° 20, i quali sono a 1 volti intorno all'asse (1), e fuori dei dischi in ferro sono applicati altri dischi di fibra vulcanizzata (3), tali dischi sono scanalati alla loro periferia per ricevere i fili di rame ricoverti di cotone (5), che sono avvolti longitudinalmente sul cilindro e poi fissati a certa distanza di loro per mezzo di cunicolature (7). Vi sono 41 fili di .42 ... in ogni fascio, ciascuno dei quali passa attorno al cilindro longitudinalmente sopra tali diametralmente opposte; la parte opposta di ogni filo dei diversi fasci sono ad essere saldate alle sbarre di rame del commutatore sopra tali appoggi dei cilindri di questo (7). Vi sono 40 fasci avvolgenti l'armatura ed il cilindro comprende 3 grandi dischi due tali estremità e un terzo in mezzo ...ove sono ...ti interrompono la corrente. L'asse (1) ...sua puleggia di 0 m. 23 di diametro per 0 m. 12 di superficie faciale, la quale puleggia comanda l'asse dell'armatura, di cui la velocità è di

LONDON, Dec. 23, 1878.

Mr. Vanderbilt, in the course of his brief visit to this city, was asked by the Associated Press correspondent to give his opinion of the invention of Mr. Edison, of Menlo Park, which has created so much excitement in this city and throughout the country. Mr. Vanderbilt said: "I have not had time to examine Mr. Edison's invention, but I have no doubt it is all right. I have known Mr. Edison for many years, and he is a very intelligent man. I have seen his electric light, and it seems to be a very good one. I have also seen the electric pen, which works well, and I have no doubt that Mr. Edison will succeed in his experiments with the electric light. I am not a scientific man myself, but I have a very high opinion of Mr. Edison's ability, and I have no doubt that he will succeed in his present undertaking."

Mr. Vanderbilt left this city for Paris at 10:30 this morning.

Mr. Darr, also a similar American, believed in 1850, that there would be a time when gas would be driven out of the houses by electric light. Mr. Darr's invention was the first step in this direction, and, although he died before the invention was perfected, he succeeded in securing the services of Mr. Starr, the original inventor of the incandescent burner, who, when a young man, was known as a very ingenious mechanic, and would have been almost entirely forgotten in connection with the history of electric lighting, were it not for the fact that he lived, would know about other experimental electricians. He worked for a number of years with two associates, William Starr and Moses G. Farmer, in conducting experiments in electric lighting, and succeeded in obtaining a light, I am told, equivalent to 75 gas burners, but it was not considered practical for general use, as the cost of working was too great. Starr, however, was not satisfied with this result, and continued his experiments for a number of years, and finally succeeded in producing a light which was considered practical for general use, and which could be produced at a cost of working much less than that of gas. Starr's invention consisted of a carbon burner, which he placed in a glass globe, from which the air was exhausted, thus filling the globe with a vacuum. The carbon burner was in the form of a horseshoe, and was connected with a platinum wire by means of which the electric current was conducted to the burner. Starr's invention was exhibited at the Centennial Exhibition in Philadelphia, and was awarded a medal. Starr's invention was sealed into the upper part of the globe. One terminal of the electric current was connected with the platinum wire, and passed through it, the other terminal was connected with the carbon burner, and thus the connection in the circuit was easily effected. The carbon burner was placed in the globe, and the globe was filled with nitrogen with a battery of 20 cells, each element about 4 × 2 inches. The light was very brilliant, about half an inch long, and the carbon stick (made of gas-retort coke) stood firmly, but the glass was dimmed with a carbon deposit.

Mr. Starr's invention was exhibited in Europe, and was highly spoken of by the press, as unusually successful. He obtained out by his death, and it was left for Edison, by expanding the upper part of a large globe, and by using a carbon burner, to make the invention commercially successful. Edison's invention consists in using a platinum wire in connection with the carbon burner, and in using in cup of mercury, through which the current passes to the carbon burner. The platinum wire is sealed into the upper part of the globe, and passed through it, the other end of the wire being connected with the carbon burner, and thus the connection in the circuit is made. The carbon burner was placed in the globe, and the globe was filled with nitrogen with a battery of 20 cells, each element about 4 × 2 inches. The light was very brilliant, about half an inch long, and the carbon

800 giri per minuto. Malgrado che la corrente dell'armatura possa essere utilizzata per eccitare l'elettro-calamita, il signor Edison, per ottenere più economia, preferisce caricare l'elettro-calamita con una macchina separata, difatti egli intende caricare una batteria di questi generatori, con una macchina Faraday semplice di questa forma.

Un fatto importante è stato scoverto durante gli esperimenti fatti con questo generatore. Edison ha trovato che, rimanendo la estremità dell'elettro-calamita con un filo di ottone, quando la macchina è in movimento, l'elettro-calamita raggiunge prestissimo il suo *maximum* di carica che conserva per tutto il tempo che il generatore resta in attività continua.

Il peso dell'elettro-calamita sola è di circa 500 kil. e vi bisogna quasi un minuto per caricarlo sino a tale tensione.

La resistenza interna dell'armatura è solamente d'un 1/2 Ohm. ed Edison pretende di realizzare 90 0/0 della forza trasmessa a questa macchina, in corrente esterna effettiva.

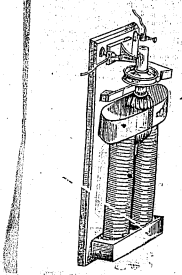
Per ricavare dalla sua macchina tutto l'effetto, di cui essa è capace, è necessaria una forza di 5 cavalli; con tale forza, la macchina può generare una corrente sufficiente, a mantenere 40 lampade, producendo eguale una luce equivalente a 16 bogie.

L'economia della macchina, è provata dal fatto, che un sol unico grandioso può generare abbastanza corrente per mantenere l'arco elettrico d'una Cabina di Jablochkoff.

Questo generatore rassomiglia in prima vista a tutti gli altri del suo genere come il Brush-Wallace-Weston e si avvicina più particolarmente alla macchina Siemens; somiglia, ma non ne differisce intanto grandemente. Questa differenza consiste in ciò che essa genera una corrente doppia, paragonata a tutte le macchine della sua specie.

La macchina Siemens produce dalla corrente di circuito 92 0/0 dell'energia ricevuta, mentre che pravee meglio stabilite hanno dato 83 per cento; e dicesi, questi dati la più parte dei nostri scienziati sono d'avviso che non vi sia ormai più poco o punto margine per miglioramenti. Ora l'energia così portata vien distribuita sull'intera resistenza, di modo che, se la resistenza della macchina è rappresentata da 1 nel circuito esterno da 9, noi avremo 9/10 dell'energia totale effettivamente risultante, giacchè essa è tale al di fuori della macchina; 1/10 è perduta nella resistenza della macchina. La macchina Siemens, come quasi tutte le altre, ha la resistenza esteriore eguale a quella del circuito; per questione ecc. di eguagliare a zero, utilizzare questi risultati; quelle la molte ricerche Edison nei suoi lavori sono state le principale scientifiche la maggior parte ecc. ma egli non ha perduto il coraggio ed ha ritatto questo formolo come esso dovevano essere per raggiungere lo scopo.

Nel generatore di Edison 5 cavalli vapore sono trasferiti senza ecc. residenza di 5 cavalli del quali 1/2 Ohm. nella macchina; essa libera quindi 1/10 di cavallo, totale sul circuito esterno della macchina, ottenendo in questa condizione del *maximum*. Il economia, mentre, studi, condizioni le altre macchine non ne produrrebbero quasi come una lampada non bastava ad una illuminazione elettrica: bisognava anche, anzi innanzi tutto, un generatore economico, ed Edison, come s'è veduto, deve averlo trovato.



Questo figura rappresenta il nuovo motore elettrico di Edison; esso è stato ideato allo scopo di essere situato dappertutto, ove una forza molto importante sia necessaria, come quella per muovere una macchina da cucire, un tornio, un elevatore ecc. ecc.; basta per ciò di staccare il filo della lampada e di comunicarlo al piccolo motore: avuto così la scelta sia d'illuminare, sia di far lavorare il vostro motore. Il disegno rappresenta la macchina a meno di 1/8 della grandezza reale.

La sua costruzione non differisce in niente per così dire dal generatore. L'armatura è actuata parallelamente all'elettro-calamita, invece di essere trasversale, e l'elettro-calamita è fissa in un sol pezzo invece di essere in diverse sezioni, come nel generatore (figura A). Tutto il resto è assolutamente simile al generatore avendo la stessa armatura e lo stesso commutatore con spazzoli di rame.

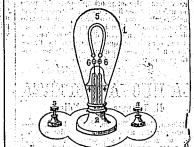


Figura B. Questo disegno rappresenta la nuova lampada di Edison, la quale, come si vede, è molto semplice, ed è approssimativamente 1/4 della grandezza reale.

(1) È il globo di vetro che ricopre tutto e nel quale si produce il vuoto.

(2) Base della lampada, per la quale base s'introducono i fili conduttori della corrente.

(3) Piccolo filamento di carta carbonizzata.

(4) (5) Fili di platino che conducono alle viti (6) (7) o di là al generatore.

Uno dei grandi vantaggi della luce elettrica è di non dare calore: e di più l'incandescenza nella nuova lampada prodotta nel vuoto, nella non ha consumazione vizziata.

La qualità de del costo comparato al gas sarà di circa 60 a 70 per cento a migliore mercato per la nuova lampada; ciò che in gas costava 2.50 a 3 franchi per ora, ora al massimo a costare 1 franco, colla superiorità incontestabile sulla qualità dell'illuminazione.

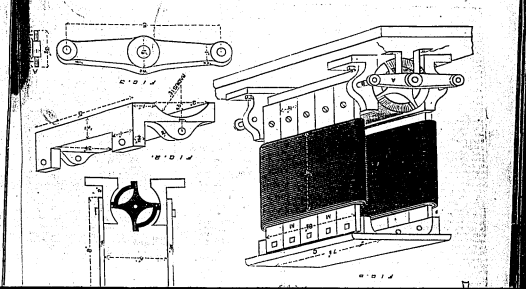
La maneyra della lampada è molto è delle più semplici; essa può essere regolata da un fanciullo. La luce può essere a volontà, portata istantaneamente ad una grande intensità ed essere ridotta ad una luce impercettibile.

È una fortuna che Edison abbia trovato il nuovo elemento di carbone fatto colla carta; senza questo la questione sarebbe rimasta allo stato di arco elettrico, perchè per farsi un'idea del costo attuale che si produce colla dinamo, basterà dire che nel momento dell'accendere si può mantenere l'arco elettrico per circa 3000 e qualche volta più d'ora per quelli grandi.

Edison dopo molte ricerche ha adottato il carbone che ora egli impiega e che è fatto con carta tagliata in forma di ferro di cavallo; forto e poi esposto ad una temperatura molto elevata; ciò per ottenere carbone fatto puro per quanto è possibile e depurato da tutte le materie volatili. Ciò fatto e fatto il vuoto quasi perfetto nella campana della lampada, i risultati sono stati soddisfacentissimi, poichè il carbone, visto l'assenza, dell'ossigeno non deteriora punto.

Se tutto va di questo passo avviamo a luogo andare alla stato d'assenza in formola: — = — è che essa può senza alcuna spesa nè alterazione essere impiegata nei luoghi ordinari, invece del gas; invece dei becco di gas s'introduce la piccola lampada: i semplici fili conduttori fanno il resto.

Per stabilire la luce in una città basta di avere un poste dove lavalore una macchina a vapore, secondo la forza necessaria, o per questa macchina fa muovere la quantità necessaria di macchine del tipo della figura A. Basta che ci sia la comunicazione fra questo ultimo e la lampada per fili di rame, e tutto è fatto. Le lampade per fili di rame, e tutto nell'interno dei possono essere situate farvi alcuna le fanali a gas esistenti senza si otterrebbe alla vendita di tutti i materiali inutili che servirono al gas pagherebbe il nuovo sarebbe ecc. decuplato? La nuova speculazione che abbe essere intrapresa da questa scoperta



currents induced in them which pass out to the lamps.

Four types of the machine are at present manufactured, viz.:

No. 1 Type.

	4 millimetre candles.			3 millimetre candles.
Number of Candles ...	4	6	8	12
Horse-power consumed ...	1·75	1·5	1·6	...
Speed of Machine in revolutions per minute ...	1250	1300	1450	1460 to 1500
Light per candle produced, in Candlelamps ...	72	60	50	30

No. 1a Type.

The No. 1a machine is specially adapted for lighting 12 3-millimetre candles, which, with 4 horse-power consumed, will each give a light equal to 30 Carcel lamps.

No. 2 Type.

This type of machine will light 8, 12, or 16 4-millimetre candles, or 24 3-millimetre candles.

No. 2a Type.

This machine is specially constructed for burning 24 3-millimetre candles with a consumption of 8 horse-power.

The cost of the candles with 3-millimetre carbons is 2d. The circuits of No. 1 machine, when it is required for burning 4, 6, or 8 lights, are grouped for quantity, as this gives the best effect. If the 12 lights are used then the circuits are joined up in series. In the case of 8 large or 12 small lights a resistance is introduced between the two parts of the machine.

EDISON'S ELECTRIC LAMP.

Details of this invention are now to hand, the *New York Herald* having published an illustrated description of the apparatus. The following extracts from that paper will show the nature of the new lamp. Commencing with a description of Mr. Edison's first experiments, the *Herald*, quoting Mr. Edison's words, writes as follows:—"When wires or sheets of platinum, iridium or other metallic conductors of electricity that fuse at a high temperature are exposed to a high temperature near their melting-point in air for several hours by passing a current of electricity through them and then are allowed to cool, the metal is found to be rarefied, and under the microscope there are revealed myriads of cracks in various directions, many of which reach nearly to the centre of the wire. I have also discovered, continues Mr. Edison, that, contrary to the received notion, platinum or platinum and iridium alloy loses weight when exposed to the heat of a candle; that even heated air causes it to lose weight; that the loss is so great that a hydrogen flame is tinged green. After a time the metal falls to pieces; hence wire or sheets of platinum or platinum and iridium alloy are now known in commerce are useless for giving light by incandescence.—

"1st. Because the loss of weight makes it expensive and unreliable, and causes the burner to be rapidly destroyed.

"2nd. Because its electrical resistance changes by loss in weight, and its light-giving power for the total surface is greatly reduced by the cracks or ruptures.

"The melting-point also is determined by the weakest spot of the metal. By my invention or discovery I am able to prevent the deterioration of the platinum or its alloys by cutting off or intercepting the atmospheric action. A spiral wire, or other form of platinum, is placed in a glass tube or bulb, with the wire near its ends passing through and sealed in the glass, and the air is exhausted from the globe. The platinum wires of the spiral are then connected to a magneto-electric machine or battery, the current of which can be controlled by the addition of resistance. Sufficient current is allowed to pass through the wire to bring it to about 150 degrees Fahrenheit. It is then allowed to remain at this temperature for ten or fifteen minutes. While thus heated both the air and gases confined in the metal are expelled by the heat or withdrawn by the vacuum action.

"While this air or the gases are passing out of the metal the mercury pump is kept continually working.

"After the expiration of about fifteen minutes the current passing through the metal is augmented so that its temperature will be about 300 degrees Fahrenheit, and it is allowed to remain at this temperature for another ten or fifteen minutes.

"The mercury pump is to be worked continuously and the temperature of the spiral raised at intervals of ten or fifteen minutes until it attains vivid incandescence and the glass is contracted where it has passed to the pump and melted together.

"The wire is now in a perfect vacuum and in a state heretofore unknown, for it may have its temperature raised to a most dazzling incandescence, emitting a light of twenty-five standard candles, whereas before treatment the same radiating surface gave a light of only about three standard candles. The wires after being thus free from gases are found to have a polish exceeding that of silver and obtainable by no other means. No cracks can be seen even after the spiral has been raised suddenly to incandescence many times by the current, and the most delicate balance fails to show any loss of weight in the wire, even after it is burning for many hours continuously. I have further discovered that if an alloy of platinum and iridium is coated with the oxide of magnesia and subjected to the vacuum process described, a combination takes place between the metal and the oxide, giving the former remarkable properties. With a spiral having a radiating surface of 3-16 of an inch light equal to that given by forty standard candles may be obtained, whereas the same spiral, not coated by my process, would melt before giving a light of four candles. The effect of the oxide of magnesia is to harden the wire to a surprising extent and render it more refractory. A spiral made of this wire is elastic and springy when at high incandescence. I have found that chemically pure iron and nickel drawn in wires and subjected to the vacuum process may be made to give a light equalling that of platinum in the open air. Carbon sticks also may be freed from air in this manner, and be brought to a temperature where the carbon becomes pasty, and on cooling it is homogeneous and hard."

Notes.

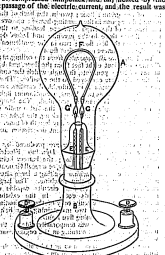
Edison's New Electric Lamp.—A strip of cardboard bent into a horse-shoe form and converted into carbon by baking in an iron mould, is the basis of the new lamp; the strip is placed in an exhausted globe, and a current of electricity being sent through the strip renders the latter incandescent. As regards durability, &c., the *Times* correspondent says:—"About 60 lights were burning. On Saturday night I saw them burn seven hours. Two have been burning continuously for ten days without injury to the carbon. One in the little globe gives a fine light. Cardboard seems sufficiently durable, successfully resisting quite rough usage, such as dropping, shaking, &c. Thousands of times, and to that of 200 candles. Epps, Mr. Edison will put up 25 lights in the Inventions Exhibition in New York. He has also a number of small machines by the Siemens and Gramme gauge. By successively Mr. Edison gets individual inch lamps having 100 ohms on or off and the current ran gas is, while the current was small at No. 36. The an even current, while the to supply furnished to each a that the best generators ever, each one here spoken

Each lamp costs about while a supply equivalent educed for tenpence or less. ut of furnishing light thus— tool in a steam engine will e one hour. Mr. Edison's power for small industries, since, Mr. Edison's light ably does away flickering ptic gas, and consequently Mr. Edison lights at block a street lamps, also laborer. It available for every ts is used."

ceed Mr. Edison's invenn, and we think it a matter ental journal as the *Times* ral announcements, which, for what they are worth by ridical the general public is

About this time another truth dawned upon the inventor, namely, that economy in the production of light from incandescence demanded that the incandescent substance should offer a very great resistance to the passage of the electric current. Concerning this the inventor writes—"It is essential to reverse the present practice of having lamps of but one or two ohms (electrical units) resistance, and to construct lamps which when giving their proper light shall have at least two hundred ohms resistance."

Having perfected the platinum lamp apparently, Mr. Edison was led to try, "by accident," a filament of compressed lampblack and tar, heated by the passage of the electric current, and the result was



satisfactory. A piece of carbonised cotton was next tried, with better results still; a light equal to several gas-jets being obtained. Several other experiments with various carbonised substances were then tried, and finally the carbonised strip of cardboard was found to give the best results.

"With a suitable punch there is cut from a piece of 'Bristol' cardboard a strip of; the same in the form of a miniature horse-shoe, about two inches in length and one-eighth of an inch in width. A number of these strips are laid flatwise in a wrought iron mould about the size of the hand, and separated from each other by tissue paper. The mould is then covered and placed in an oven, where it is gradually raised to a temperature of about six hundred degrees Fahrenheit. This allows the volatile portions of the paper to pass away. The mould is then placed in a furnace and heated almost to a white heat, and then removed and allowed to cool gradually. On opening the mould the charred remains of the little horse-shoe cardboard are found. It must be taken out with the greatest care, else it will fall to pieces. After being removed from the mould it is placed in a little globe and attached to the wires leading to the generating machine. The globe is then connected with an air pump, and the latter is at once set to work extracting the air. After the air has been abstracted, resting on a stand, n, n is the little carbon filament connected by fine platinum wires, c c, to the wires, g g, leading to the screw posts, a a, and thence to the generating machine. The current, entering at a, passes up the wire g to the platinum clamp, c; thence through the carbon filament n to c', down the wire g' to the screw post a', thence to the generating machine. It will be noticed, that the lamp has no complex regulating apparatus, such as characterised the inventor's earlier labours. All the work he did in regulators was practically wasted, for he has lately realised that they were not at all necessary—no more so than a fly wheel is to a coach.

"He finds that the electricity can be regulated with entire reliability at the central station, just as the pressure of gas is now regulated. By his system of connecting the wires the extinguishment of certain of the burners affects the others no more than the extinguishment of the same number of gas burners affects those leaving the supply from the same mains. The simplicity of the completed lamp seems certainly to have arrived at the highest point, and Edison asserts that it is scarcely possible to simplify it more. The entire cost of constructing them is not more than twenty-five cents.

"The lamp shown in the fig. is a table lamp. For chandeliers it would consist of only the vacuum globe and the carbon filament attached to the chandelier, and connected to the wires leading to the generating machine in a central station perhaps a half-mile away, the wires being run through the gas pipes, so that in reality the only change necessary to turn a gas-jet into an electric lamp is to run the wires through the gas pipe, take off the jet, and screw the electric lamp in the latter's place. Although the plans have been fully contemplated for general illumination, the outline of the probable system to be adopted is the heating of a central station in large cities in such a manner that each station will supply an area of about one-third of a mile. In each station there will be, it is contemplated, one or two engines of immense power, which will drive several generating machines, each generating machine supplying about fifty lamps.

"The apparatus for measuring the amount of electricity used by each householder is a simple contrivance consisting of an electrolytic cell and a small coil of wire, appropriately arranged in a box, the latter being of about half the size of an ordinary gas meter, and like a gas meter it can be placed in any part of the house. The measurement is obtained by the deposit of copper particles on a little plate in the electrolytic cell, such deposit being caused by the electric current passing through the cell. At the end of any period, say one month, the plate is

taken by the inspector to the central office, where the copper deposit is weighed, and the amount of electricity consumed determined by a simple calculation.

The Comte du Moncel has addressed a letter on the subject of Mr. Edison's invention to Dr. Cornelius Herz which was published in *Le Temps*. The Comte expresses astonishment at the excitement caused in the money market by the praises bestowed on the lamp, which is called, "A great discovery." "Edison," says the writer, "is an ingenious and fertile inventor, but is not acquainted with the discoveries made before his time. Neither the idea of the telephone nor the realisation of the phonograph belongs to Edison. His first lamp was a modification of the one invented by Changy in 1858. The one now announced is the modification of those of several inventors. In 1875 much noise was made about the incandescent carbon lamp of Korloff, the pretension being that one Alliance machine could feed fifteen lamps, and yet no more than two have ever been seen working. Regnier and Werdermann, by adding the cellulo are to that combination, obtained better results. The new Edison lamp revives the Lodiguyne lamp in a different shape. The small carbon needles are replaced by laminated carbon, or carbonised bristol, paper separated by metallic tissues carved into the form of a horse-shoe, and joined to the circuit by platinum wires, the whole being in a vacuum, as in Lodiguyne's system. That arrangement may be better than anything previously devised, but it is not an invention of the importance assigned to it by the American papers. The idea of intercalating metallic bodies in the carbonised mass is not new, for it had been realised by Jablochkoff and Reimer. It is difficult for the carbon horse-shoe, so loose and delicate, not to be deteriorated by pumping and disintegrating the carbonic particles and by the mechanical action of the current which carries them away and deposits them on the sides of the recipient, as in Geissler's tubes. The metallic tissues separating the layers of carbon would be damaged. Experience alone will be able to decide, and it is prudent to wait, in spite of the announcement of fifty or sixty feet fed from a single machine. The same may be said of the dynamo-electric machine which offers nothing new about which the theories put forth would upset the laws of Ohm and Joule, theories which are at variance with the experiments made with every other machine. Edison has given no account of the maximum effects." The writer finally protests against the *sans façon* of the Americans with regard to European inventions. "For them electrical science, which sprang up yesterday, was discovered in America. Many examples might be cited, to which the name of Mr. Prescott is not foreign, but we prefer to say no more. Let the public be on their guard against the pompous announcements which reach us from the New World."

ERRATUM.—At the end of the article on the "Brush" Electric Light system, which appeared in our last issue, "2,000" candles were, by a printer's error, given as "20,000."

THE ELECTRIC LIGHT AT LUDGATE HILL.

THE premises of Messrs. Samuel Brothers, Merchant Tailors, of Ludgate Hill, London, have been fitted up with the electric light, and the inauguration of the lighting took place on Wednesday evening, the 14th inst., in the presence of a large number of gentlemen interested in the question of electric lighting, representatives of the press, &c., &c.

They are lighted by means of thirteen electric lamps of the Jablochkoff system, and which are distributed as follows :—

One in each of the two windows on each side of the principal entrance in Ludgate Hill; two in the front of the ground floor; two in the back of the ground floor; one in the counting-house; one over the landing of the large staircase leading to the upper floor; three in the juvenile and ladies' department on the first floor; two in the gentlemen's bespoke department on the first floor.

The lamps are all suspended from the ceiling, at a distance of about eight feet from the floor, and by means of lamp pendants, through which the conducting wires are conveyed to the candles. They are made to contain four Jablochkoff candles, and as each candle lasts two hours, a continuous light for eight hours is therefore provided. The lamps can easily be replenished when the last candle is burning, so that, practically speaking, the light can be made to be continuous for any length of time.

The globes are of the opalescent description and are 20 inches in diameter.

The currents of electricity are produced by a battery of Gramme Patent Dynamo Electric Machines of the 20-light size; the battery being composed, as is well known now, of a small Gramme continuous current machine exciting a large alternating current distributing machine. The large machine is divided into four circuits, capable of maintaining five lights each. In the existing arrangement three circuits only of the distributing machine are utilised, two maintaining four lights each, and one maintaining five lights.

An additional lamp was temporarily added to that number, and was kept burning in the engine-room, which it lighted admirably.

The lights are arranged so as to be all switched from a switch board placed at one of the cashier's desks on the ground floor. This arrangement is an important feature, and the switching was shown in operation.

The motive power for working the electric machines is obtained from a 12 horse-power "Otto" gas engine, made by Messrs. Crossley Brothers, of Queen Victoria Street, London.

It is within the mark to say that this form of engine is taking the place of steam at the rate of twenty-five engines a week, a fact that should go a long way to re-assure holders of gas-stock.

The Gramme machines are driven directly by means of suitable pulleys fixed on the shaft of the engine, the small one, or exciter, running at a speed of 812 revolutions, and the large one, or distributor, at a speed of 688 revolutions per minute. They are together with the gas engine erected in a room situated in the basement at the back of the building.

The whole mechanical and electric plant, which has been fitted up under the immediate supe

Notes.

EDISON'S NEW ELECTRIC LAMP.—A strip of cardboard bent into a horse-shoe form and converted into cashon by baking it in an iron mould, is the basis of the new lamp; the strip is placed in an exhausted globe, and a current of electricity being sent through the strip renders the latter incandescent. A correspondent writing to the *Times* correspondent says that the globes were burning. On Saturday night I saw them burn seven hours. Two have been burning continuously for ten days without injury to the baked cardboard horse-shoe in the little glass globe which furnishes the light. Cardboard seems sufficiently durable, successfully resisting quite rough usage, such as dropping, shaking, turning the current on and off thousands of times, and raising the intensity of light to that of gas candles. All the arrangements are simple. Mr. Edison will put about 800 lights at Menlo Park, while the inventions immediately go into practical operation in New York city. The globe containing the horse-shoe is exhausted to one-millionth of an atmosphere by the Sprengel pump, measured by the M'Leod gauge. By successfully sealing up the electric current Mr. Edison gets individual lamps of any desirable power, each lamp having one ohms resistance. Light is turned on or off and the current regulated with the same ease as gas is, while the current can be transmitted over wire as small as No. 56. The central regulator maintains an even current, while the meters accurately measure the supply furnished to each consumer. Mr. Edison finds that the best generators are of five to seven horse-power, each one horse-power maintaining eight lamps. Each lamp will require one shilling to manufacture, while a supply sufficient to 10,000 cf. gas can be produced for 8*d.* expense or less. Mr. Edison calculates the cost of lighting that 1000 to the consumption of 3lb. of coal in a steam engine will maintain eight to ten lamps one hour. Mr. Edison's system also furnishes electric power for small industries, such as running sewing machines, &c. Edison's light is bright, clear, mellow, regular, free from flickering or pulsations, while the observer gets more satisfaction from it than from gas. Mr. Edison lights at Menlo Park, dwellings, offices, docks, street lamps, also laboratory and workshop, making it available for every lighting purpose for which gas is used."

THE telegram which announced Mr. Edison's invention created great excitement, and we think it a matter for regret that such an influential journal as the *Times* should publish such sensational announcements, which, although they will be taken for what they are worth by all scientific men, yet tend to mislead the general public.

Ce dernier fonctionne dans d'excellentes conditions sur

par oui-dire. Or, comme nous avons toujours dans notre pays le triste courage de ne trouver bien que ce qui vient de l'étranger, nous n'avons nullement encouragé les constructeurs habiles qui, comme MM. Ratier et Monier, auraient parfaitement pu construire nos grands câbles. Il est résulté de cet abandon de nos ressources, que l'Angleterre s'est trouvée avoir sans contestes le monopole de la construction des câbles sous-marins, et c'est elle, en effet, qui a fourni les câbles à tous les pays du monde qui en font usage. Cette industrie nouvelle ayant naturellement créé un débouché pour les électriciens, il s'en est formé un grand nombre en Angleterre, et ce sont eux qui, en faisant progresser la science de la télégraphie sous-marine, l'ont conduite au point

à Paris; il a été aussi employé pour les lampes installées par

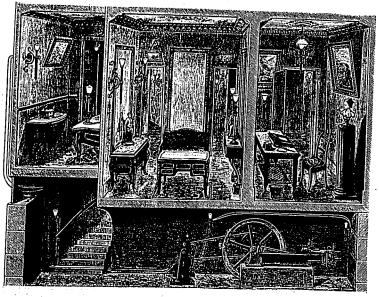
où nous la voyons aujourd'hui. Certainement il devient alors facile pour des compagnies anglaises de trouver des directeurs techniques pour leurs opérations; on n'a que l'embarras du choix; mais il n'en est pas de même pour les autres pays, et c'est ce qui fait que nous sommes obligés d'avoir recours à nos voisins, même pour le personnel, lorsqu'il s'agit d'une entreprise un peu importante. Dans tous les cas nous ne voyons pas de raisons pour qu'on indique sur des programmes, comme électriciens français, des noms complètement inconnus dans la science électrique.

TH. DU MONCEL.

(A suivre.)

1 Dec 1879

LA LUMIÈRE WERDERMANN

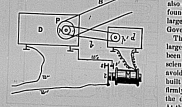


Les expériences remarquables qui ont eu lieu dernièrement à l'Opéra nous engagent à donner quelques détails sur les importants perfectionnements qui ont été apportés à la lampe Werdermann dans ces derniers temps et qui ont permis de résoudre d'une manière très-satisfaisante le grand problème de la division de la lumière électrique.

Les figures 1 et 2 représentent une vue et une coupe du dispositif que Richard Werdermann a installé pour l'éclairage

ZANNI'S IMPROVED MAGNETIC CUT-OFF FOR DYNAMO-ELECTRIC MACHINES.

The object of this invention is to prevent a reversal of the polarity of the electricity employed in the process of the electro-deposition of metals and generated by means of dynamo-electric machines. It is a well known fact that in the process of depositing metals by means of an electric current generated by a dynamo machine, that whenever the machine ceases to work a current generated by the action of the electricity on the depositing bath returns through the dynamo machine and reverses its polarity, consequently when the machine is again started the metal deposited on the article being plated leaves, by a reversal of the required process, denuded of its metallic coating, instead of having the thickness of the same increased. Several devices have been suggested and tried for overcoming this defect, but most of them, for some cause or other, have been unsatisfactory and uncertain in their action. The invention of Mr. Zanni



for effecting the object in view has been tested and proved to be thoroughly reliable in its action, and is therefore a very valuable addition to the electro-plater's plant.

The principle of the invention is shown by the fig.

It is the dynamo machine driven by the hand in, which is connected with the source of power. On the same axle to which the driving pulley, *p*, of the machine is fixed, is also attached another pulley, *f*, which drives by means of a band, *h*, and pulley, *f'*, a small magneto machine, *d*, the circuit of this machine is closed through the electro-magnet, *w*, press against the insulated stop, *i*; but when the magnet is excited it is attracted against the stop, *i'*, thus completing the circuit of the wires *n* or *n'*, which lead to the depositing bath through the connection, *x*.

The action of the apparatus is almost self-evident: when the machine is at rest the circuit of *n*, or *n'* is open, but when the dynamo machine, *b*, is rotated and with it the magneto machine, *d*, the current from the latter is sent through the electro-magnet, *w*, and attracts the tongue, *i*, against the stop, *i'*, thus closing the circuit of *n*, or *n'*; the moment the machine stops, the tongue, *i*, falls back against the stop, *i*, thus opening the circuit and preventing the return of the current from the depositing bath through the machine, *b*.

In the number of the *Journal* for December 13th, 1879, in a notice of Mr. Urquhart's book on electroplating, we expressed our surprise that a simple form of reostat had not been adopted in electro-plating operations for the purpose of regulating the strength of the current; on reference to a patent of Mr. Zanni's we find that this has been suggested and practised by him together with the use of a galvanometer in the circuit, by which the current strength could be seen.

Although fully recognizing the efficiency of Mr. Zanni's magnetic "cut-off," we should have thought that the same end could be effected in a simpler manner by working the electro-magnet, *w*, by a "derived" circuit from the machine, *b*, the resistance of the electro-magnet being sufficiently high to avoid drawing off more of the current than is actually required to excite the electro-magnet. The amount of current required to excite it is evident, would be but an infinitesimally small portion of the total current, and would therefore in no way diminish the efficiency of the machine.

An Electric Tramway.—According to the *Neue Frankfurter Presse*, Messrs. Siemens & Halske, of Berlin, are reported to be in a position to make public in every short time a new plan which they have devised to propel tramways by electric currents. The inventors claim for their system, amongst other advantages, that of greater economy than can be obtained in the steam or horse drawn tramways. It is said that there are yet some technical difficulties to overcome, the principal one being to find out an efficient manner of insulating the axles of the wheels, which, it seems, must not come in direct contact with any metallic part of the carriage. Other special features of this system are that the line will have to be laid on a plan similar to the American aerial railways, and that one carriage only will be set in motion at the time. The engine, it is said, will be of a very light and inexpensive pattern.

AMERICAN INDUSTRIES.—No. 67.

THE MANUFACTURE OF DYNAMO-ELECTRIC MACHINES AND ELECTRIC LAMPS.

The Weston machine for electro-deposition of copper, silver, nickel, and gold is too well known to need any description here. Nearly all the large electroplating and electrotyping establishments in this country use them. They are also extensively used in England, France, Belgium, and are found in nearly all parts of the civilized world. A large machine of this kind was recently built for the Italian Government for the deposition of copper.

The light machine shown in our engraving, although largely used in this country, is not so well known. It has been designed and constructed strictly in accordance with scientific principles, the utmost care having been taken to avoid loss of energy in the machine itself. The armature is built up of a set of thin perforated iron disks, which are firmly secured to the shaft by means of two nuts. Between the disks there are spaces of about one-eighth of an inch. At the end of the armature there is a tube surrounding the shaft, but larger in diameter than the shaft, and terminating at one end in a flange nearly equal in diameter to the armature disks. Each end of the armature consists of a large iron disk, having ribs on its periphery extending from one side of and parallel with the shaft. In the end of this thick disk a deep circular groove is cut, and a number of holes are bored through it parallel with the shaft. When the flanged tube is passed over the shaft and fixed to the end of this thick disk the deep groove forms a chamber.

Quite an important feature in this machine is the means adopted to keep the coils and other parts of the machine as cool as possible. This is accomplished in the armature by making the armature perform the function of an ordinary blower. The flanged tubes which envelope the shaft extend beyond the ends of the coils, and thus leave an opening at the ends near the center of the armature through which air may enter and pass into the chamber between the thick iron disks forming the ends and the flange of the tubes, and from these through the holes in the end disks into the perforated sheet iron disks, and thus pass between them and escape through the spaces between the disks on the periphery of the armature. In order to increase the circulation, air-vanes extend through these iron disks from end to end of the armature. The ends and poles of the magnets are also perforated in order to allow the air to circulate through them and cool them.

The report of Professor Morton to the American Institute Board shows the remarkable performance of this machine. The machines entered at this competitive test were the Siemens, Brush, Maxim, Wallace, Hochhausen, and Weston. The Weston machine greatly excelled all others, and now, in claiming the Electrical Exhibition, says:—"Our attention has been specially directed to the Weston machine, which is both compact and efficient, and which, in addition, is made to run very steadily. The machine is a small locomotive, and can be run on a single circuit by the current from one machine; and Mr. Weston hopes soon to be able to double this number. Mr. Weston has spent much time and devised many ingenious plans for working a large number of lamps on one circuit. Several hundred of these lamps are now in constant use in factories, hotels, stores, steamboats, etc.

The Weston Electric Light Company are also building machines for the transmission of power by electricity, machines for telegraphy, etc. The works are run night and day, and use the electric light exclusively for lighting the factory.

The engraving shows several of the departments of the above works.

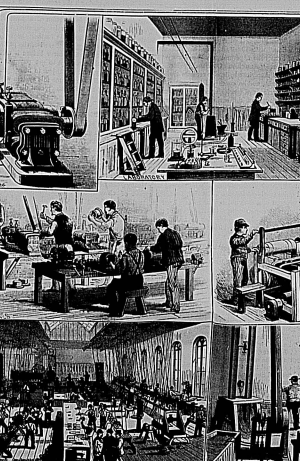
[*Continued on page 405.*]

AMERICAN INDUSTRIES.

[*Continued from first page.*]

establishment, and conveys a good idea of the activity prevalent here. The experimental work is carried on in the laboratory, which is fitted with all of the modern appliances for making electrical tests, and with a full line of chemical and physical apparatus. The machine work is all done in a machine shop covering an area of 80 × 100 feet, well stocked with machinery from the shops of the best makers in this country.

The wire used in winding the armatures and magnets is insulated by a simple, machine shown in one of the views



THE MANUFACTURE OF DYNAMO-ELECTRIC MACHINES AND ELECTRIC LAMPS.—THE WESTON ELECTRIC LIGHT CO., NEWARK, N.J.

Mr. Kinnon, an American electrician, has turned his attention to electricity as a motive power for railways. He has not seen, however, the Siemens & Halske electric railway, but is under more than one form of application of the same principle to a tramway trunk line, which he has laid down in Melle Park for electric locomotives. The line laid out consists of a single Melle Park built over natural ground, with little or no cutting. The present rolling stock consists of one single locomotive and one open car. The current is conveyed to the track by two insulated rails, worked by means of a Gramme machine. The armature of the machine is driven by a belt from the engine driving wheels. A separate rail is provided for the return current. At present a speed of ten miles an hour is maintained, but greater speeds are to be attained. The locomotive is designed to test the application of the current to develope a railway system on a large scale, and for mining districts.

I. RAILWAY DRIVEN THIRTY-THREE YEARS

Electrical Power.

Mr. Colton, of Pittsburg, Pa., have invented a system of electric railway, which is both economical and efficient. The machine is a small locomotive, upon a circular railway, around which it is driven, and from which it receives its motive power. The current is applied not to the locomotive, but to the track, and is of a very curious manner. Two carbon pencils, negative and positive, are applied to the rail by them commercially to the engine. The use is facteries, hotels, stores, steamboats, etc.

The Weston Electric Light Company are also building machines for the transmission of power by electricity, machines for telegraphy, etc. The works are run night and day, and use the electric light exclusively for lighting the factory.

The engraving shows several of the departments of the above works.

[*Continued on page 405.*]

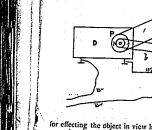
d in this country more than thirty years before motor was introduced to the public." To which that, at the period mentioned, for want of a tro-motor, such an invention was altogether le.

A Mr. Lemuel W. Gaylor, of Castle Rock, Colorado, recently, on visiting Denver, bought a pair of Edison electric lights, and after having them in operation for a few days, he wrote to the Edison Electric Light Co. stating that he was highly pleased with the lights, and that he intended to have the Edison system with which to do away with the use of lamps and oil in his house. Mr. Gaylor is a same circuit, and can be used or extinguished separately.

old down an electric railway, be an inspector now of that ractical work, by Dr. Werner and which is on view at the tion. Mr. Edison has already ermile length of electric rail- and is about to add to it many miles. The public has done nothing practical which the Edison system is responsible. In the electric system in the I, where the available water ial experiment.

ZANNI'S PATENT MAGNETIC CUT OFF FOR DYNAMO-ELECTRIC MACHINES.

The object of this invention is to prevent a reversal of the polarity of the electricity employed in the process of the electro-deposition of metals and generated by means of dynamo-electric machines. It is a well known fact that in the process of depositing metals by means of an electric current generated by a dynamo machine, that whenever the machine ceases to work a current generated by the action of the electrodes in the depositing bath returns through the dynamo machine and reverses its polarity, consequently when the machine is again started the metal deposited on the article being plated becomes a reversal of the required process, denuded of its metallic coating instead of having the thickness of the same increased. Several devices have been suggested and tried for overcoming this defect, but most of them, for economic or other, have been unsatisfactory and uncertain in their action. The invention of Mr. Zanni



for effecting the object in view has been tested and proved to be thoroughly reliable in its action, and is therefore a very useful addition to the electroplater's plant.

The principle of the invention is shown by the accompanying fig.

It is the dynamo machine driven by the band, *b*, which is connected with the source of power, so that the same acts to which the driving pulley, *p*, of the machine is fixed, is also attached another pulley, *p'*, which drives by means of a band, *b*, and pulley, *p*, a small magneto machine, *d*, the circuit of which is established as a controlling circuit and counterbalance, the armature, *i*, of the electro-magnet, *e*, resting against the insulated stop, *s*; but when the magnet is excited it is attracted against the stop, *t*, thus completing the circuit of the wires, *w*, *w'*, which lead to the depositing bath through the contact section, *x*.

The action of the apparatus is almost self-evident: when the machine is at rest the circuit of *w*, *w'*, is open, but when the dynamo machine, *a*, is rotated and with it the magneto machine, *d*, the current from the latter at once excites the electro-magnet, *e*, and draws the tongue, *i*, against the stop, *t*, thus closing the circuit of *w*, *w'*; the moment the machine stops, the tongue, *i*, falls back against the stop, *s*, thus opening the circuit and preventing the return of the current from the depositing bath through the machine, *a*.

In the number of the *Journal* for December 15th, 1879, a review of Mr. Urquhart's book on electroplating, we expressed our surprise that a simple form of rheostat had not been adopted in electroplating operations for the purpose of regulating the strength of the current; on reference to a patent of Mr. Zanni's we find that this has been suggested

An Electric Tramway.—According to the *New Freie-fonter Presse* Messrs. Siemens & Halske, of Berlin, are reported to be in a position to make public in a very short time a new plan which they have devised to propel tramways by electric currents. The inventors claim for their system, amongst other advantages, that of greater economy than can be obtained in the steam or horse driven tramways. It is said that there are yet some technical difficulties to overcome, the principal one being to find out an efficient manner of insulating the axles of the wheels, which, it seems, must not come in direct contact with any metallic part of the carriages. Other special features of this system are that the line will have to be laid in the middle of the road, as in American axial railways, and that one carriage only can be set in motion at the time. The engine, it is said, will be of [illegible] horse-power.

[illegible] copies—five copy of THE SCIENTIFIC AMERICAN will be supplied gratis for every club of five subscribers at $3.20 each; additional copies, same proportion. Postage prepaid. Remit by postal order. Address

MUNN & CO., 37 Park Row, New York.

☞ To Advertisers.—The regular circulation of the SCIENTIFIC AMERICAN is over Fifty Thousand Copies weekly. For 1880 the publishers anticipate a still larger circulation.

The Scientific American Supplement

has a distinct paper from the SCIENTIFIC AMERICAN, but of the same character in general scope. Every number contains it octavo pages, uniform with SCIENTIFIC AMERICAN. Terms of subscription for SUPPLEMENT, $5 per year, postage paid, to subscribers. Single copies, 10 cents. Postage stamps received. Remit by postal order. Address

MUNN & CO., 37 Park Row, N. Y.

The Scientific American and Supplement will be sent for one year, postage free, on receipt of seven dollars. Both papers in one subscription in connection with any foreign publication. The safest way to remit is by postal order, or registered letter. Address MUNN & CO., 37 Park Row, N. Y.

Scientific American Export Edition.

The SCIENTIFIC AMERICAN Export Edition is a large and splendid periodical, issued once a month. Each number contains about one hundred large quarto pages, profusely illustrated with original wood engravings. The 12 numbers of the Export Edition for 1879 will contain about one thousand pages and one thousand engravings, forming a complete and elegant encyclopedia of the progress of the world in Science, Industry and Art during the year. Subscription price, $3.00 a year, or $1.00 for each number. Remit by postal order. Address MUNN & CO., 37 Park Row, New York.

Scientific American Supplement.

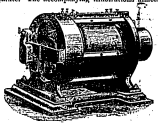
The SCIENTIFIC AMERICAN SUPPLEMENT is a weekly publication, forming a complement to the SCIENTIFIC AMERICAN, with its splendid engravings and valuable information. Terms, $5.00 a year. Single copies, 10 cents. Manufacturers and inventors will find in the SCIENTIFIC AMERICAN and SUPPLEMENT the most effective combination for bringing their business before the public. Terms of advertising, 50 cents a line. Address MUNN & CO., 37 Park Row, New York.

Back Numbers.

Back numbers of the SCIENTIFIC AMERICAN and SUPPLEMENT can always be obtained. Price of the SCIENTIFIC AMERICAN, 10 cents each. Price of the SUPPLEMENT, 10 cents each. Back volumes of the SCIENTIFIC AMERICAN for the last five years can be obtained. Price, $2.00 each, or $10.00 for the five volumes. Back volumes of the SUPPLEMENT can also be obtained. Price, $2.00 each. Bound volumes of the SUPPLEMENT for the last five years can be obtained. Price, $5.00 each. Numbers of the SUPPLEMENT can be obtained from the commencement, January 1st, 1876, to the present time. Price, 10 cents each. Back numbers of the SCIENTIFIC AMERICAN can be obtained from the commencement of the present volume, January 1st, 1879. Price, 10 cents each. Bound volumes of the SCIENTIFIC AMERICAN for the last five years can be obtained. Price, $2.00 each, or $10.00 for the five volumes. Back volumes of the SUPPLEMENT for the last five years can

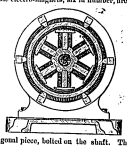
A NEW GRAMME MACHINE.

M. Hippolyte *Fontaine* describes in the *Nuova Industrielle* a new Gramme machine, diagrams of which we believe were exhibited by the British Electric Light Company at the recent conversazione of the Physical Society at King's College. In his old machine, M. Gramme used a small continuous machine (the exciter) to send a current through a larger machine, which has been termed the distributor. The inventor has now combined the two machines, and obtains better results than when they were separate. The accompanying illustrations almost explain

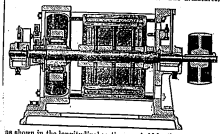


themselves. The arrangement is thus made :—On a low cast-iron bed are bolted two almost circular cast-iron plates, connected together by six square bolts, and provided with bearings for the main shaft. One of these plates is furnished on the inner side with an annular rib on which the electro-magnets of the exciting apparatus are fixed. As in the earlier machines the coils for the alternating currents rest on three square bolts, connected to the end plates by means of packing pieces of hard wood.

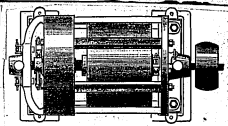
The movable electro-magnets, six in number, are fixed radially



round a hexagonal piece, bolted on the shaft. The armatures,

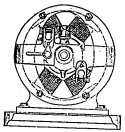


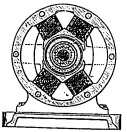
as shown in the longitudinal section, are held by the same screw. On one side the shaft carries the small exciting coil, on the other



an induction coil. The bearings are large, and in the larger machines are automatically lubricated.

A small handle serves to put the movable electro-magnets in





communication with the current of the exciting coil. This current is collected and transmitted by brushes of silvered copper wire. The brushes work by means of an endless screw, furnished with a counter screw placed outside the frame. To regulate the magnetisation of the inductors, and, consequently, the power of the machine, M. Gramme has fixed between the exciting coil and the electro-magnets a copper wire, the length and section of which can easily be varied. The winding of the wires upon the coil differs somewhat from that of ordinary machines, which consist of two parts, the exciter and distributor. Instead of winding one single wire at a time he winds two, in order to have, as required, currents of tension for small candles, or currents of quantity for larger candles.

Two types of these machines are now made :—First, one weighing 250 kilos, and supporting 12 candles of from 20 to 30 bees each, or eight candles of from 40 to 50 bees each; second, one weighing 470 kilos, and supporting either 24 of 20 to 30 bees, or 16 of 40 to 50 bees each.

The following experiments have been made with these machines :—

Order	No. of Revolutions per minute.	Motive Power in kilogrammètres.	No. Fasi.	Intensity of each fasci in Carcel bees.
1	1,140	185	4	45
2	1,200	204	4	49
3	1,330	230	4	57
4	1,400	260	4	62
5	1,450	292	12	52
6	1,250	340	8	58
7	1,300	360	8	61
8	1,360	397	8	57·5
9	1,460	440	8	60·2
10	1,000	270	8	47
11	1,200	—	16	61
12	1,300	—	20	61
13	1,200	—	22	31·5

The first four experiments were made with a small machine, worked by an Otto gas engine. The coils were made to form successively two, three, and four distinct circuits. The expenditure of motive power was measured by a Prony break. The candles used had carbons 4mm. diam., and lasted two hours. Experiments 5, 6, and 7 were made on the same machine, coupled in tension. The candles had carbons of 5mm. diam., and lasted 1·5 hours.

The division of the light weight has been pushed further; but it was observed that, when reduced to an intensity of 20 bees, the candles lost much of their regularity. Only one experiment was made in this direction. With a machine specially arranged for small lights, there were obtained, with a velocity of 1,250 revolutions, 14 foci of 20 Carcel bees, with an expenditure of motive force of 350 kilogrammètres. The candles used had carbons of 3 mm in diameter.

Experiments 8 and 9 were made with a small machine, with the help of a steam motor, the speed of which varied considerably. Several candles went out during the working, but, when the speed was slightly accelerated, this accident no longer occurred.

Experiments 10, 11, and 12 were made at the works of the Société Jablochkoff, at Paris, on two of the larger machines. They are shortly to be repeated on the Place de l'Opéra.

In all the experiments a greater fixity of light was observed than in machines possessing independent exciting coils. It is stated, moreover, that the price of the new apparatus is about 20 per cent. less than that of the old. Two years ago the Gramme machines cost 1,000f. for 16 lights, and half that amount for six lights; whilst the *bougies* cost 75 centimes, and lasted for one hour and 20 minutes. At the present time the machines are sold at 4,500f. for 20 lights, and 2,800f. for eight lights; whilst the *bougies* cost only 50 centimes, and last for two hours and 30 minutes. Great progress has, therefore, been effected from an economical as well as from other points of view; nor is there any reason to think that the maximum reduction in cost has yet been effected.

131

present purpose to enter upon the complete study of electrolysis, interesting and important as that study is. The changes are usually considered to consist of two orders—1. Direct actions of the current upon a single constituent. 2. Secondary or chemical actions of the separated elements upon other substances present. I have endeavoured to trace a law which supersedes this distinction, and connects all the actions together as due to energy, and have formulated this as p. 256 of my "Electricity as a "Physical Law of Electrolysis." At the electrodes these substances are set free which absorb, in becoming free, the lowest specific energy. This is, in fact, the converse of the law recently formulated by Berthelot(also long known as a general fact) as the principle of maximum work, viz., every chemical change accomplished without the intervention of a foreign energy (heat, electricity, light) tends to the production of the body, or system of bodies, which liberates most heat. But when we seek to study causes or operations, we should look for them in their very simplest form, where they are least disturbed by other agencies, and their action most easily to be found out. The simplest form of electrolysis is that of fused chloride of silver, where there is nothing else present, and the substance breaks up into chlorine and silver. The chlorine goes to the positive conductor, or anode, and all the silver to the negative, or cathode. Now let us conceive Fig. 4

FIG. 4

as representing a line of molecules of Ag Cl, chloride of silver arranged in its order order by the electric action as shown in outline 1. It is evident that there cannot be an action at each electrode which breaks up or pulls a molecule apart; such an action is shown in line 2, and it would result in both the chlorine and the silver appearing at each end of the chain. We are driven to the conclusion that such an action takes place as is shown in line 3, namely, in a complete interchange of the arrangement of all the molecules, forming the line of transmission; one element of the terminal molecules separates and becomes free, the other element, unburdened with the energy it is transmitting, breaks up the adjoining molecule, to which it is in fact the electrode, and forms a fresh molecule thus—

$$\overset{\ominus}{Ag\,Cl}\;Ag\,Cl\;Ag\,Cl\;Ag\,Cl\;\overset{\oplus}{Ag\,Cl}$$

the upper brackets showing the original order and the lower ones the new arrangement of molecules. I must defer the following out this subject to another time, and will now make a few remarks upon such criticisms as have so far appeared upon the first paper on this subject. As to Mr. FitzGerald, p. 153, I feel sure that it will be found that the difference between us, fundamental as it looks, will prove to be but very slight in reality, and of no consequences as to its results. He says, "it is almost certain that the modus operandi of electrical conduction is a rotation of molecules," and I hold that this rotation of molecules is what we measure as quantity and call electricity. I am interested in the addition he has made to my diagram, but it does not satisfy me; it seems to me that what he measures by it is the tension, or pressure in the pipes, not the inductive effect upon all surrounding matter, which is the distinction between the hydraulic and electric currents, when the tension is common to both.

"Ignorimus," p. 175, must allow me to defend my own position. I do not accept his statement that "Mr. Sprague agrees with Mr. Preece in choosing the latter horn of the dilemma," viz., that electricity must be either a "form of matter or a form of force, and that there is no other category in which to class it." I say there is another category. Electricity is simply a word, and like other words it has a variety of meanings; it practically embodies, links together, and confuses those two things, actions, or properties embodied in E and W, which both Mr. FitzGerald and myself seek to distinguish. Therefore, I cannot even accept altogether the modification of a form of energy instead of a form of force, although I have myself often used it. That which we call electricity and measure quantitively cannot be either force or energy, Mr. FitzGerald says it is matter—a special matter, I say it is a function or action of the molecules of all matter. I am hereticenough to doubt if it can be expressed by any combination of M L and T, but think it involves the introduction of a considerations (that is a fundamental quantity) belonging to the field of chemistry. The accepted mathematical formula I consider a mere artificial contrivance, having its uses in calculation, but representing no natural truth. But electricity is a word commonly employed to mean what is really energy, that which is embodied by W. This use of the word, general as it is, is a misconception and confusion which exist. Hence, in fact, Mr. Preece falls in the quotation referred to. When he was speaking of wire really electric-potential or energy, either force or energy? but he, like many others, has confused the two in the one word electricity. The result is not merely a dilemma, but a dilemma both of whose alternatives result in a *reductio ad absurdum*. But then the dilemma itself is a myth, we have to deal with phenomena, their cause, and the mode of action and production. If we call them by one name, what of it? There are conveniences enough in theological disputes where a word commonly accepted often serves to hide very different meanings, but science must be exact and define exactly what is meant by words. My friend Mr. Phillips, p. 184, seems to be meant by what he calls "my strange duality," a motion convertible and inconvertible into work. I thought my suggestion was clear enough, but I think a familiar illustration may be given, which will carry the idea into every mind, whether it carries my intention along with it not. Take a wheel or winch with a rope wound upon it connected to work to be done; we shall now have two distinct forms of motion—1. That of the winch or its axle; 2. That of the rope. The first of these may be called, and, if each term represents a given work, such as raising one article from one floor to another, these terms will represent "quantity," that is to say, so many articles lifted; but it is evident that this number or motion as the axle (which is the thing represented in my diagram 2) is to do some convertible work. It will be the same whether each single article raised be light or heavy, just as the one "quantity" of electricity sets upon one grain of hydrogen, or 108 of silver. I hence also it does and represent either force or energy, nor is it matter. But the other motion (linked though it be to the first) is converted into work; it, in fact, transmits the energy applied to the winch. Its velocity depends upon the relations of the diameters, and the energy represented by time continued by force of motion and tension on the rope will be as the square of the motion, or, what is the same thing, as the square of the first motion, which is the analogue of C or current in electricity, while the conditions of the second motion are analogous to the E × C or W or C², which measure the energy connected to the electric current, itself measured as C or as $\frac{E}{R}$. But does not Mr. Phillips rather beg the question when he says, "current is actually *my current*, in the sense that something analogous to a grain of water is actually transmitted?" That is just what is being debated, and I contend and hope to prove that *no thing* is actually transmitted, but only energy, causing motion. When he says "the binary action is such that metal is projected on one side, and the unknown E on the other," surely this is stating a mere hypothesis as though it were experimental fact. We know that metal or bases are projected on one side, and we know that an equivalent "action" is set free on the other side—*that is fact*. That the unknown E is acid, from is pure hypothesis. Of course, there can be no objection to any hypothesis on the mere ground that it is one; in fact, we are all at work upon hypotheses, and must needs be so in the field of atoms and molecules and their motions, seeing that their very existence is a matter of hypothesis; but let us clearly distinguish between a proved fact and a hypothesis, however probable.

The Electromagnet.

ON MAGNETIC CIRCUITS IN DYNAMO AND MAGNETO ELECTRIC MACHINES.—No. 2.

BY LORD ELPHINSTONE AND CHARLES W. VINCENT, F.R.S.E., F.C.S., F.I.C.

[Communicated by Professor G. G. Stokes, Sec. R.S. Received March 10, 1880.]

A large amount of magnetism is retained by the soft iron cores of electro-magnets, when arranged so as to form a complete magnetic circuit; and sparks and other indications of the passage of an electric current can be obtained at the end of the bells when surrounding these soft iron cores each time the masses of iron are separated and the closed magnetic circuit opened. In order to procure a spark, the breaking of the circuit

MANUFACTURER AND BUILDER

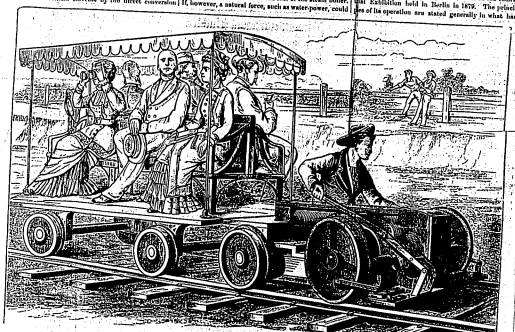
Vol. XII.—No. 6. JUNE, 1880. TWELFTH YEAR.

Electrical Railways.

The suggestion that electricity might be made to serve as a motive power for railways is not entirely a new one. The idea has been entertained for years, but until lately has remained an idea, or at best has found expression only in some scientific toy, which, like a baby, might or might not amount to something in time. The development and recent rapid perfection of dynamo-electric machines, however, which have given us what before was lacking—that is, a comparatively cheap means of generating and maintaining powerful electrical currents by the direct conversion of mechanical force into electricity, has supplied the long-sought-for means of supplying this agent to us in such variety of practical uses, for which its cost and ubiquity have no insuperable obstacle. For, as most of our readers will be aware, these machines have practically solved the problem of the cheap production of electricity, enabling us to convert mechanical energy—no matter how generated, whether from steam engine, wind, or waterfall—directly into electricity, and have opened up a wide field of speculation as to the possible extensive introduction of electric engines to do the work of steam, over which it possesses a number of advantages, the most obvious of which resides in the fact, that it may be transmitted with very little loss over great distances by metallic conductors, and made to drive electrical engines located at distant points, or to furnish light for towns, cities, etc. The practicability of the use of electricity was tersely presented before the British Iron and Steel Institute in the following terms: The president of that association declared that, so long as the source of electrical power depended upon the galvanic (chemical) battery, it must, in the present state of things, remain far more expensive than steam power, for the obvious reason that zinc, which is the fuel of the galvanic battery, is vastly more expensive than coal—the fuel of the steam boiler. If, however, a natural force, such as water-power, could be utilized to generate electricity economically, the case would be very different. A dynamo-electric machine, driven by water power, could be made to generate powerful electrical currents, which could be transmitted through insulated metallic conductors to a great distance with but little loss, comparatively speaking, and could then be made to run magneto-electric engines to do the work of steam in our factories and workshops, to ignite electric lamps, etc.

We have cited the foregoing simply in verification of our statement of the possible future substitution of electricity for steam power on an extensive scale. It will be apparent also to our mechanical readers that there may be numerous cases where it will be advantageous on the score of convenience, if not of economy, to employ steam-driven dynamo-electrical machines, not only for the production of light, for which use they have already been very largely introduced, but also for the production of mechanical effect. It is on this principle that the latest novelty in the application of electricity—the electrical railway—is based.

The credit of having first practically demonstrated the possibility of success in this direction must be accorded to Dr. Siemens, who constructed and operated a electrical railway as a practical aids at the Industrial Exhibition held in Berlin in 1879. The principles of its operation are stated generally in what has preceded—that is, the conversion of motive force into electricity, and the conversion of the current back again into motive force. The details will be sufficiently clear from the following explanations: If we have two dynamo-electric machines, designated as A and B, which we connect by metallic conductors, they form a complete system for the transmission of power. Motion imparted to the machine A will generate an electrical current, which the machine B will convert back again into motive power. "In the electric railway of Dr. Siemens, the machine A is driven by a stationary engine located at one end of the road; the rails are used as conductor, the current generated by the machine A being taken from an insulated



EDISON'S ELECTRICAL RAILWAY.

roll by a metallic brush, actuates zanzibar B, its motion being communicated by suitable gearing to wheels on which it is mounted, and the current is returned to the electric generator by the ordinary unisolated rails.

Mr. Edison, it appears, has been turning his attention to this same interesting problem, and has lately constructed an electrical railway at Menlo Park, with, which some practical experiments have been made with very promising results. The railway in question is a circle about half a mile long. The motive is substantially one of Mr. Edison's electrical generators, the motive power being supplied by a stationary engine, and this power converted into electricity by a similar generator. The general principles of this arrangement are, therefore, identical with those employed by Siemens. The details, so far as they have been given, however, appear to be somewhat different. In Mr. Edison's arrangement, the electrical current from the stationary generator is conveyed to the track by two copper wires, one wire being connected with each rail at the proper time full details of the motor and of its operation are promised. The design of the experiment is said to be to test the applicability of this system for the use of mining districts, large farms, plantations, etc. What its future development may be no one can affirm. Dr. Siemens has already progressed so far with his system as to have applied to the municipal authorities of Berlin for permission to erect an elevated electric railway across that city, so that no question exists as to the score of practicability. It is not at all unlikely that in the not very remote future we may have electrical tramways and elevated railways in common use in our cities.

Mr. Edison's motor, on a recent trial trip, developed a speed estimated at about 25 to 30 miles per hour, and he claims to realize 70 per cent of the power supplied to the generator. The engraving on the preceding page shows the general appearance of this novel railway and its equipments.

such a system is provided, namely, the kerosene works of the Downer Company at South Boston, and the workshops of Morris, Tasker & Company of Philadelphia; in the first named, the effectiveness of this safeguard has repeatedly demonstrated itself; in the second, the opportunity of testing its utility has happily not yet been afforded.

The arrangement is extremely simple. A series of independent steam pipes lead from the boiler-room to the several departments of the works, while one of the most open and easily accessible positions on the ground floor is chosen as the place where the steam service may be controlled. At this place (in the case of Morris, Tasker's & Co's. works), the pipes leading to the different quarters of the works, are painted, each of a different color, and for additional security against mistakes in the excitement of the moment, the name of the department to which it leads is printed in distinct letters on each of these, and the threatened apartment can be instantly deluged with steam by the simple turning of the appropriate valve, so soon as warning of the danger is given.

A similar plan could be readily adapted to large buildings like churches, public halls, theaters, etc., wherever steam is used for heating purposes, and would doubtless amply prove its efficiency should occasion call for its use.

A Nuisance that should be Abated.

One of our contemporaries, in referring lately to the immense increase in telegraphic communication, and the rapid improvement of telegraphic methods, and extending to the visible evidences of these facts, in the net-work of wires stretching from building to building and from chimney to pole, which everywhere meet the eye in our cities and towns, designates the age we live in, as the "wire-age." The term is not inappropriate, but it would be, we submit, in better keeping with the eternal fitness of things, if the wonderful progress in telegraphy that we refer to above, had been accompanied with similar progress in telegraphic service. America has played a distinguished part in the tele-
